PROCEEDINGS

OF THE

AMERICAN SOCIETY OF CIVIL ENGINEERS

VOL. 72 FEBRUARY, 1946 NO. 2, PART 2

TRANSACTIONS

NUMBER 110

1945

Edited by the Secretary, under the direction of the Committee on Publications.

Reprints from this publication, which is copyrighted, may be made on condition that the full title of Paper, name of Author, and page reference are given.

PUBLISHED BY THE SOCIETY
1946

Entered as Second-Class Matter, September 23, 1937,
at the Post Office at Lancaster, Pa., under the
Act of March 3, 1879. Acceptance for
mailing at special rate of postage
provided for in Section 1103,
Act of October 3, 1917,
authorized on
July 5, 1918

Published at Prince and Lemon Streets, Lancaster, Pa.,
by the American Society of Civil Engineers

Copyright 1946, by the American Society of Civil Engineers.

Note.—The Society is not responsible for any statement made or opinion expressed in its publications.

CONTENTS

PAPERS AND DISCUSSIONS

(Alphabetical Indexes Begin on Page 1917)

No. PAGE

2236 RAINBOW ARCH BRIDGE OVER NIAGARA GORGE: A SYMPOSIUM 1

FOREWORD 2

DESIGN.
By Shortridge Hardesty, J. M. Garrelts, and I. G. Hedrick, Jr. 6

MOMENTS IN FLEXIBLE TWO-HINGED ARCHES.
By Elmer K. Timby, Lawrence M. Mead, Jr., and Robert McEldowney, Jr. 35

FABRICATION AND ERECTION CONTROLS.
By John I. Copp, Karl de Vries, William H. Jameson, and Jonathan Jones 50

ERECTION OF STEEL SUPERSTRUCTURE.
By E. L. Durkee 82

Discussion:
By Egidio O. Di Genova 120
Charles Mackintosh 121
C. M. Goodrich 123
T. Kennard Thomson 125
C. M. Spofford 127
L. J. Mensch 128
O. H. Ammann 135
Louis Balog 137
William G. Rapp 139
Leon Beskin 139
Neil Van Eenam 150
C. H. Gronquist 150
M. Hirschthal 159
George Stern 163
Shortridge Hardesty, J. M. Garrelts, and I. G. Hedrick, Jr. 167
Elmer K. Timby, Lawrence M. Mead, Jr., and Robert McEldowney, Jr. 176
John I. Copp, Karl de Vries, William H. Jameson, and Jonathan Jones 178

2237 DEWATERING, INCINERATION, AND USE OF SEWAGE SLUDGE: A SYMPOSIUM 179

FOREWORD 180

DEVELOPMENTS INDICATED BY EXPERIENCE AT BUFFALO, N. Y.
By C. R. Velzy 181

VACUUM FILTERS USED IN PRIMARY SLUDGE DEWATERING.
By Ralph E. Fuhrman 188

POSSIBLE ECONOMIES IN SLUDGE DISPOSAL PRACTICE.
By George J. Schroepfer 194

USE OF SEWAGE SLUDGE AS FERTILIZER.
By LeRoy W. Van Kleeck 208

EXPERIENCE OF CHICAGO, ILL., IN THE PREPARATION OF FERTILIZER.
By William A. Dundas and C. P. McLaughlin 218

BIBLIOGRAPHY.
By the Symposium Authors 241

No. PAGE

Discussion:
By A. L. GENTER 243
WILLEM RUDOLFS 251
LLOYD M. JOHNSON 254
ISADOR W. MENDELSOHN 255
LANGDON PEARSE 261
C. R. VELZY 263
GEORGE J. SCHROEPFER 264

2238 GEOLOGY IN HIGHWAY ENGINEERING.

By Marshall T. Huntting 271

Discussion:
By W. W. CROSBY 298
CARL B. BROWN 299
F. H. KELLOGG 300
BERLEN C. MONEYMAKER 302
E. F. BEAN 305
A. T. BLECK 305
LYMAN W. WOOD 306
PHILIP KEENE 306
JACOB FELD 307
H. E. MARSHALL 309
K. B. WOODS 312
D. J. BELCHER 316
R. WOODWARD MOORE 320
GEORGE E. EKBLAW 322
ALLEN S. CARY AND ADE E. JASKAR 323
KARL TERZAGHI 324
D. P. KRYNINE 328
ROBERT F. LEGGET 332
IRVING B. CROSBY 334
HYDE FORBES 337
A. A. EREMIN 341
MARSHALL T. HUNTTING 342

2239 SURGES IN PANAMA CANAL REPRODUCED IN MODEL.

By F. W. Edwards and Edward Soucek 345

Discussion:
By HAROLD A. WEGGEL 356
HARRY LEYPOLDT 356
C. J. POSEY 358
F. W. EDWARDS AND EDWARD SOUCEK 359

2240 ORIGINAL AND READJUSTED REPAYMENT CONTRACTS, BOULDER CANYON PROJECT.

By Clay C. Elder 363

Discussion:
By W. L. CHADWICK 384
A. R. ARLEDGE 388
CLAY C. ELDER 390

2241 SHEAR EFFECT ON THE STRENGTH OF STRUTS.

By S. Sergev 391

Discussion:
By LEON BESKIN 404
MARSHALL HOLT 408
DAVID B. HALL 410
S. SERGEV 413

No. PAGE

2242 ECONOMICAL CANAL CROSS SECTIONS.

By Victor L. Streeter 421

Discussion:

By V. A. Endersby 431

Julian Hinds 433

D. C. McConaughy 435

C. J. Posey 436

Victor L. Streeter 438

2243 RIGIDITY AND AERODYNAMIC STABILITY OF SUSPENSION BRIDGES.

By D. B. Steinman 439

Discussion:

By Edward Adams Richardson 476

R. K. Bernhard 485

J. M. Robertson 487

C. H. Gronquist 490

F. B. Farquharson 492

H. Reissner 501

Blair Birdsall 509

Hardy Cross 511

Frederick C. Smith, Hermann Friedlaender, and George S. Vincent 512

Louis Balog 522

D. B. Steinman 532

2244 ERECTION OF HYDRAULIC TURBINES AND GENERATORS.

By Andrew M. Komora 581

Discussion:

By Paul E. Gisiger 593

Frank I. Morgan 594

J. F. Roberts 595

D. E. Brainard 596

Andrew M. Komora 598

2245 SHEAR AND BOND STRESSES IN REINFORCED CONCRETE.

By Stanley U. Benscoter and Samuel T. Logan 599

Discussion:

By F. R. Shanley 607

B. J. Aleck 607

Dean Peabody, Jr. 610

William E. Wilbur 612

L. E. Grinter 614

Anders Bull 616

Victor R. Bergman 619

Phil M. Ferguson 622

Stanley U. Benscoter and Samuel T. Logan 627

2246 COEFFICIENTS FOR VELOCITY DISTRIBUTION IN OPEN-CHANNEL FLOW.

By William S. Eisenlohr, Jr. 633

Discussion:

By A. A. Kalinske 645

Edward H. Taylor 646

E. R. Van Driest 648

Hunter Rouse and John S. McNown 651

William S. Eisenlohr, Jr. 657

2247 MILITARY AIRFIELDS: A SYMPOSIUM 669

CONSTRUCTION AND DESIGN PROBLEMS.

By James H. Stratton 670

DESIGN OF DRAINAGE FACILITIES.

By Gail A. Hathaway 697

No. PAGE

BIBLIOGRAPHY.

By the Symposium Authors 730

Discussion:

By James B. Newman, Jr. 734
Thomas E. Stanton 737
W. E. Howland 738
David S. Jenkins 743
William E. Rudolph 751
Raymond L. Irwin 752
G. G. Greulich 758
Hibbert Hill 758
Jacob Feld 763
Robert Horonjeff 766
Clarence S. Jarvis 768
D. D. McGuire 776
E. D. Parmer 776
A. Casagrande 780
Harry E. Cotton 784
D. O. Murray 790
Thomas B. Pringle 792
John R. Haswell 796
W. J. Turnbull and William H. Jervis 797
Ralph R. Proctor 799
D. M. Burmister 809
Ralph Hansen 812
H. V. Pittman 814
G. R. Schneider 818
H. M. Williams 820
Ira B. Mullis 826
C. F. Izzard 827
L. J. Mensch 831
Hibbert Hill 836
Gail A. Hathaway 845

2248 FLOOD FORMULAS BASED ON DRAINAGE BASIN CHARACTERISTICS.

By H. B. Kinnison and B. R. Colby 849

Discussion:

By Clarence S. Jarvis 877
L. R. Beard 882
M. J. Ord 886
Howard M. Turner 888
Byron O. McCoy 891
C. O. Clark 892
H. B. Kinnison and B. R. Colby 900

2249 ANALYSIS OF THE GENERAL TWO-DIMENSIONAL FRAMEWORK.

By Yves Nubar 905

Discussion:

By Leon Beskin 933
Jaroslav Polivka 940
A. A. Eremin 943
Yves Nubar 944

2250 UNUSUAL CUTOFF PROBLEMS—DAMS OF THE TENNESSEE VALLEY AUTHORITY: A SYMPOSIUM 947

DEEP SOLUTION CHANNEL, KENTUCKY DAM, KENTUCKY.

By James B. Hays 948

FLOWING WATER IN UNDERGROUND CHANNELS, HALES BAR DAM, TENNESSEE.

By L. A. Schmidt, Jr. 965

No. PAGE
Discussion:
By BERLEN C. MONEYMAKER 995
PORTLAND P. FOX 997
J. K. BLACK 1003
L. C. GLENN 1004
E. H. BURROUGHS 1005
JAMES B. HAYS 1015
L. A. SCHMIDT, JR. 1016

2251 DESIGN CONSTANTS FOR BEAMS WITH NONSYMMETRICAL STRAIGHT HAUNCHES.
By **August L. Ahlf** 1019
Discussion:
By ROBERT O. JAMESON 1037
JOHN SHERMAN 1041
DALE H. REA 1042
I. B. HOSIG 1044
AUGUST L. AHLF 1045

2252 PRESSURE ON THE LINING OF CIRCULAR TUNNELS IN PLASTIC SOILS.
By **D. P. Krynine** 1048
Discussion:
By M. A. DRUCKER 1066
JOHN M. BIRD 1068
D. P. KRYNINE 1075

2253 STABILITY AND STIFFNESS OF CELLULAR COFFERDAMS.
By **Karl Terzaghi** 1083
Discussion:
By G. G. GREULICH 1120
RAYMOND P. PENNOYER 1124
DEAN P. TSAGARIS 1133
R. T. COLBURN 1136
A. F. HEDMAN 1145
ADOLPH J. ACKERMAN 1155
SAVILE PACKSHAW 1161
MARTIN W. LAUTZ 1165
J. S. MILLER 1170
ROBERT F. LEGGET 1173
D. P. KRYNINE 1175
J. J. POLIVKA 1178
KARL TERZAGHI 1187

2254 TRANSLATORY WAVES IN NATURAL CHANNELS.
By **J. H. Wilkinson** 1203
Discussion:
By HAROLD A. WEGGEL 1226
W. M. LANSFORD 1227
M. A. CHURCHILL 1229
J. H. WILKINSON 1235

2255 CONSTRUCTION OF THE FLOW NET FOR HYDRAULIC DESIGN.
By **H. Alden Foster** 1237
Discussion:
By J. W. HOWE 1253
CLARENCE S. JARVIS 1254
H. ALDEN FOSTER 1255

No. PAGE

2256 CHARACTERISTIC REDUNDANTS USED FOR ANALYZING STATICALLY INDETERMINATE STRUCTURES.

By John B. Wilbur 1257

Discussion:

By Charles A. Ellis 1280
Ralph W. Stewart 1282
Myle J. Holley, Jr. 1283
M. W. Huggins 1284
Leon Beskin 1284
Frederick S. Merritt 1291
John B. Wilbur 1293

2257 HYDRAULIC MODEL INVESTIGATION OF MITER GATE OPERATION.

By Maurice N. Amster 1297

Discussion:

By Edward Soucek 1314
Isaac DeYoung 1316
F. W. Edwards 1319
William A. Tripp 1320
Maurice N. Amster 1322

2258 SIMULTANEOUS CONSOLIDATION OF CONTIGUOUS LAYERS OF UNLIKE COMPRESSIBLE SOILS.

By Hamilton Gray 1327

Discussion:

By Edward S. Barber 1345
Jacob Feld 1349
George W. Glick 1351
Hamilton Gray 1352

2259 LOCK MANIFOLD EXPERIMENTS.

By Edward Soucek and E. W. Zelnick 1357

Discussion:

By J. Pietrkowski 1377
John S. McNown 1378
F. W. Edwards 1385
W. M. Lansford 1388
Robert F. Kreiss 1389
Ralph G. Berk 1393
Ralph W. Powell 1394
Edward Soucek and E. W. Zelnick 1396

2260 AMPLIFIED SLOPE DEFLECTION.

By Ralph W. Stewart 1401

Discussion:

By Leon Beskin 1408
John E. Goldberg 1410
Camillo Weiss 1411
William C. Spiker 1411
Arthur B. McGee 1412
Jaroslav Polivka 1414
A. A. Eremin 1415
Ralph W. Stewart 1417

No. PAGE

2261 STORAGE AND THE UNIT HYDROGRAPH.
By C. O. Clark 1419
Discussion:
By James S. Sweet 1447
Otto H. Meyer 1448
L. K. Sherman 1449
Gordon R. Williams 1451
Ray K. Linsley, Jr. 1452
E. F. Brater 1455
L. C. Crawford 1456
Robert E. Kennedy 1459
Victor H. Cochrane 1461
Franklin F. Snyder 1465
Howard M. Turner 1471
Don Johnstone 1474
C. O. Clark 1477

2262 ANALYSIS OF RIGID FRAMES BY SUPERPOSITION.
By David M. Wilson 1489
Discussion:
By F. S. Merritt 1509
Ralph W. Stewart 1510
John E. Goldberg 1512
A. W. Fischer 1514
Leon Blog 1520
Arthur B. McGee 1522
Jaroslav Polivka 1529
Odd Albert 1533
W. C. Spiker 1539
David B. Hall 1540
A. A. Eremin 1542
Victor R. Bergman 1544
David M. Wilson 1545

2263 CONCENTRATION OF SEWAGE SLUDGE: A SYMPOSIUM 1557
EXPERIENCE IN LOS ANGELES, CALIF.
By R. F. Goudey 1558
BACK RIVER SEWAGE WORKS, BALTIMORE, MD.
By C. E. Keefer 1562
SOME RESULTS IN THE STATE OF NEW JERSEY.
By Willem Rudolfs 1565
CONCENTRATION OF SEWAGE SLUDGES, NEW YORK, N. Y.
By Wellington Donaldson 1572
Discussion:
By C. R. Velzy 1579
R. F. Goudey 1580

2264 WEDGE-SHAPED STRUCTURAL MEMBERS UNDER DIRECT STRESS AND BENDING.
By Robert B. B. Moorman 1581
Discussion:
By Phil M. Ferguson 1591
Stanley U. Benscoter 1593
George Winter 1595
Walter H. Wheeler 1599
Leon Beskin 1599
Robert B. B. Moorman 1602

2265 PRIVATE ENTERPRISE: ANNUAL PRESIDENTIAL ADDRESS.
By J. C. Stevens 1605

MEMOIRS OF DECEASED MEMBERS

FOREWORD

It is appropriate that the engineers responsible for the construction of the longest fixed arch span built to date should give the engineering profession a record of the design and erection of that monumental structure.

The selection of the proper bridge to be built at this crossing involved not only the economics of materials and erection but also that elusive item, the economics of appearance. The problem of esthetics was solved in this case by selecting the graceful arch structure for the main span, and approach spans which, in the opinion of the architect, harmonized with the surrounding structures particularly on the Canadian side.

Some of the problems encountered by Mr. Hardesty in his development of the design are discussed in the opening paper. While making his studies relating to the design, he became convinced that additional information was needed to guide engineers in the design of arch ribs. As a result, the problem was presented to Professor Timby, who supervised and directed studies on two-hinged arch models. These studies comprise the subject matter of the second paper in this Symposium.

The third paper of the Symposium gives a record of some of the problems and studies necessary to the construction of such a structure. The mathematical calculations necessary for positive control of such a structure during erection are very extensive. However, one who has seen the close check between the mathematical prediction and the measured forces in such a structure as this will have a greater confidence in future designs of statically indeterminate structures.

The fourth and last paper in the Symposium presents the solution to the many problems in the erection of a monumental bridge and describes the erection procedure.

Notation.—The following letter symbols, used in this Symposium, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = area; cross-sectional area of the arch rib:
    A_a = cross-sectional area of rib at point A;
    A_w = web area;
b = a subscript denoting base arch;
C = coefficient: C_1, C_2, C_3, and C_4 are empirical coefficients in Eq. 24;
$\overline{DL}$ = dead load; $\overline{DL}_b$ = dead load on the base arch;
E = Young's modulus of elasticity:
E_b = Young's modulus of elasticity referring to the base arch;
E_s = modulus of elasticity in shear;

- e' = accidental errors; maximum probable ordinate of a departure;
- F = a force;
- H = horizontal force, or component of force:
  - H_b = a horizontal force required, with V_b, to balance a system;
  - H_c = thrust due to camber;
  - H_r = (see V_r);
  - H_t = change in thrust due to temperature change t;
  - H_1 = horizontal force required to balance the cable;
  - H' = differential force;
  - ΔH = a horizontal increment of force resulting from the change in geometry of the rib;
- h = a subscript denoting "horizontal shear";
- I = moment of inertia of the rib cross section:
  - I_b = moment of inertia referred to the base arch;
- $\overline{I}$ = impact load;
- L = span length:
  - L_b = span length of base arch;
  - ΔL = increments of span length;
- $\overline{LL}$ = live load;
- l = length of the horizontal projection of the half arch;
- M = bending moment:
  - M_a = moment at point A;
  - M_b = bending moment in the base arch;
  - M_e = moment by usual elastic analysis;
  - M_m = total bending moment at point m;
  - M' = simple beam bending moment;
  - Δm = differences between bending moments;
- N = factor of safety;
- P = a concentrated force;
- Q = a bending moment used in Table 5;
- R = a ratio, $\frac{\overline{DL}}{\overline{LL}}$;
- r = radius of curvature of the arch rib: r_o = original radius;
- S = section modulus;
- s = unit stress; s_y = elastic limit;
- T = total direct thrust:
  - T_a = total axial thrust at the point A;
  - T_t = thrust due to temperature effect;
  - T_w = thrust due to wind;
- t = change in temperature, in degrees Fahrenheit;
- u = radial component of displacement of the arch rib:
  - u_a = radial component at point A;
  - u_e = radial component of displacement computed by the elastic theory;
  - u_f = radial component of displacement due to force F;
  - u_m = radial displacement at point m;

V = vertical shear:
    V_b = "basic" vertical shear;
    V_r = vertical shear which, with H_r, it is assumed would raise the rib to point A;
    V_1 = vertical force required to balance the cable;
v = a subscript denoting "vertical shear";
W = a total unit load, $\overline{DL} + \overline{LL} + \bar{I}$:
    W_w = working load, ordinary load;
    W_{yp} = load W that produces a yield-point stress in the arch rib;
X_c = centroid ordinate;
Y_c = centroid ordinate;
y = vertical ordinate of arch rib: y_a = ordinate at point A (nominal outline);
α = slope angle of the arch rib at any point;
Δ = horizontal deflection;
δ = deflections due to thrust, bending, shear, camber, or temperature:
    δ_h = horizontal deflection;
    δ_v = vertical deflection;
    δ' = deformation produced by a load of 1 kip;
ϵ = linear coefficient of temperature expansion;
η = vertical displacement;
θ = angle change:
    θ_m = total angle changes;
    $\Delta\theta$ = small increment of angle change;
ρ = horizontal displacement;
τ = change in angles in relation to adjacent members, due to bending:
    τ_m = angle change at point m; and
ϕ = angle change: ϕ_c = angle change at the crown.

Acknowledgments.—The bridge was built under the direction of the Niagara Falls Bridge Commission, a body created by authority of an act of Congress.

The consultants retained by the Commission were: Waddell & Hardesty of New York, N. Y., who prepared the designs and plans; the Edward P. Lupfer Corporation of Buffalo, N. Y., who supervised the construction; and Aymar Embury II, M. Am. Soc. C. E., of New York who was consulting architect.

The deformeter analysis of the superstructure, mentioned in the first paper of the Symposium, was made by Egbert Hardesty, Jun. Am. Soc. C. E., and was reported fully in a thesis entitled "Model Analysis of the Proposed Rainbow Arch Bridge Over the Niagara River," which was presented to Rensselaer Polytechnic Institute in Troy, N. Y., in 1941, in partial fulfilment of the requirements for the degree of Bachelor of Civil Engineering.

The work described in the second paper was done at Princeton University in Princeton, N. J., under the sponsorship of the School of Engineering, of which Kenneth H. Condit is Dean of Engineering and Philip Kissam, M. Am.

Soc. C. E., is chairman of the Department of Civil Engineering. Complete results of these tests, including considerable material not touched on in the Symposium paper, are presented in the form of a thesis entitled "Moments in Flexible Arches," submitted to Princeton University in June, 1941, jointly by Messrs. McEldowney and Mead in partial fulfilment of the requirements for the degree of Civil Engineer. John W. Graham, Jr., Jun. Am. Soc. C. E., made the preliminary design for the loading frame and assisted in its construction. The authors of the first Symposium paper gave many valuable suggestions during the planning of this investigation and in the preparation of the digest of the results.

Award of the general contract for the fabrication and erection of the 950-ft main arch span of the Rainbow Bridge, including the concrete deck, was made to the Bethlehem Steel Company early in May, 1940. The ribs of the Rainbow arch were fabricated in the United States by the Bethlehem Steel Company and the remainder was fabricated in Canada under a contract let to the Canadian Bridge Company. The latter, in turn, sublet the fabrication of the spandrel girders to the Hamilton Bridge Company. In the construction operations, it was required that all workmen employed should be residents of the country where such operations were being done. It was desirable, however, that the field work be under one management, and it was agreed that all construction operations would be by the Bethlehem Steel Company.

The entire erection scheme was worked out under the direction of D. S. Gendell, Jr., M. Am. Soc. C. E., General Manager of Erection for the Bethlehem Steel Company. The author of the last paper of the Symposium, Mr. Durkee, was in charge of the erection of the steelwork as Resident Engineer, assisted by W. W. Oskin, J. T. York, and W. H. Thorn as junior engineers. R. S. Smith was foreman in charge on the New York side of the river and D. S. Shuman on the Canadian side.

The McLain Construction Corporation of Buffalo was contractor for the concrete approaches on the New York side and subcontractor for the concrete deck on the United States half of the steel arch. On the Canadian side, Aiken and MacLachlan, Ltd., of St. Catherines, Ontario, were contractors for the concrete approaches and subcontractors for the concrete deck.

DESIGN

BY SHORTRIDGE HARDESTY[1] AND J. M. GARRELTS,[2] MEMBERS,
AM. SOC. C. E., AND I. G. HEDRICK, JR.,[3] JUN. AM. SOC. C. E.

SYNOPSIS

The first part of this paper treats the design of the fixed arch bridge spanning the gorge between Niagara Falls, N. Y., and Niagara Falls, Ont., Canada. The design loads and allowable unit stresses are given, together with the stresses as calculated by the conventional elastic theory.

In the second part, the effects of rib deflections are discussed. The resulting moments at the quarter point are evaluated for a preliminary, two-hinged arch rib, and for the final fixed arch rib as built. A relatively simple procedure is proposed for calculating approximate values of such moments. These results can be used for preliminary studies, and in many cases are sufficiently accurate for use in final design.

PART I.—DESIGN

INTRODUCTION

The new Niagara arch bridge (Fig. 1) spanning the Niagara gorge is about one-half mile downstream from the Falls and 400 ft north of the location of the former International Falls View arch which it has replaced. The previous structure (wrecked by river ice on January 27, 1938) was a two-hinged arch

with an 840-ft span. Each rib of this structure consisted of a truss with chords 26 ft center to center, and with a rise of 150 ft. In accordance with present-day standards, the spandrel columns and the truss members were of light design.

At the site of the new bridge, the gorge is 1,250 ft wide at the rim and about 830 ft wide at the surface of the water. The depth from the rim to mean water level is 180 ft, which, with a water depth of 175 ft, makes a total of 355 ft. The walls of the gorge on both sides of the river drop almost vertically for a distance of 80 ft at the top, and then slope down at approximately 45° to the water line. The talus covering on the slopes is from 10 ft to 35 ft thick. The vertical cliffs are of dolomite, and the rock beneath the talus slopes consists of Rochester shale, Irondequoit limestone, Wolcott limestone, Sodus shale, Thorold sandstone, and Albion shale and sandstone. All strata are practically horizontal. A cross-sectional view of the various strata is shown in Fig. 2, a further description being as follows:

Clinton Formation.—

Rochester shale is rather soft on top. It weathers badly, but is a good firm rock requiring blasting where unexposed. It has irregular horizontal and vertical seams.

Irondequoit limestone is hard, firm, durable, and deeply bedded.

Wolcott limestone is a durable rock which does not occur in such a heavy strata as the Irondequoit limestone.

Sodus shale is bluish in color and is firm where not exposed.

Albion Sandstone Formation.—

Thorold sandstone is white, hard, and durable.

The Albion shale and sandstone stratum is a rather soft red sandstone interlaid with reddish shale. The stratum directly beneath is a much harder gray and red sandstone, which on the east shore is mottled, with thinner shale seams than in the overlying shale and sandstone stratum.

Preliminary Studies

Considerable thought was given to the esthetics of the new bridge and to the creation of a structure that would blend with the natural beauty and grandeur of the Niagara gorge. Architectural studies and preliminary designs showed definite advantages in favor of an arch-type structure for this location. In addition to its esthetic superiority, the arch is structurally appropriate; and the inclined rock walls provide a perfect support for the arch abutments. The approach structure favored by the Bridge Commission was one with massive concrete shafts and arches. This contrast in type of construction served to define the main arch span (Figs. 1 and 3).

The plate girder rib type was selected, rather than the trussed rib or the spandrel braced arch, because of its architectural simplicity. Transverse and longitudinal bracing between the spandrel columns was avoided in order to maintain the clean-cut lines of the structure (see Fig. 4). Horizontal forces are transferred from the floor to the plane of the arch through shear in the columns, except at two points near the center where inconspicuous sway bracing was used.

The effects of the participation of the deck with the superstructure, and of expansion joints in the deck floor system, were investigated by a deformeter analysis, using a celluloid model of one rib with spandrel columns and spandrel girders. This analysis demonstrated that the joints for the spandrel structure should be made as flexible as would be consistent with the desired rigidity of the construction and that at least two expansion joints in the spandrel girders and the floor system would be desirable.

FIG. 2.—ELEVATION OF

The first intention was to build a two-hinged arch structure; but a preliminary design of this type of structure proved to be so flexible, for a span of this length, as to show that a design which would be satisfactory would require ribs of excessive moment of inertia and sectional areas. The hingeless type then was investigated, and it was found that a rib with considerably less area and moment of inertia would be safe, and would be subject to much smaller deflections. Since both economy and rigidity favored the hingeless type, it was selected.

DESIGN LOADS AND ALLOWABLE UNIT STRESSES

The live load used for design was the H-20 loading of the 1935 Standard Specifications for Highway Bridges of the American Association of State Highway Officials. For the design of the arch rib, this is equivalent to a uniform live panel load of 54.4 kips and a concentrated live panel load of 26.7 kips, the panel length being 39.4 ft. The impact effect was calculated in accordance with the forementioned specifications. The intensity of the wind force was assumed to be 30 lb per sq ft on one-and-a-half times the projected area of the structure in a vertical plane, plus 200 lb per lin ft applied 6 ft above the roadway.

The design provided for a temperature variation of ±60° F from an arbitrary normal of 50° F. Allowance also was made for a possible error of ±1 in. in span length. Such an error would produce stresses equivalent to those due to a change in temperature of ±15° F.

The allowable unit stresses and the requirements for the details of design are in accordance with the 1938 Specifications for Steel Railway Bridges of the American Railway Engineering Association (A.R.E.A.). The basic unit stresses, in pounds per square inch, were:

	Carbon	Silicon
Tension, net section..............	18,000	24,000
Compression, gross section........	$15{,}000 - \frac{1}{4}\left(\frac{l}{r}\right)^2$	$20{,}000 - 0.46\left(\frac{l}{r}\right)^2$

The allowable unit stresses for the silicon steel arch ribs, for use with stresses computed by the elastic theory, in pounds per square inch, were:

Dead load+live load+impact load+temperature+error..............	20,000
Dead load+live load+impact load+temperature+error+wind load..	25,000

FIG. 3.—PLAN AND ELEVATION OF SUPERSTRUCTURE

DESIGN OF MAIN ARCH SPAN

Floor System.—The bridge carries two 22-ft roadways (see Fig. 5) separated by a 4-ft mall, and a 10-ft walkway on the south side facing the Falls. The roadway floor consists of 7½-in. concrete slab reinforced with welded-bar reinforcing trusses, which is supported on 30-in. wide-flange 108-lb rolled-beam stringers, a maximum of 5 ft 5 in. apart. The walkway is a 4-in. concrete slab. The stringers frame into silicon steel floor beams 6 ft 0¾ in. in depth, 39 ft 4 in. apart. Box-type spandrel girders, 6 ft 0¾ in. in depth, consist of a top cover plate, two top-flange angles, two web plates, and two bottom-flange angles. The spandrel girders are connected to the columns at most points with short, flexible angle connections which allow some relative movement in the longitudinal direction. However, rigid connections were used at panel point 5 (see Fig. 6) in order to provide longitudinal stiffness in the floor system, and at the

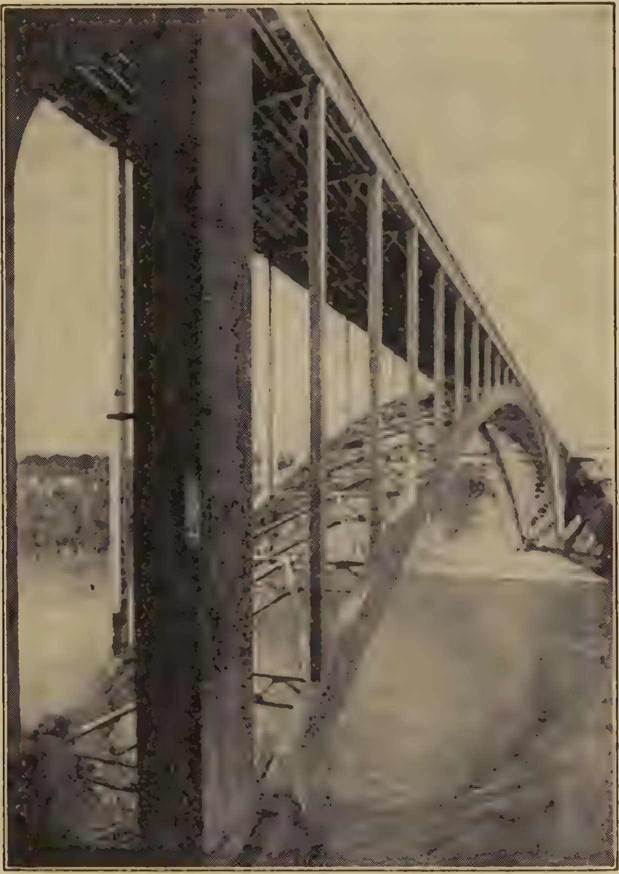

FIG. 4.—VIEW OF SPANDRELS AND WIND BRACING

long columns near the ends which were so flexible that rigid connections were found desirable.

Spandrel Columns.—The spandrel columns are rectangular box sections. They were designed for dead load, live load, wind loads, and stresses due to participation effects. Shears and moments are produced in the columns when the supporting arch ribs rotate or are displaced. Transverse wind loads also produce shears and moments in the columns, due to unequal transverse dis-

Fig. 5.—Cross Section of Deck

placements of the floor system and arch ribs. The base of each column was milled to a plane, tangent to the curved top cover plate of the arch rib; and high restraining moments in the connections for the columns were reduced by using flexible base connections, the connection angles having sufficient spring to allow the columns to rock slightly in the longitudinal direction on the arch rib. The tops of the columns at panel point 5 were fixed to the spandrel girders, as has been stated previously.

Wind loads on the deck are carried partly by the roadway lateral system and partly by shear in the spandrel columns. The part of the load carried by each was determined by distributing the loads to the laterals and to the columns in such a manner that the resulting deflections would be consistent. An expansion joint was provided in the deck and the floor lateral system at panel point 3.

Laterals.—The arch rib laterals consist of a plane of K-type bracing at both the top and bottom flanges of the rib, with transverse sway frames at each panel point. These laterals are designed for the wind forces acting directly on the rib and also for the wind forces transferred from the deck to the rib through the spandrel columns.

Arch Ribs.—The arch ribs are silicon steel box girders 12 ft deep. Design loads and stresses are shown in Table 1. In addition to the stresses computed by the elastic analysis, stresses due to the deflection effects were calculated at certain points. The resulting effect of these secondary stresses is discussed subsequently. Each arch rib, except at the springings, has two 144-in. by $\frac{13}{16}$-in. web plates and eight 8-in. by 8-in. flange angles. Top and bottom cover plates 54 in. wide vary from $1\frac{1}{8}$ in. to $2\frac{1}{2}$ in. in thickness. A longitudinal diaphragm at the center of the web plates and longitudinal angles at the quarter points provide adequate stiffness to prevent buckling of the web plates between the normal diaphragms, which are placed at panel points and mid-panel points.

The rib splices were designed to transmit at least 60% of the total stress through the splice material. The abutting ends of the rib sections at the splices were faced accurately to secure an even bearing when assembled in the structure. For access to the rib sections, manholes were cut in the inner web plates, the area around the holes being reinforced to compensate for the area taken out. The web manholes are spaced at intervals of about 120 ft, and openings in the diaphragms permit longitudinal passage through the inside of the rib sections. Typical details for a section of the rib are shown in Figs. 7 and 8.

The make-up of Section 1 is as follows:

Main material	Details
Two web plates, 144 in. by $\frac{13}{16}$ in.	Two angles, 7 in. by 4 in. by $\frac{5}{8}$ in.
Two cover plates, 54 in. by $1\frac{1}{8}$ in.	Two angles, 4 in. by 4 in. by $\frac{1}{2}$ in.
One plate, 34 in. by $\frac{3}{4}$ in.	Four angles, 4 in. by 4 in. by $\frac{7}{16}$ in.
Eight angles, 8 in. by 8 in. by 1 in.	....
Four angles, 7 in. by 4 in. by $\frac{5}{8}$ in.	....

The make-up of Section 2 is identical except that $1\frac{1}{4}$-in. cover plates were used.

cutting the surface of the rock into a series of horizontal and vertical steps that provided sufficient bearing area for both components of the rib thrust under any combination of loads. By referring to Fig. 2, it will be noted that the abutments rest on the upper layers of the Albion sandstone, and exert thrust against the Irondequoit and Wolcott limestones and the Thorold sandstone.

APPROACHES

The reinforced concrete approach structures on the two sides of the river are similar. Each approach consists of three arched spans over the sloping walls of the gorge and a beam span over a transverse highway. The concrete box arches are 12 ft wide and frame into columns 12 ft in width. The bridge deck between the arches is carried by reinforced concrete beam and girder construction, as shown in the cross-sectional view in Fig. 9. The longitudinal view at the center line of the bridge indicates the method of framing for this part of the structure. An expansion joint at the crown of the middle arched span completely separates the two halves, so that they act as cantilevers. The design for the concrete structures was made to provide for continuity. The girders for the spread girder span over River Road on the Canadian side are particularly heavy, the north and south girders having span lengths of 85 ft and 91 ft, respectively.

SUMMARY OF QUANTITIES

The principal quantities in the bridge are as follows:

Main Arch Span.—	
Concrete in deck, in cubic yards	1,800
Reinforcing bars in deck, in pounds	210,000
Reinforcing trusses for roadway slab, in pounds	300,000
Carbon steel in floor system, in pounds	2,410,000
Silicon steel in floor system (floor beams), in pounds	480,000
Carbon steel in spandrel columns, in pounds	1,140,000
Carbon steel in rib laterals, in pounds	900,000
Silicon steel in arch ribs and skewbacks, in pounds	6,220,000
Concrete in arch abutments, in cubic yards	7,100
Reinforcing steel in arch abutments, in pounds	300,000
American Approach.—	
Concrete, in cubic yards	7,800
Reinforcing steel, in pounds	840,000
Canadian Approach.—	
Concrete, in cubic yards	10,800
Masonry facing, in cubic feet	5,400
Reinforcing steel, in pounds	1,290,000

PART II.—DEFLECTION EFFECTS AND DESIGN FORMULAS FOR FLEXIBLE ARCHES

The elastic theory has been in use for many years in the design of structures. In general, any change of geometry of the structure due to strain is neglected in this theory. When the elastic displacements are small, the error involved is usually small; but, when the elastic displacements are appreciable, the error introduced may be an important factor in the design.

More exact methods have been developed for some of the problems of structural design in which deflections should be considered. The "deflection theory" for suspension bridges, which takes into account the elastic displacements of the structure, was first used in the United States in the design of the Manhattan Bridge in New York. It was amplified and developed further in the design of later suspension bridges. This theory, which results in lower bending moments in the stiffening truss of a suspension bridge than those calculated by the elastic theory, is considered applicable for practically all spans.

Columns under eccentric load or with initial curvature and columns under the combined action of axial and transverse loads continue to receive considerable attention. The rib of an arch bridge, being a compression member subject to both direct and bending stress, will have deflection characteristics similar to those of a column under the same type of loading.

Several deflection theories are available for arch ribs (see Appendix I). In each of these theories, certain assumptions have been made as to the variation of moment of inertia in the arch rib, and, in some cases, the part of span loaded with live load is specified. However, in one of these theories, referred to as "Stern's" in Appendix I, the arch axis can be divided into any desired number of sections, each having a constant moment of inertia, and live load can be placed on any part of the structure. This latter method was used to compute the quarter-point deflection for a preliminary two-hinged arch design, using the same loading as that required to produce the maximum elastic-theory moments at the quarter point. This computed deflection was 60% greater than the value given by the elastic theory.

When the Niagara design was started, a two-hinged arch rib was analyzed first by the elastic theory, with total stresses not exceeding those set up as allowable working stresses. The resulting rib, which was 14 ft in depth and weighed 3,000 lb per ft, then was checked by an analysis which included the effect of the deflection. This more exact calculation showed that the quarter-point deflection of 12 in., due to (dead + live + impact)-load, as computed by the elastic theory, increased to 21 in. under the exact method, and that the true unit stresses were 28% greater than those indicated by the elastic theory. Perhaps more important, this calculation showed that an increase in dead and live loading of 30% above the design loads would increase the stresses to the yield strength of the steel, so that the safety factor of the structure, instead of being 1.875 as indicated by the elastic-theory unit stresses, was only 1.30. A two-hinged arch rib with a true safety factor of 1.875 under the design loads could have been obtained with a rib of 15-ft depth, weighing 3,800 lb per ft.

In the case of the two-hinged arch rib, the calculation of the quarter-point vertical deflection of 12 in. indicated that the rib had moved radially away from the thrust line approximately 13.6 in. This would produce an additional moment equal to the thrust at that point times the 13.6-in. displacement. In the case of this preliminary design, such a moment amounted to more than 8,600 ft-kips as compared to the elastic-theory moment of 22,950 ft-kips. Furthermore, this additional moment would produce still more deflection, which finally would total 23.4 in. in the radial direction, and a total additional moment of more than 14,500 ft-kips.

In contrast to the flexibility of the aforementioned two-hinged arch rib, the hingeless arch rib which was used in the final design of the bridge is 12 ft deep and weighs 2,600 lb per ft. It has a quarter-point deflection due to (dead + live + impact)-load of 5.5 in. by the elastic analysis. This increases to 6.9 in. by the more exact computation taking deflections into account.

The preliminary calculations for the two-hinged arch rib were sufficient to show that the elastic theory was inadequate for the design of such a structure. Had the two-hinged rib of the first preliminary design been built, the structure undoubtedly would have been unsatisfactory in its performance.

The results of the calculations also suggested the advisability of further study by the use of models, especially for those structures in which large displacements occur. Such a project was undertaken at Princeton University under the supervision of Professor Timby, as reported elsewhere in this Symposium. Three different models were used and a number of different loading conditions were applied to each.

The factor of safety (N), as used in the preceding paragraphs and elsewhere in this paper, is defined by the following relation:

$$N = \frac{W_{yp}}{W_w} \quad \text{(1)}$$

in which W_{yp} is the (dead + live + impact)-load which, together with the effects of temperature and wind, produces a yield point stress in the arch rib, and W_w is the (dead + live + impact)-working load or design load. For this purpose W can be assumed to be the panel load.

The computations for the deflection effects in the preliminary two-hinged arch rib and for the hingless rib as built were based upon finding the equilibrium position of the arch rib by trial. That is, after computing the displacements from the elastic-theory moments and the change in moments resulting from the displaced position of the arch axis, correction moments to displace the arch rib to its equilibrium position were estimated. From these moments, displacements were calculated and second correction moments estimated; and this procedure was repeated until the equilibrium position of the rib had been determined. The values for deflections and moments computed by this procedure will be referred to herein as "exact."

Complete calculations were made for the loading condition that produces maximum bending moment at the quarter point of the span. After exact values were calculated and confirmed by the results of model tests, a simple, approximate procedure was developed which gives an accuracy sufficient for preliminary design and, in the ordinary structure, for final design.

DEFLECTION EFFECTS IN TWO-HINGED ARCH RIB

The relations between the forces acting on the structure and the resulting radial displacements are expressed by the differential equation (see Fig. 10):

$$\frac{d^2u}{ds^2} + \frac{u}{(r_o)^2} = -\frac{M}{E\,I} - \frac{T}{r_o\,E\,A} \quad \text{(2)}$$

in which ds = differential element of length of the arch rib; u = radial component of displacement of the rib; r_o = original radius of curvature of rib; M = final bending moments; T = final direct thrust; I = moment of inertia of rib cross section; A = cross-sectional area of rib; and E = modulus of elasticity. The vertical and horizontal displacements η and ρ are

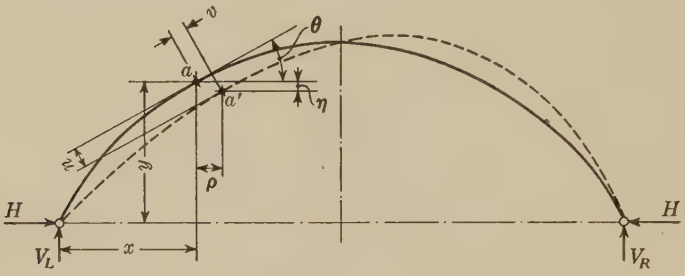

FIG. 10.—DEFLECTION EFFECT IN A TWO-HINGED ARCH RIB

$$\eta = u \cos \theta - v \sin \theta \ldots\ldots\ldots\ldots (3a)$$

and

$$\rho = u \sin \theta + v \cos \theta \ldots\ldots\ldots\ldots (3b)$$

in which v is the tangential displacement.

In the usual elastic analysis for the two-hinged arch, the condition for equilibrium at any point, A, is expressed by the equation,

$$M_{ae} = M'_a - H\, y_a \ldots\ldots\ldots\ldots (4)$$

If the effects of displacements are included, Eq. 4 becomes,

$$M_{af} = M'_a + \Delta M'_a - (H + \Delta H)\,(y_a - \eta_a) \ldots\ldots\ldots\ldots (5)$$

in which M'_a = simple beam moment at point, A; H = horizontal component of end reactions; y_a = vertical ordinate of point, A, nominal outline; η_a = vertical component of deflection of point, A; and $\Delta M'_a$ and ΔH = change in M'_a and H resulting from the change in geometry of the rib.

The correct position of the arch axis is one for which Eqs. 2 and 5 are satisfied. In the analysis, the terms $\frac{u}{(r_o)^2}$ and $\frac{T}{r_o\, E\, A}$ of Eq. 2 were neglected, since these terms are relatively small for ribs of the curvature considered.[3a] Eq. 2 then reduces to:

$$\frac{d^2u}{ds^2} = -\frac{M}{E\,I} \ldots\ldots\ldots\ldots (6)$$

As a first approximation, the moments M_e determined by the elastic analysis were applied to the rib and the resulting displacements determined. If the rib is considered to be in this deformed position, it is not in equilibrium under the action of the computed forces because Eq. 5 is not satisfied.

A second approximation was made by calculating the moments M_1 for the rib in the deformed position, the coordinates being $x + \rho$ and $y - \eta$, instead of x and y.

[3a] See corrections and revised Eqs. 16, 17, and 21, in the closing discussion.

The moments M_1 differed from the moments M_e by $\Delta m_1 = M_1 - M_e$. This difference for the two-hinged arch can be considered to consist of the following terms:

$$\Delta m_1 = \Delta M' - y\,\Delta H + H\,\eta + \eta\,\Delta H \ldots\ldots\ldots\ldots (7)$$

By applying these moments to the rib and finding the resulting deflections, moments M_2 can be computed from the new deformed position. By continuing this procedure, the equilibrium position of the arch when the moments and deflections are consistent can be determined.

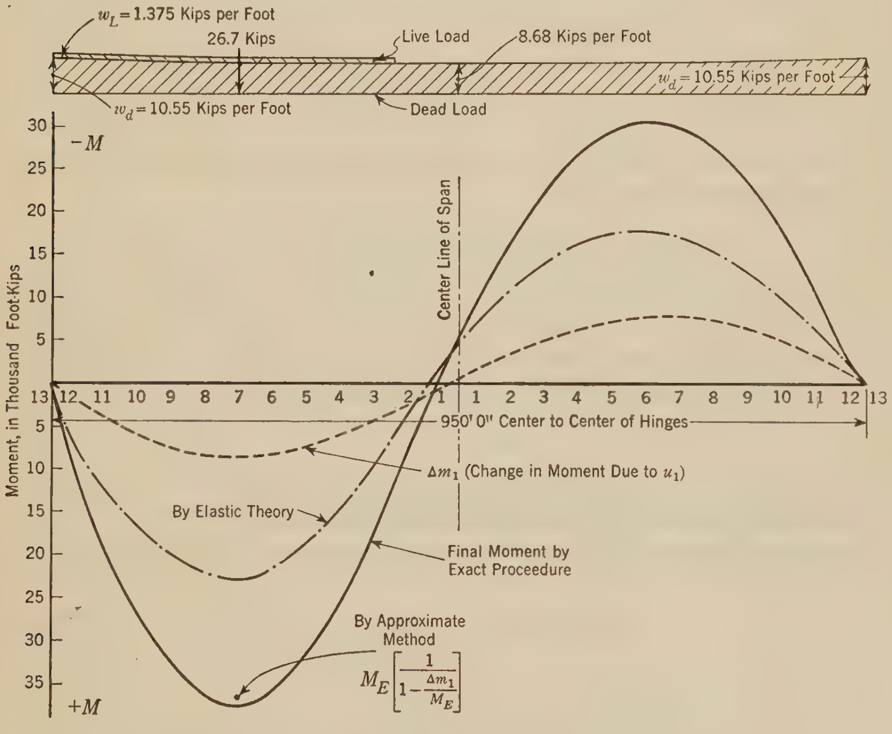

Fig. 11.—Variation in M_e for a Two-Hinged Arch Bridge (L = 950 Ft; Rise = 150 Ft; I = 116.14 Ft^4 at the Crown and 120.24 Ft^4 at the Quarter Point)

For the Niagara two-hinged arch rib, it was noted that the variation in Δm_1, under loadings which produce maximum moment in sections near the quarter points of the span, was similar to the variation in M_e (Fig. 11), and that a close approximation could be obtained by assuming that the deflections at point A in the vicinity of the quarter point, produced by moment Δm_1, are given by:

$$\Delta u_{a1} = u_{ae}\left(\frac{\Delta m_{a1}}{M_{ae}}\right) \ldots\ldots\ldots\ldots (8)$$

Similarly the additional moment Δm_{a2}, resulting from the deflection Δu_{a1}, is given by:

$$\Delta m_{a2} = \Delta m_{a1} \left(\frac{\Delta u_{a1}}{u_{ae}} \right) = \Delta m_{a1} \left(\frac{\Delta m_{a1}}{M_{ae}} \right) = M_{ae} \left(\frac{\Delta m_{a1}}{M_{ae}} \right)^2 \ldots\ldots.(9)$$

Assuming successive corrections to be obtained in a similar manner, the final moment M_{af} at point A can be written:

$$M_{af} = M_{ae} + M_{ae} \left(\frac{\Delta m_{a1}}{M_{ae}} \right) + M_{ae} \left(\frac{\Delta m_{a1}}{M_{ae}} \right)^2 + M_{ae} \left(\frac{\Delta m_{a1}}{M_{ae}} \right)^3 + \cdots.(10)$$

or

$$M_{af} = M_{ae} \left(\frac{1}{1 - \dfrac{\Delta m_{a1}}{M_{ae}}} \right) \ldots\ldots\ldots\ldots(11)$$

An approximate value for the radial displacement can be obtained in a similar manner, giving:

$$u_{af} = u_{ae} + u_{ae} \left(\frac{\Delta m_{a1}}{M_{ae}} \right) + u_{ae} \left(\frac{\Delta m_{a1}}{M_{ae}} \right)^2 + \cdots = \frac{u_{ae}}{1 - \dfrac{\Delta m_{a1}}{M_{ae}}} \ldots.(12)$$

Furthermore, it was found that, for a rib of the Niagara arch properties, the following relation was a very close approximation:

$$\Delta m_{a1} = T_a \, u_{ae} \ldots\ldots\ldots\ldots(13)$$

in which T_a = the total axial thrust at the point A and u_{ae} = the radial displacement of point A as computed by the elastic theory.

Substituting Eq. 13 in Eqs. 9 and 10, the following expressions result:

$$M_{af} = M_{ae} \left[\frac{1}{1 - T_a \left(\dfrac{u_{ae}}{M_{ae}} \right)} \right] \ldots\ldots\ldots\ldots(14a)$$

and

$$u_{af} = u_{ae} \left[\frac{1}{1 - T_a \left(\dfrac{u_{ae}}{M_{ae}} \right)} \right] \ldots\ldots\ldots\ldots(14b)$$

A comparison of the moments computed by Eq. 14*a* and those obtained by model tests at Princeton University (described in the succeeding paper in this Symposium) shows that the agreement is quite good when the value of the term in brackets in Eqs. 14 is less than 2.

For a perfectly fabricated rib, the final (dead load + live load + impact load) moment being given by Eq. 14*a*, the total resulting (dead load + live load + impact load) stress in the extreme fiber at a point A (this point being assumed as between 0.10 L and 0.30 L from either hinge) can be written as:

$$s = \frac{T_a}{A_a} \pm \frac{M_{ae}}{S_a}\left[\frac{1}{1 - T_a\left(\frac{u_{ae}}{M_{ae}}\right)}\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which A_a = cross-sectional area of rib at the point A; and S_a = section modulus of rib at the point A.

If the useful capacity of the structure is defined as the load that produces a stress at any section equal to the elastic limit s_y of the material and the factor of safety N, as previously defined, is introduced, the following equation should be satisfied by a properly designed rib:[3a]

$$s_y = N\left(\frac{T_a}{A_a}\right) + N\,\frac{M_{LL+I}}{S_a}\left[\frac{1}{1 - N\,T_a\left(\frac{u_{ae}}{M_{LL+I}}\right)}\right] + \frac{N\,M_{DL}}{S_a} + \frac{T_t + T_w}{A_a} + \frac{M_t + M_w}{S_a} \quad \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which T_a is the elastic-theory thrust at point A due to (dead + live + impact)-load; T_t and T_w are the thrusts at that point due to temperature effect and wind, respectively; and M_{DL}, M_{LL+I}, M_t, and M_w are the elastic-theory moments due to (dead + live + impact)-load, temperature effect, and wind, respectively.

In the special case of a perfectly formed rib carrying loads that produce no bending moment, the following condition should also be satisfied: $N\,T_{0.25}\left(\frac{u_{0.25E}}{M_{0.25E}}\right) < 1$—in which $u_{0.25E}$ and $M_{0.25E}$ are radial displacement and the moment that would be produced at the quarter point of the span by an assumed uniform live load over half the span, and $T_{0.25}$ is the thrust at the quarter point due to dead load only. Inspection of Eq. 14*b* shows that as the term $T_{0.25}\,\frac{u_{0.25E}}{M_{0.25E}}$ approaches unity, any small displacement of the rib at the one-quarter point becomes very large. The rib, therefore, would buckle in a two-loop form. The value of thrust which makes this term equal to unity agrees closely with the critical buckling thrust obtained for special cases by more nearly mathematically exact theories.[4]

Practically, of course, it is impossible to fabricate and erect an arch rib that will conform exactly to a prescribed outline. The worst form of the variation for accidental errors in rib outline would be the same variation as the live-load displacements, u. With accurate workmanship, the maximum probable ordinate of a departure of this type can be expressed approximately as: $e' = \frac{\sqrt{L}}{30}$, but not less than 0.25 . . . when e' is in inches and L, in feet.

For the Niagara arch span, L = 950 ft, e' = 1.03 in.; and, for a span of 225 ft, the value of e' would be 0.5 in.

---

[4] "Theory of Elastic Stability," by S. Timoshenko, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1936, p. 225.

An error of this magnitude, although insignificant in an elastic-theory analysis, may produce appreciable secondary moments and should be considered in design. The effect of such error incorporated in Eq. 16 gives finally:[3a]

$$\frac{s_y}{N} = \frac{T_a}{A} + \frac{M_{LL+I} + T_a \frac{e'}{N}}{S_a} \times \frac{1}{1 - N\,T_a \frac{u_{ae}}{M_{LL+I}}}$$

$$+ \frac{M_{DL}}{S_a} + \frac{1}{N}\left(\frac{T_t + T_w}{A_a} + \frac{M_t + M_w}{S_a}\right) \ldots\ldots\ldots\ldots\ldots (17)$$

Eq. 17 is proposed for design use. The following values of s_y and N, which have been taken from the 1941 A.R.E.A. Specifications for Steel Railway Bridges, Appendix A, indicate the numerical values used in current design for (dead + live + impact)-load stresses:

	s_y (lb per sq in.)	N	$\frac{s_y}{N}$
Structural steel	33,000	1.833	18,000
Silicon steel	45,000	1.875	24,000
Nickel steel	55,000	1.83	30,000

When unusual outline or loadings are encountered, or when the importance of the structure warrants, a check of Eq. 16 can be obtained at a few critical points by successive approximations of the elastic theory, previously described and referred to as the "exact method."

As a numerical example, Eq. 15 will be applied to a preliminary two-hinged arch design for the Niagara span: The stresses at the quarter point are shown in Table 2. For this case: The depth of the rib is 14 ft; the section area is 614 sq in.; the section modulus is 29,000 in.^{3}; u_{ae} = 13.6 in. for positive moment and 14.0 in. for negative moment. Using the moments and thrusts computed by the elastic theory, the following stresses are found:

TABLE 2.—STRESSES AT THE QUARTER POINT IN A PRELIMINARY TWO-HINGED ARCH

Loading	Elastic Theory				Deflection Theory	
	Thrust (Kips)		Moment (Ft-Kips)		Thrust (Kips)	Moment (Ft-Kips)
	+M	−M	+M	−M	+M	+M
Dead load	−7,126	−7,126	+353	+353	−7,554	353
Live load	−425	−709	+22,594	−22,076		+37,123
Impact	−37	−62	+1,990	−1,943	−37	+3,270
Σ	−7,588	−7,897	+24,937	−23,666	−7,591	+40,746

For maximum positive moment—

$$s = \frac{7,588}{614} + \frac{24,937 \times 12}{29,000} = 12.36 + 10.31 = 22.67 \text{ kips per sq in.}$$

For maximum negative moment—

$$s = \frac{7{,}897}{614} + \frac{23{,}666 \times 12}{29{,}000} = 12.86 + 9.79 = 22.65 \text{ kips per sq in.}$$

The stress, computed from the moments and thrusts obtained by the deflection analysis, is:
For maximum positive moment—

$$s = \frac{7{,}591}{614} + \frac{40{,}746 \times 12}{29{,}000} = 12.36 + 16.86 = 29.22 \text{ kips per sq in.}$$

Using the approximate Eq. 15, the resulting stresses are:
For maximum positive moment—

$$s = \frac{7{,}588}{614} + \frac{24{,}584 \times 12}{29{,}000} \times \frac{1}{1 - 7{,}588 \times \dfrac{13.6}{12 \times 24{,}584}}$$

$$+ \frac{353 \times 12}{29{,}000} = 12.36 + 10.17 \times \frac{1}{0.6502} + 0.15 = 28.15 \text{ kips per sq in.}$$

For maximum negative moment—

$$s = \frac{7{,}897}{614} + \frac{24{,}019 \times 12}{29{,}000} \times \frac{1}{1 - 7{,}897 \times \dfrac{14.0}{12 \times 24{,}019}}$$

$$- \frac{353 \times 12}{29{,}000} = 12.86 + 9.94 \times \frac{1}{0.6164} - 0.15 = 28.83 \text{ kips per sq in.}$$

DEFLECTION EFFECT IN A HINGELESS ARCH RIB

In the elastic analysis for the fixed arch rib, the condition for equilibrium at any point A is expressed by the equation:

$$M_a = M'_a + M_{oa} - H\, y_a \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

When the effects of displacements are included, Eq. 18 becomes:

$$M_{af} = M'_a + \Delta M'_a + M_{oa} + \Delta M_{oa} - (H + \Delta H)(y_a - \eta) \ldots\ldots (19)$$

in which M_{oa} = moment at point A due to end moments; and $\Delta M'_a$, ΔH, ΔM_{oa} = increments resulting from the change in geometry of the rib. The correct position of the arch axis is that for which Eqs. 2 and 19 are satisfied.

The equilibrium position was determined for the Niagara arch rib for the live-load condition which produces maximum positive moment at the quarter point of the span. This was accomplished in a manner similar to that used for the two-hinged rib. The results of this analysis are shown partly in Fig. 12 in which the first correction moment Δm_1 is approximately proportional to the moments of the elastic theory. Assuming then that this relation exists, the final moment and radial displacement can be estimated by the same procedure used in obtaining Eqs. 10 and 12 for the two-hinged arch.

For the hingeless arch, these equations cannot be simplified by introducing $T\, u_e$ as an approximation for Δm_1, as in the case of the two-hinged arch.

The stress is given by:

$$s = \frac{T_a}{A_a} \pm \frac{M_{ae}}{S_a}\left(\frac{1}{1 - \dfrac{\Delta m_{a1}}{M_{ae}}}\right) \quad \text{(20)}$$

The moment produced by an initial error in rib outline was found to be about 70% of the moment that would be produced in a two-hinged rib by the same

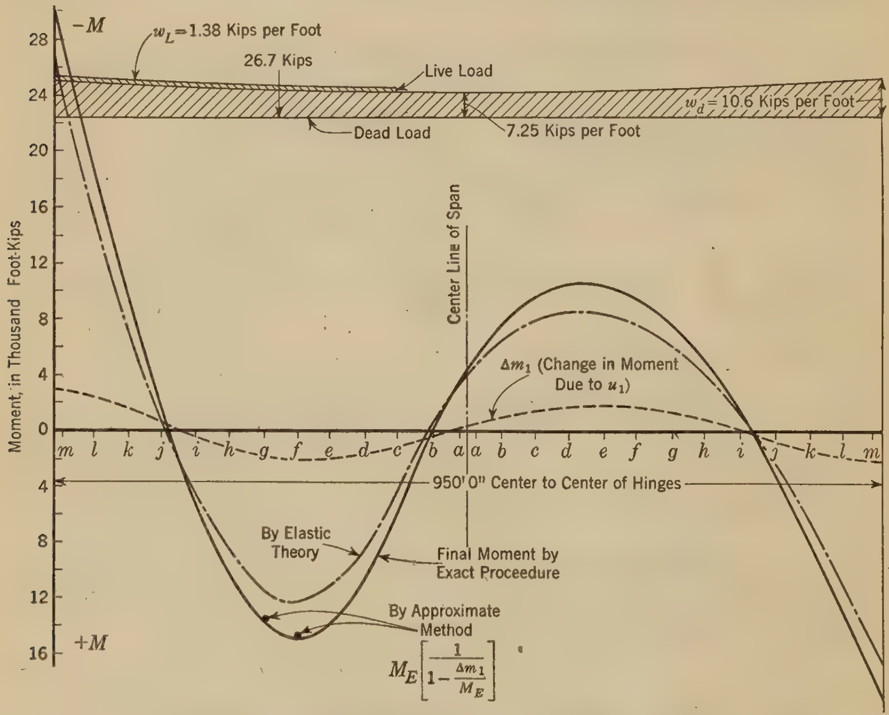

FIG. 12.—VARIATION IN M_e FOR A FIXED ARCH (L = 950 FT; RISE = 150 FT; I = 81.17 FT^4 AT THE CROWN AND 88.20 FT^4 AT THE QUARTER POINT)

error. Therefore a properly designed hingeless arch rib should satisfy the following equation:[3a]

$$\frac{s_y}{N} = \frac{T_a}{A_a} + \frac{M_{LL+I} + 0.7\,T_a\dfrac{e'}{N}}{S_a}\left[\frac{1}{1 - N\left(\dfrac{\Delta m_{a1}}{M_{LL+I}}\right)}\right] + \frac{M_{DL}}{S_a} + \frac{1}{N}\left[\frac{T_t + T_w}{A_a} + \frac{M_t + M_w}{S_a}\right] \quad \text{(21)}$$

The calculations for Δm_{a1} are quite lengthy as the rib outline is generally unsymmetrical after the first deflections are added to the ordinates. However, when a sufficient variety of ribs has been computed exactly, or when model tests, comparable to those made at Princeton University for the two-hinged rib, have been made for the hingeless rib, it may be possible to write an approximate expression for the value Δm_1.

As a numerical example Eq. 20 will be applied to the final Niagara ribs. Similarly to Table 2, the stresses at the quarter point are shown in Table 3. For this case: The depth of rib is 12 ft; the section area, 553.96 sq in.; the section modulus, 24,600 in.^{3} and $\Delta m_{a1} = 2{,}018$ ft-kips, for positive moment, and $\Delta m_{a1} = -1{,}888$ ft-kips for negative moment.

TABLE 3.—STRESSES AT THE QUARTER POINT IN THE HINGELESS NIAGARA ARCH

Loading	Elastic Theory				Deflection Theory	
	Thrust (Kips)		Moment (Ft-Kips)		Thrust (Kips)	Moment (Ft-Kips)
	$+M$	$-M$	$+M$	$-M$	$+M$	$+M$
Dead load	−6,062	−6,105	+2,138	+657	−6,455	+16,628
Live load	−398	−763	+11,948	−10,640		
Impact	−35	−67	+1,051	−937	−35	+1,230
Σ	−6,495	−6,935	+15,137	−10,920	−6,490	+17,858

As before, using the moments and thrusts computed by the elastic theory, the following stresses are found:

For maximum positive moment—

$$s = \frac{6{,}495}{553.96} + \frac{15{,}137 \times 12}{24{,}600} = 11.72 + 7.38 = 19.10 \text{ kips per sq in.}$$

For maximum negative moment—

$$s = \frac{6{,}935}{553.96} + \frac{10{,}920 \times 12}{24{,}600} = 12.52 + 5.33 = 17.85 \text{ kips per sq in.}$$

The stress obtained from the deflection-theory moments and thrusts is as follows:

For maximum positive moment—

$$s = \frac{6{,}490}{553.96} + \frac{17{,}858 \times 12}{24{,}600} = 11.72 + 8.71 = 20.43 \text{ kips per sq in.}$$

Using the approximate Eq. 20, the following stresses are obtained:

For maximum positive moment—

$$s = \frac{6{,}495}{553.96} + \frac{12{,}999 \times 12}{24{,}600} \times \frac{1}{1 - \dfrac{2{,}018}{12{,}999}} + \frac{2{,}138 \times 12}{24{,}600}$$

$$= 11.72 + 6.34 \times \frac{1}{0.8448} + 1.04 = 20.27 \text{ kips per sq in.}$$

For maximum negative moment—

$$s = \frac{6{,}935}{553.96} + \frac{11{,}577 \times 12}{24{,}600} \times \frac{1}{1 - \dfrac{1{,}888}{11{,}577}} - \frac{657 \times 12}{24{,}600}$$

$$= 12.52 + 5.65 \times \frac{1}{0.8369} - 0.32 = 18.95 \text{ kips per sq in.}$$

CONCLUSIONS

Four basic conclusions seem justifiable from this paper:

1. The useful strength of an arch rib is dependent in part upon the magnitude of the product of deflection under live load and total thrust.

2. In flexible arches the usual method of applying the elastic theory will lead to an appreciable overestimate of the strength of the structure. This error is especially serious in the case of long spans with heavy dead load, such as the Niagara arch bridge.

3. An attempt has been made to set up practical design formulas, for both two-hinged and hingeless ribs, that include deflection effects.

4. Additional model tests would aid greatly in confirming and simplifying the basis of design suggested in this article.

APPENDIX I

RÉSUMÉ OF AVAILABLE DEFLECTION THEORIES

J. Melan[5] developed a deflection theory for two-hinged arch ribs with parabolic axis and constant cross section. Horizontal displacement components were neglected and the further approximation was used that $\frac{d^2u}{ds^2} = \frac{d^2\eta}{dx^2}$.

S. Kasarnowsky[6] obtained a solution for the deflection stresses in a constant-section two-hinged arch rib with parabolic arch axis. He assumed that $\eta = u \cos \theta$ and that there was no horizontal displacement. The analysis is restricted to the case of live load extending over one half of the span.

B. Fritz[7] developed equations for three-hinged, two-hinged, and hingeless arch ribs of constant cross section and parabolic arch axes. Horizontal displacements were neglected and the assumption was made that $\eta = u \cos \theta$. Fritz's equations are applicable for a uniform live load over any part of the span length.

A. Freudenthal[8] assumed that the radial displacement is equal to the vertical component of deflection η. He obtained a solution for the stresses in either a two-hinged rib or a hingeless arch rib with parabolic axis and a variation of cross section given by $I = I_c \sec \theta$.

In a deflection theory for two-hinged arch ribs, George Stern,[9] Assoc. M. Am. Soc. C. E., assumed that there were no horizontal displacements of vertical loads and that $\eta = u \cos \theta$. The variation in cross section of rib was taken into account by assuming the arch to be divided into any number of subdivisions with constant section over each element. This theory may be used for any shape of arch axis and any loading condition.

MOMENTS IN FLEXIBLE TWO-HINGED ARCHES

By Elmer K. Timby,[10] Assoc. M. Am. Soc. C. E.,
Lawrence M. Mead, Jr.,[11] Jun. Am. Soc. C. E.,
and Robert McEldowney, Jr.,[12] Esq.

Synopsis

The research described in this paper was planned to furnish information to assist in the design of arch ribs sufficiently flexible to sustain appreciable deflections before becoming overstressed. Experience has shown that the classic elastic theory, when applied to such arches, yields calculated stresses which are considerably less than existing stresses unless extended by successive approximations which consider the effect of the rib deflections on the moments. The work consisted of experimental observations of the behavior of loaded circular two-hinged steel arch models of constant section. The results of these observations are presented graphically and have been treated analytically to provide: (*a*) Practical limits of flexibility for the design of two-hinged arch ribs by straight elastic theory; (*b*) material assistance in the preliminary design of arches; and (*c*) actual design methods for certain two-hinged arch ribs which are too flexible for analysis by elastic theory. Within reasonable limits, the results may be applied to noncircular profiles and to varying sections by use of proper relative dimensions.

Test Procedure

Experimental observations were made on three models, having properties described in Fig. 13. Each rib had a section 1.00 in. wide by 0.25 in. deep and was formed cold to fit a template of the desired circular radius to within 0.01 in. Material was cold finished steel with an average value for E of 29,520,000 lb per sq in., maximum variation noted being 1.03%. One of these models is shown mounted in the special loading frame built for these tests in Fig. 14.

Both dead load and live load, accurate to 0.01 lb, were suspended from the model on hanger rods (Fig. 14) at the E-points (Fig. 13). Several different values of dead load, $\overline{DL}$, were used, and each was defined by its intensity in pounds per unit of length at the crown. The intensity of any particular dead load was varied along the arch in a manner calculated to keep the resultant dead-load thrust line on the center line of the rib. Live loads were maintained uniform for the extent of the loading.

[12] 2d Lt., U. S. Marine Corps (formerly, Apprentice Engr., Taylor-Wharton Iron and Steel Co., High Bridge, N. J.).

Dead loads and live loads designed and used on the models are listed in Table 4, in which R denotes the ratio of dead load to live load ($\overline{DL}/\overline{LL}$). These various loads were designed to extend beyond practical limits in both directions of magnitude, varying from loads which would be considered very light, in view of the stiffness of the section, to loads which caused the arch to approach a buckling condition. The particular loads that corresponded most closely to the original two-hinged design for the Niagara Rainbow arch mentioned in the preceding paper in the Symposium were: $\overline{DL} = 2.50$ lb per in.; $\overline{LL} = 0.50$ lb per in.; $R = 5.00$.

TABLE 4.—LIVE LOADS, IN POUNDS PER INCH

Dead-load intensity, $\overline{DL}$, in lb per in.	Values of $R \left(= \frac{\overline{DL}}{\overline{LL}}\right)$				
	2.50	5.00	7.50	10.00	15.00
1.25	0.50	0.25	0.167	0.125	0.083
2.50	1.00	0.50	0.333	0.250	0.167
3.75	1.50	0.75	0.500	0.375	0.250
5.00	2.00	1.00	0.667	0.500	0.333

The models were mounted in the apparatus shown in Fig. 14, and observations were made to determine deflection, horizontal component at the reactions, and maximum moment at a point (only the latter being presented in this paper). All observations for maximum moment were made between the condition of dead load on the arch, and the condition of dead load plus live load placed to produce the maximum value of moment at the point being studied—the extent and position of the live load being determined by trial. The hinges were made free to rotate by using clean ball bearings and vibrators at each reaction. Checks indicated that friction was negligible. A constant span was maintained by a horizontal adjustment of one support during each loading cycle to provide a specified constant distance between hinges. This distance was controlled by two 0.0001-in. micrometer dials, shown at the left reaction in Fig. 14.

FIG. 13.—CONTROLLING DIMENSIONS OF MODEL ARCH RIBS TESTED

Deflection measurements were made in two ways: (1) By direct observation with filar micrometer microscopes; and (2) by observing with a microscope a photographic film on which exposures had been made for both the unloaded and the loaded condition, in respect to live load. The latter method checked the first for accuracy and proved to be much more rapid, in addition to preserving the information for observation and study at a later date. Fig. 15 indicates such a double exposure for one of the more flexible conditions. Although photographs were made for each condition of loading, time has not permitted the study of these data, except in certain instances when they were used in conjunction with the observed horizontal reaction component and the statically determined vertical components, to check the directly observed moments.

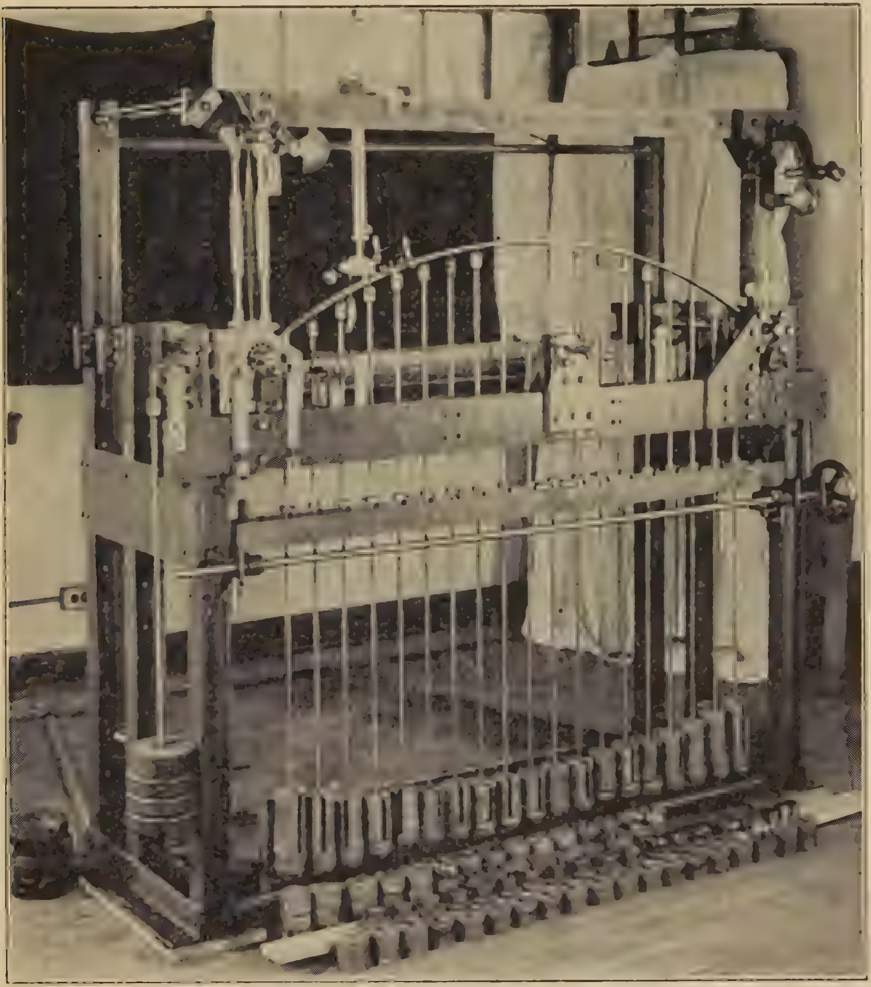

Fig. 14.—View of Model in Special Loading Frame

The horizontal component was measured as follows: One hinge was mounted in a block fixed in the loading frame, whereas the other hinge was mounted elastically in a block relatively free to translate in the direction of the span length. Calibrated piano wires, long enough to allow the use of 20-in. extensometers, with one end attached to the movable block and the other attached to blocks capable of being moved by worm threads and gears, were used to adjust the movable block to correct position for accurate span length. The strain readings on the extensometers indicated the magnitude of the horizontal component.

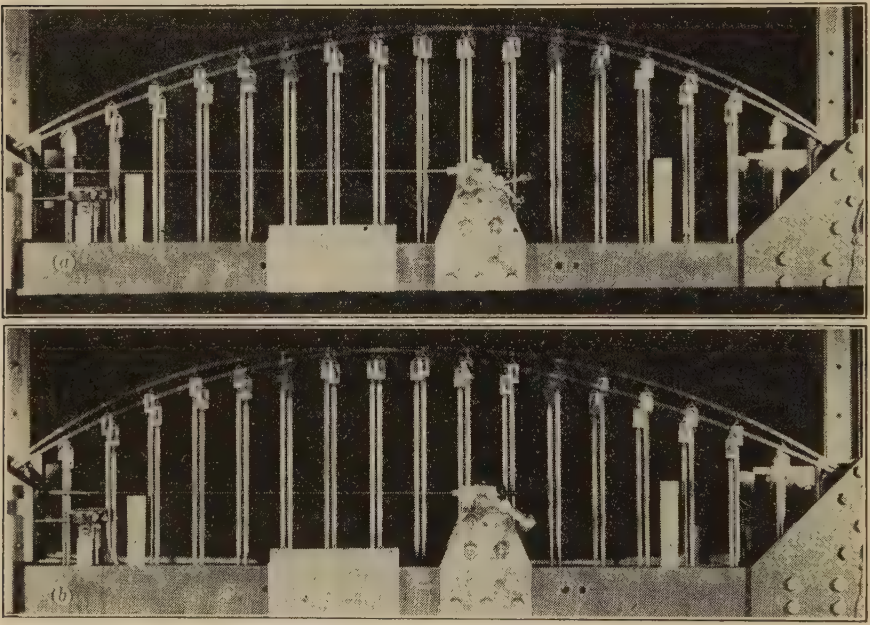

Fig. 15.—Double-Exposure Photographs to Observe Deflections; Model of Arch No. 1 at Point 6 C

Moment in the arch rib was determined by

$$M = E\,I\,\frac{\Delta\theta}{\Delta L} \qquad (22)$$

in which the various terms on the right side of the equality sign were evaluated as follows:

- $E\,I$—by calipered dimensions and repeated stress-strain measurements on a piece of steel cut from that used in making the model.
- $\Delta\theta$—by use of two optically flat mirrors attached to the two ends of the elastic element (see Fig. 13 at point 5 E). In the plane of the model and about 15 ft from its near end, $\frac{1}{20}$-in. scales were supported on an engineer's transit. The images of these scales were observed in the mir-

rors through the transit, and the readings translated into differential angular deflections.

ΔL—by a mechanical spacing bar used in setting mirror mountings in position. The value used was 2.00 in. measured along the rib.

The accuracy of the equipment and the reliability of the experimental technique were such that reported results should be accurate within an error of not more than 3%.

To enable the apparatus to be used for the study of flexible fixed-end arches, levers and weight pans were provided, designed to introduce, at the hinged reactions, moments sufficient to maintain the springing planes in their normal position. This produced fixed-end conditions and a means of measuring the fixed-end moments. Time permitted only a few tests of fixed-end conditions, but these indicated that further study would be profitable.

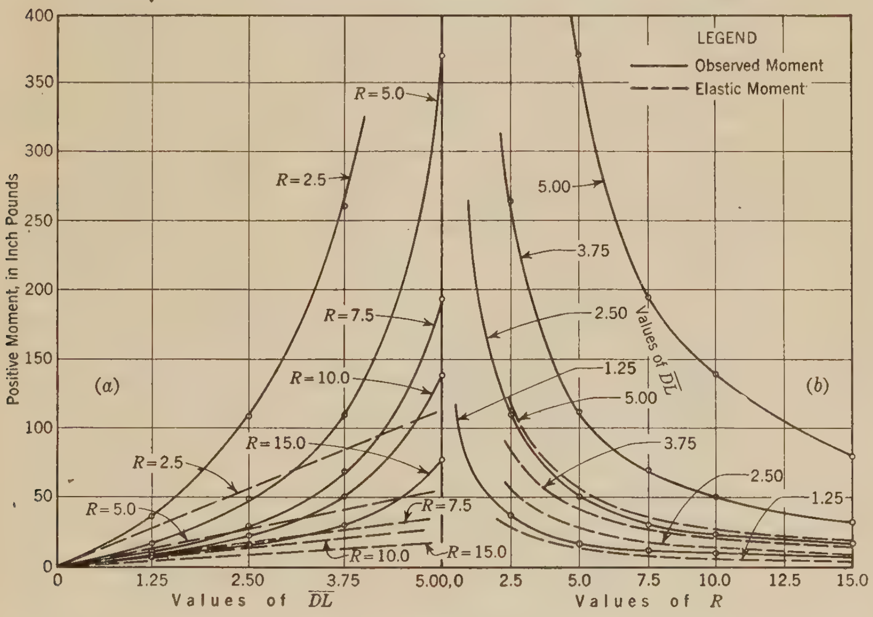

Fig. 16

Experimental Data

Maximum positive and negative moments were observed at five different points in the semispan of each of the three arches tested and for the complete range of loadings in Table 4. Fig. 16 shows two typical linear plots of the same data for maximum positive moment M at point 6 C of arch No. 1, and indicates the consistency of the observed data. Values of the moment as given by the elastic theory also are shown in these figures for comparison. In most cases the differences are rather marked.

Fig. 17 is a log-log plot of the same data as in Fig. 16, using the same coordinates but omitting the elastic-theory data and including the maximum negative moment ($-M$) data. It will be observed that straight lines approximate the trends with remarkable accuracy. This tendency was found to be general for all the points on all arches within certain ranges whose extremes have been adopted as the limits of practicality for the use of the data presented in this paper.

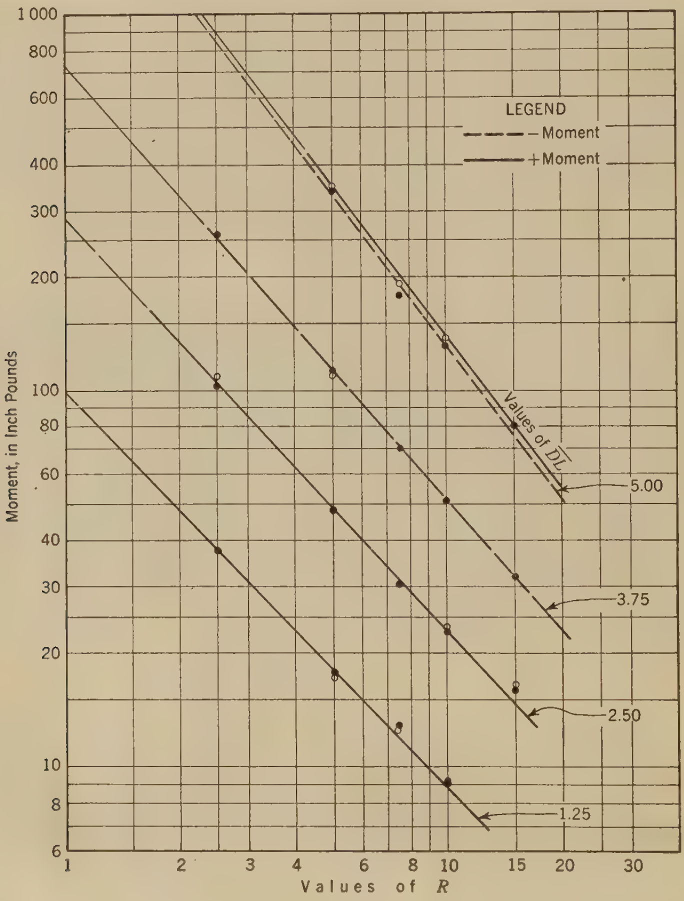

Fig. 17.—Log-Log Plot of Data in Fig. 16(b)

These data are more useful to practical engineers if presented in terms of arches whose dimensions correspond more closely to those of actual structures. For this reason, the complete data for maximum moments were translated to refer to so-called "base arches," of similar geometric shape (in elevation) to that of the models. In these base arches, L = 1,000 ft; I = 100 ft^4;

$E = 29{,}000{,}000$ lb per sq in.; and loads and other values are proportional to those of the models. This translation was accomplished by applying to the model results the laws of similitude, familiar to any engineer using these data, in which

$$\overline{DL}_b = \overline{DL}\,\frac{E_b\,I_b}{E\;I}\left(\frac{L}{L_b}\right)^3 \qquad (23a)$$

and

$$M_b = M\,\frac{E_b\,I_b\,L}{E\;I\;L_b} \qquad (23b)$$

Values without a subscript in Eqs. 23 refer to any arch such as the model, and the values with the subscript, b, refer to the base arch. All subsequent data presented in this paper refer to these base arches.

Space prevents including a complete set of curves for the base arches similar to those of Fig. 17. These curves, complete sets of curves of the type shown subsequently in Figs. 19 and 20, and additional data not presented herein are available in the form of a thesis entitled "Moments in Flexible Arches," by Messrs. McEldowney and Mead, presented to the School of Engineering, Princeton University, in partial fulfilment of the requirements for the degree of Civil Engineer.

Equations for Maximum Moment.—The fact that the observed data plot as straight lines on log-log paper (see Fig. 17) suggested the possibility of writing equations for these lines by the usual intercept-and-slope relation. Calculations for the lines of Fig. 17 show that their slopes, $\frac{\log M}{\log R}$, also vary in a linear manner with the value of log M for $R = 1$ (the intercept of Fig. 17). Furthermore the values of log M for $R = 1$, the intercept, are found to vary approximately linearly with $\overline{DL}$. It was possible therefore to write two equations for the intercepts and slopes of the lines of Fig. 17 in terms of $\overline{DL}$ and log M for $R = 1$, respectively. These two equations then could be substituted into the slope-intercept equation for the lines of Fig. 17, giving a single equation for all the lines for M in terms of $\overline{DL}$, R, and four empirical coefficients, C_1, C_2, C_3, and C_4. This equation is general for all points on each of the three arches and, for the base arches, reduces to

$$\log_{10} M_b = (C_1\,\overline{DL}_b + C_2)\,(1 - C_3 \log_{10} R) - C_4 \log_{10} R \qquad (24)$$

in which C_1, C_2, C_3, and C_4 are selected for any particular point and any arch from the curves of Fig. 18.

By use of Eq. 24 and its accompanying coefficient curves it is possible to obtain values of the maximum bending moment, M_b: For any point on the three arches; for any selected value of $\overline{DL}_b$; and for R within the range of the tests. It should be emphasized that the position of the loading is not needed by the designer, since this was determined experimentally when testing. A designer need know merely $E\,I$, $\overline{DL}$, $\overline{LL}$ and the ratio of rise to span. Having converted these to the base arch, the designer can enter Fig. 18 at the selected span point and pick the coefficients for use in Eq. 24. The calculations are rapid and can

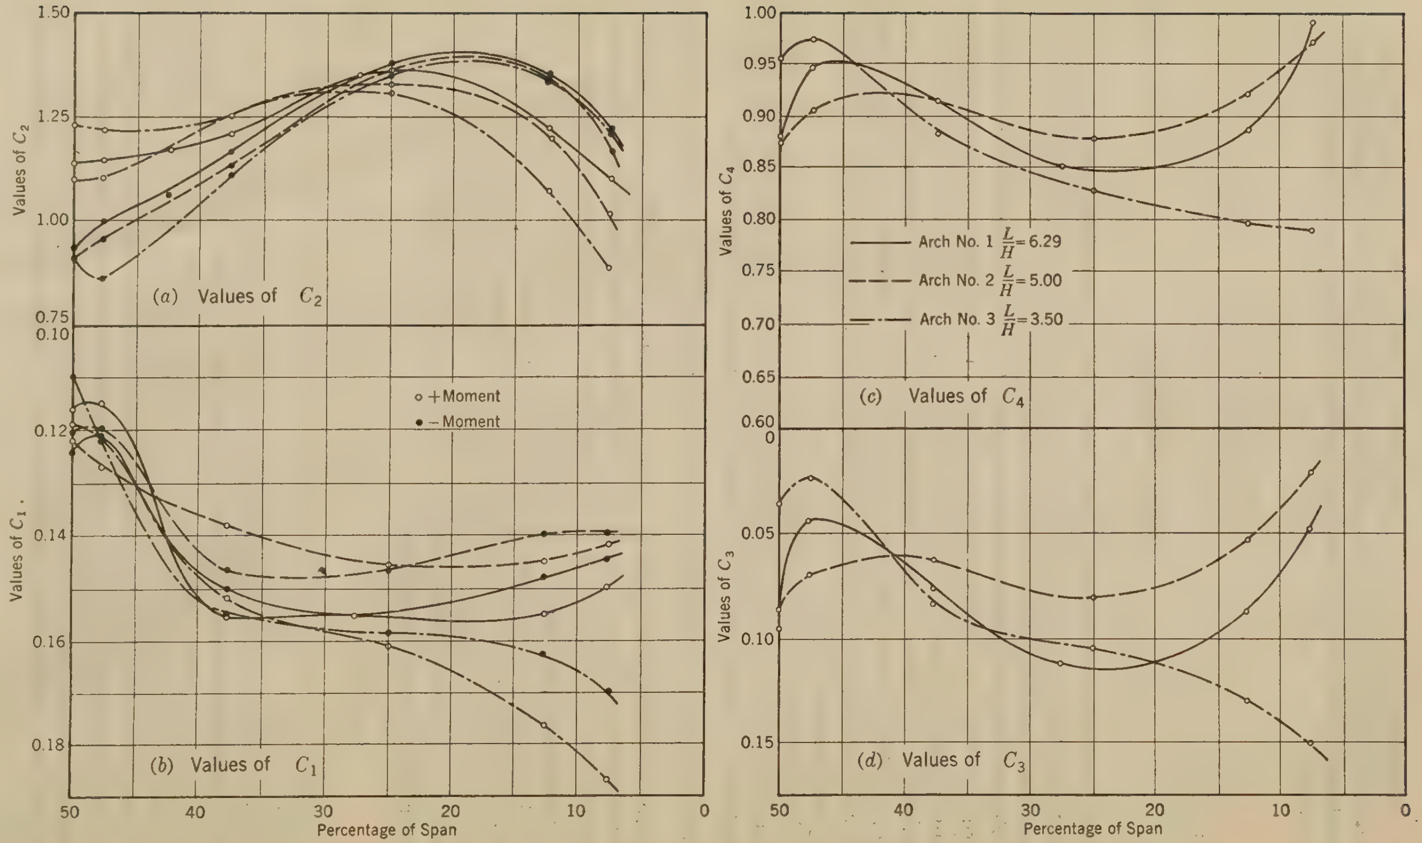

FIG. 18.—CURVES FOR DETERMINING COEFFICIENTS IN EQ. 24

be tabulated for convenience. The value of M_b then may be reconverted to the value for the designer's arch.

It should be noted that the small inconsistencies in the coefficient curves, as plotted from calculations from test results, are not an indication of unreliability in the final equation resulting from their use. The four coefficients are all interdependent, and small changes in one are accompanied by compensating shifts in the others. Eq. 24 and the coefficients have been checked thoroughly by taking values of the coefficients from the various curves for points on the arches between plotted points and by computing the value of M_b for some particular values of $\overline{DL}_b$ and R. This computed value then was plotted with corresponding observed data and found to be entirely consistent.

Accurate results (2%) should be obtained for values of $\overline{DL}_b$ between 2.50 and 7.0 and for all values of R between 1.5 and 15. Use of the equations for other values outside this range will give less accurate results and is not recommended. Interpolating between the coefficient curves for arches with intermediate values of span to rise $\left(\frac{L}{H}\right)$ also is not recommended, as the curves do not vary in a linear manner. The moment M_b for other $\frac{L}{H}$-ratios may be obtained with fair accuracy by computing M_b for all three ratios covered herein, plotting the results against $\frac{L}{H}$, and then selecting the value of M_b for the desired $\frac{L}{H}$ from this curve.

Eq. 24 should offer valuable assistance to a designer in selecting preliminary sections and in checking designs of arches, even if not used for final design.

Dimensionless Plots.—Another useful method of presenting the data is shown in Fig. 19, in which dimensional analysis has been used. It will be noted that the ordinate, $\frac{M}{\overline{DL}\,L^2}$, and abscissa, $\frac{E\,I}{\overline{DL}\,L^3}$, are both dimensionless, since M is in inch-pounds, $\overline{DL}$ in pounds per inch, L in inches, and $E\,I$ in pound-inches^2. Ratio R is also dimensionless, since it is the ratio of two load intensities in pounds per inch. The points in Fig. 19 were obtained from M on the model, by calculating $\frac{M}{\overline{DL}\,L^2}$ and $\frac{E\,I}{\overline{DL}\,L^3}$ for the corresponding model values of $\overline{DL}$, L, E, and I, and by drawing curves of constant R. The ordinates are plotted to logarithmic scale in order to keep the values within reasonable plotting limits and so that the percentage error in plotting would be constant for all values of the ratio R.

The importance of the dimensionless plotting lies in the fact that Fig. 19 applies to any arch that is geometrically similar to the test arch, regardless of size and relation of load to stiffness. For example, suppose a designer has selected certain values of E, I, L, $\overline{DL}$, and $\overline{LL}$ (or R) for his bridge and wishes to find M at a certain point, say near the quarter point, and that his arch has an $\frac{L}{H}$-ratio corresponding to test arch No. 1. Then, he would compute the value of

$\frac{E\,I}{\overline{DL}\,L^3}$; enter Fig. 19 until he reached the appropriate value of R; and, from the corresponding $\frac{M}{\overline{DL}\,L^2}$-value, he would compute the desired M. Care should be exercised to keep all the variables in consistent units (pounds and feet, for example).

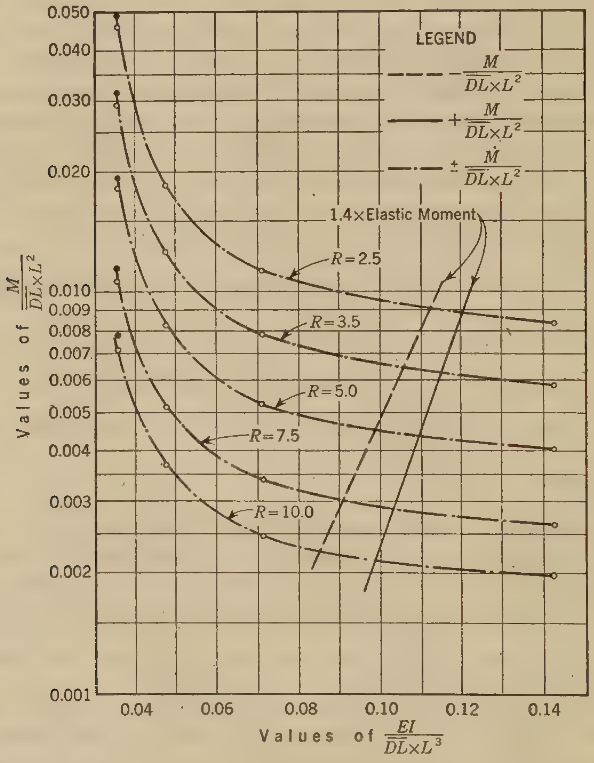

FIG. 19.—DIMENSIONLESS CURVES; ARCH NO. 1, AT POINT 6 C

On the other hand, suppose the designer wishes to investigate the effect on M resulting from a change in $E\,I$. The curves show that an increase in $E\,I$ produces a decreasing effect on the value of M and that $E\,I$ will decrease M effectively only up to a certain point, beyond which thickening the section plays little part in reducing M. In other words, the secondary moments due to deflection become negligible.

In this connection, the elastic-theory moments plot as straight horizontal lines on these dimensionless coordinates, since they are entirely independent of $E\,I$ (as long as it is constant) and $\overline{DL}$. To show how much the plotted curves vary from the elastic-theory values, the points, where the curves are equal to 1.4 times the elastic-theory values, are shown by the two lines in Fig. 19 which intersect the curves of constant R.

Lack of space prevents including the complete set of curves which were calculated for each point on each arch tested.

Curves of Percentage Increase.—The preceding part of the paper has dealt entirely with the absolute values of the moment in the model arches or in arches of geometrically similar shape. This form of presentation is perhaps the most direct, but has certain limitations that can be eliminated by plotting the test results in the form of a percentage increase of observed moment over calculated elastic-theory moment. This is done in a set of curves, an example of which is shown in Fig. 20, giving values for approximately the $\frac{1}{8}$, $\frac{1}{4}$, $\frac{3}{8}$, and $\frac{1}{2}$ span points for each of the three base arches. These curves are similar also to Fig. 16 except that percentages are used instead of absolute values for the ordinate. Values for other arches may be obtained readily by use of Eq. 23.

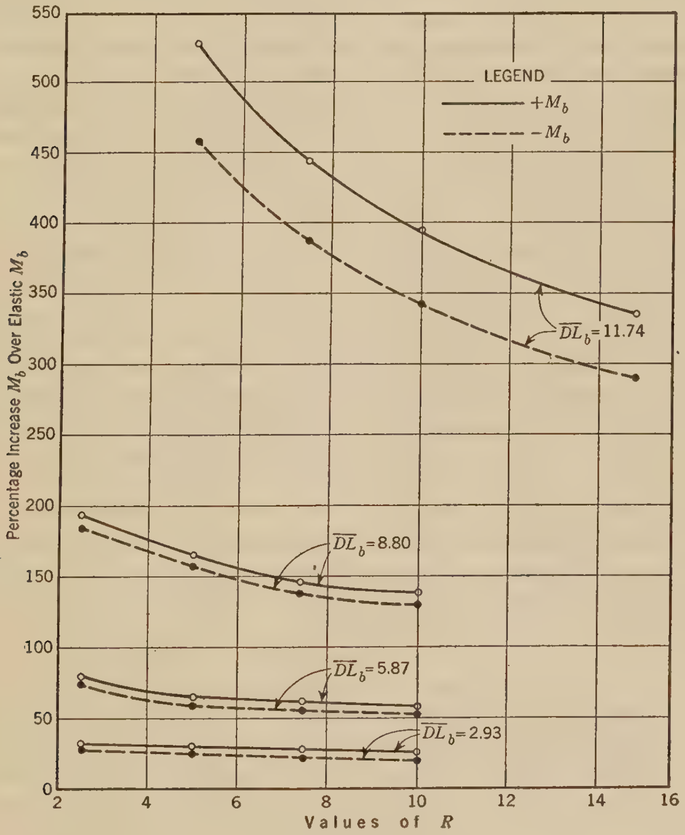

FIG. 20.—PERCENTAGE INCREASE OF ACTUAL M_b OVER ELASTIC M_b, BASE ARCH NO. 1, POINT 6 C

There are three major advantages to such curves:

1. Arches can be classified into three main groups—the first group including those that are stiff enough to permit the use of the elastic theory with no cor-

rections for secondary effects; the second group comprising those arches which can be used satisfactorily, after proper corrections for deviations from the elastic theory have been made; whereas the third group includes those arches which are so flexible as to be entirely unsatisfactory. Conclusions of this nature can be drawn directly from curves of percentage increase, whereas those for actual observed moment must be compared with elastic-theory values to be interpreted.

Most of the tests made in this investigation fall in the second and third categories. For example, assume an arch rib for which $\overline{DL}_b = 5.87$ and $R = 5.00$ and design it in silicon steel for 20,000 lb per sq in. with a direct stress of 10,000 lb per sq in. and a bending stress of 10,000 lb per sq in. If both live load and dead load are increased by 50% so that $\overline{DL}_b = 8.80$ and $R = 5.00$, the direct stress will increase to 15,000 lb per sq in., but, from Fig. 20, the bending moment is now 264.4% of the elastic moment instead of 168.5%. Therefore, the bending stress is now $\frac{2.644}{1.685} \times 1.5 \times 10{,}000 = 23{,}535$ lb per sq in. The total stress would be 38,535 lb per sq in., a stress readily carried by many alloy steels or aluminum alloys. Such an arch would fall in the second category of foregoing arch types.

Had the dead load and live load of the previous example been increased to $\overline{DL}_b = 11.57$ and $R = 5.00$, the direct stress would become 20,000 lb per sq in., but the bending stress would have increased to 74,540 lb per sq in., giving a total of 94,540 lb per sq in. Even if available materials could carry such stresses safely, the deflections coincident with them would rule out such an arch except in very special cases where large deformations could be tolerated.

2. A second use for curves of the type of Fig. 20 is in applying the test results to arches of varying $E\,I$ and to forms other than exactly circular, such as parabolic or three-centered arches. Calculated elastic-theory moments for such ribs are likely to be fairly different from those for circular arches of constant $E\,I$ and of similar general proportions. It is also probable that observed moments of flexible models of such ribs would vary from those on flexible circular arches. However, the percentage increase of actual moment over elastic-theory moment for circular arches of constant $E\,I$ will be almost identical to percentage increases for noncircular arches of variable $E\,I$, provided the variations in stiffness with span and the change in outline are not too pronounced.

Therefore, a designer could use curves of the type of Fig. 20 by: (1) Idealizing his arch into a circular arch of constant $E\,I$ and of very similar proportions; (2) entering the curves to select the proper value of percentage increase; and (3) applying this percentage increase to the calculated elastic moment for the designer's own structure. Thus he could tell readily whether deflection or secondary moments were important in his particular situation.

3. There is a third advantage of the percentage-increase curves. All the test results were for moments caused by a uniform loading of an extent and location such as to produce maximum moment at the observed point. Many highway loading specifications include concentrated loads applied to the arch rib in addition to a uniform load, whereas railroad loadings specify several concentrated loads followed by a uniform load. For such load patterns, the

calculated elastic-theory moment and actual moments are certain to be different from those obtained in these tests. However, it is reasonable to assume that the percentage increase of actual over elastic-theory moment will be approximately the same for any loading pattern. This is particularly true since this increase is largely a function of the relation between $E\,I$ and the dead weight intensity $\overline{DL}$, and not the actual live load intensity (R), as illustrated by the relatively small variation of the curves with R for the majority of the test range.

A small point of interest concerning the curves for percentage increase may be revealed by examination of the curves for the various points across a single arch. Except for the midspan point (10 E) the percentage increase for the corresponding curves at the different span points is found to be substantially the same, particularly for low values of $\overline{DL}_b$.

Application of Data to Niagara Rainbow Arch Bridge

The original two-hinged design of the Rainbow Arch Bridge at Niagara Falls is an excellent practical check on the experimental work, since this arch was a good example of flexibility, and has been studied for deflection moments as described in the preceding paper of this Symposium. By applying the geometrical shape, loadings, and sections of this prototype design to the equations and curves of this paper, the values of moment along the arch can be evaluated and checked with the values as obtained by the designers in their "deflection theory." Furthermore, the calculations which follow more clearly illustrate the use of the experimental data.

The following data were used for the original two-hinged design of the Niagara arch: Span, 950 ft; rise, 150.75 ft; ratio of span to rise $= 6.32 = \frac{L}{H}$; depth of rib, 14 ft (average); I, 119 ft^4; E, 29,400,000 lb per sq in.; dead load $= \overline{DL} = 8.6$ kips per ft at the crown; live load $= \overline{LL} = 1.5$-kips-per-ft intensity; and the ratio $\frac{\overline{DL}}{\overline{LL}} = R = 5.73$.

To illustrate the application of the curves to this arch, the maximum positive moment at the quarter point will be obtained by the use of Eq. 24 and checked with the dimensionless curves and the percentage-increase curves. Since the $\frac{L}{H}$-value for the Niagara arch (6.32) is very close to the experimental value of 6.29 for arch No. 1, the curves and coefficients for this model arch and its base arch will be used.

Eq. 24 is correct in terms of the base arch, so that values of the Niagara arch variables must be converted to the base arch before using the equation. From Eq. 23a:

$$\overline{DL}_b = \frac{8.6 \times 29 \times 10^6 \times 100 \times 950^3}{29.4 \times 10^6 \times 119 \times 1{,}000^3}$$

which, in terms of the base arch $= 6.1$ kips per ft. From Fig. 18, for the quarter point of arch No. 1: $C_1 = 0.156$; $C_2 = 1.37$; $C_3 = 0.846$; and $C_4 = 0.115$. Also, $R = 5.73$ (does not change between model and prototype); and, by

Eq. 24:

$$\log M_b = [(0.156 \times 6.1) + 1.37](1 - 0.115 \log 5.73) - 0.846 \log 5.73$$

or

$$M_b = 30{,}200 \text{ ft-kips (30.2 thousand ft-kips).}$$

Converting this base-arch value of moment back to the prototype, by Eq. 23*b*:

$$M = \frac{30{,}200 \times 29.4 \times 119 \times 1{,}000}{29 \times 100 \times 950} = 38{,}350 \text{ ft-kips.}$$

This value of moment is close to the value arrived at by the designers at working loads, using their "deflection theory," from which the moment was calculated to be 37,130 ft-kips. The elastic-theory value for the same loading condition was 22,600 ft-kips.

The moment can be determined also at approximately the quarter point by using the dimensionless curves, referring to Fig. 19:

$$\frac{E\,I}{\overline{DL}\,L^3} = \frac{29 \times 10^6 \times 144 \times 119}{8.6 \times 1{,}000 \times 950^3} = 0.0685$$

From Fig. 19, interpolating between R-curves for $R = 5.73$: $\dfrac{M}{\overline{DL}\,L^2} = 0.0047$; from which $M = 0.0047 \times 816 \times 1{,}000 \times 950^3 = 36{,}500$ ft-kips.

The moment at this point (one-half panel toward the center from the quarter point) is not appreciably different from the value at the quarter point.

As a final check the moment will be determined from the percentage-increase curves. Referring to Fig. 20, for $\overline{DL}_b = 6.1$ and $R = 5.73$, the percentage increase of actual moment over elastic-theory moment is 70%. Therefore, the actual moment is $M = 1.70 \times 22{,}600 = 38{,}420$ ft-kips, which is almost identical to the foregoing value calculated from Eq. 21.

CONCLUSIONS

1. The experimental results obtained from this investigation, together with the method of presentation, furnish a control and a check on analysis methods for flexible arches which have been developed or may be developed in the future.

2. The data will be of particular assistance in the selection of preliminary or trial sections of two-hinged arch ribs which, in the opinion of the designer, should be sufficiently stiff for practical reasons to make the application of the elastic theory entirely proper.

3. The data supply a basis for the design of relatively flexible, two-hinged arches where such designs are proper—for example, in hanger roofs in which large deflections might not be objectionable if economies can be effected with safety.

4. In flexible arches, the dead load becomes an important consideration when determining moments and any theory which ignores it—such as the elastic theory—is not reliable.

5. Previously published opinions on the effect of reasonable variation of $E\,I$ on the moments in an arch, and of the close agreement between moments in

circular arches and closely similar parabolic arches (in each of which the dead-load resultant follows the center line of the arch) support the contention that the results presented will be of value in the study of arches of noncircular profile and nonuniform section.

6. The relation of load to unit stress in a flexible arch rib is not linear. Accordingly, the safe capacity of such an arch should be estimated by calculating its ultimate (or yield) loads, and then by applying the desired factor of safety to the critical design loads.

7. Conventional methods of calculating temperature stresses are satisfactory for the flexible two-hinged arch rib. (Although not described herein, this matter was checked.)

8. The refined method of analysis developed by the designer of the preliminary two-hinged design for the Rainbow Arch Bridge should yield reliable results.

9. Limited observations were made on the arch models in a fixed-end condition. Although, as might be expected, the secondary moments due to deflections were much smaller than for the two-hinged condition, certain inconsistencies with the elastic theory, of a different sort from those observed on the two-hinged arches, were noted, thus recommending this as a subject for future study.

FABRICATION AND ERECTION CONTROLS

Members, Am. Soc. C. E.

Synopsis

The hingeless arch ribs were erected by cantilevering symmetrically from each skewback. The first three rib sections were cantilevered from the anchor bolts, a statically determinate condition. Thereafter, the resisting moment at each skewback was augmented by one, two, or three groups of wire-rope strands passing from the forward rib sections to a temporary tower placed behind the skewback, and thence to a concrete anchorage embedded in rock.

A complete description of the erection procedure appears in the fourth paper of this Symposium. It is assumed in this paper that the reader is acquainted with that description. The present paper discusses briefly the shop controls used to insure the correct geometry of the ribs as fabricated and erected.

Throughout the statically indeterminate phases of the erection, it was necessary not only to compute and control the stresses in the permanent steelwork, but to compute the coexisting stresses in the temporary wire-strand tiebacks. This paper describes the procedure using a method of successive approximations for resolving this indeterminacy.

It was also considered desirable to measure, prior to closure, the thrust and moment at the crown of the braced arch-rib sections after they had been made self-supporting by the removal of the wire-strand tiebacks. The thrust and moment thus measured could then be changed, if necessary, by varying the shape of the "keystone" rib section. Thus, the stresses locked in the structure for this loading condition could be controlled, and the effect on the stresses due to accumulated errors in span length, fabricated lengths or angles, skewback angles, etc., could be eliminated. It is believed that this is the first instance of such planned control of crown thrust and moment.

By correcting the shape of the "keystone" rib section properly, agreement of the actual stresses with the calculated stresses for the loads on the arch in this erection stage was assured. However, the fact that no correction was required is an indication of the extreme accuracy of fabrication and pier location.

INTRODUCTION

As described in the first paper of this Symposium, the Rainbow Bridge is a hingeless arch with a span between skewbacks of 950 ft and a rise of 150 ft. As such, the structure is triply indeterminate and the stresses must be calculated from its elastic properties. Initial errors in span survey, in fabricated length or contour, in skewback angle, or in angles at the field joints as riveted could introduce serious errors in the stresses due to the weights in place at the time of closing and swinging, errors that might be an important percentage of the total stresses at some points. Unusual efforts were made, in closing at the crown, to determine and eliminate the accumulated effect of such errors. The fact that they were found to be negligible and did not require correction testifies to the accuracy attained in survey, fabrication, and erection.

The arch center line was established by the designer to follow very closely the dead-load equilibrium polygon, the ordinates thus determined at all panel points being tabulated on the contract plans. The contractor then undertook, for purposes of drafting and fabrication, to pass a compounded series of circular arcs through these points of control.

The spacing between spandrel columns is approximately 40 ft, and the weight of the rib material necessitated a field splice in each rib in advance of each successive spandrel column. A preliminary study of splices determined a distance (usually about 6 ft) from center of column to center of splice which would keep the splice material clear of the column connections. The rib-center radii were then so selected that changes of radius occurred only on radial lines to alternate splice centers. Thus, two successive pieces of rib as fabricated had a constant radius, and changes of radius never occurred within a fabricated piece. The resulting working curve involved five centers on each side, plus one on the vertical axis, the radii varying from 781.6 ft to 970.6 ft. This curve passed through the twenty-five stipulated points with errors not exceeding $\frac{1}{8}$ in.

The specifications required that the arch ribs conform to the stipulated outline under full dead load at 50° F. This required that each rib section be cambered, or increased in length, by the amount that it would shorten under dead load, and that its length be adjusted for the difference in temperature between 50° and 68°, the temperature at which the fabricator's shop tapes are all standardized. This increase in length of each rib section was assumed as a wedge-shaped piece attained by lengthening the top and bottom arc lengths through the angular increment determined by the increment of length on the center line. This meant that, if the complete rib had been shop assembled under no stress, both the chord distance between skewbacks and the angle between radii through the skewbacks would have been greater than the intended values as erected under dead load.

In connection with the problem of camber, the "effective" areas for computing deformations were of considerable importance. It was decided finally to consider the unspliced longitudinal stiffeners as part of the effective area (see Fig. 6), in addition to all spliced material that is effective in resisting stress.

A set of the contractor's erection drawings and calculation sheets, showing the basic outline, arch-rib radii, splice locations, weights of rib sections, effective areas, and cambering details, has been placed on file at Engineering Societies Library, together with copies of all sheets recording the computations referred to hereafter. A descriptive index of the filed material is given in Appendix II.

Fabrication

In the fabrication of the individual 40-ft rib pieces, the 12-ft web plates were subdrilled to the intended radii of the top and bottom angle gage lines, and the 8-in. by 8-in by 1⅛-in. angles and the 54-in. cover plates were subdrilled straight and pulled in, cold, to the required curvature. It was felt that the local bending stresses thus locked in the angles by the riveting would do no harm in a ductile material, whereas "gagging" to curvature would require stressing beyond the yield point and, in all probability, would produce a series of approximate chords rather than a smooth curve. The smooth curve was desirable not only for appearance, but to accommodate the designer's intention that the straight-line bearing edges of the spandrel columns should "rock" slightly on the curved ribs.

To insure that the rib sections would be of the proper depth and curvature, each web with its flange angles was assembled in a jig. The diaphragm plates between the two parts of the box girder were milled on all four edges, and the sections were then boxed in pairs against squaring brackets to obtain and maintain the rectangular cross section. While held against these squaring brackets, the sections were reamed and riveted. They were then removed to the milling machine and milled accurately to length and bevel. While the sections were in position on the milling machine, center lines and working points were established, and the pads for the column bearings were set.

Assembly

After considerable study of the problem of maintaining accuracy of length and angle, the fabricator decided to shop assemble the rib sections on their sides, starting from the skewback and checking the position of each section accurately as it was placed, until seven sections were assembled. After the splices between these sections had been reamed, the first six sections were pulled out ready for shipment, the seventh section was moved back to the starting point, and the remaining five sections were assembled in sequence to the seventh.

According to the terms of the contract, the rib sections were fabricated in the United States, whereas the rib laterals, spandrel columns, and all floor steel were fabricated in Canada. Each fabricator independently prepared metal templates for the common holes—that is, those at the connections of the spandrel columns and the rib laterals to the rib itself. These templates were set, with great precision, on the assembled rib to center lines which had been located while the rib section was in position on the milling machine. Although there was no physical exchange of templates by the two fabricators, the matching of the holes in the field was practically perfect.

The assembly shop, with four rib assemblies being worked on simultaneously, is shown in Fig. 21. The pieces standing upright at the far end of the shop have been assembled, their splices reamed or drilled, and they are now being painted. Assembling of the piece in the left foreground has also been completed, and the piece removed from the assembly prior to painting. The box sections on the right are the completed grillage and skewback sections, and are loaded on cars ready for shipment. The trapezoidal section in the center foreground is the top section of the cable bent to which the forward ties and backstays attach, standing upside down. Near the center of Fig. 21, a horizontal reamer is shown drilling on a cover-plate splice.

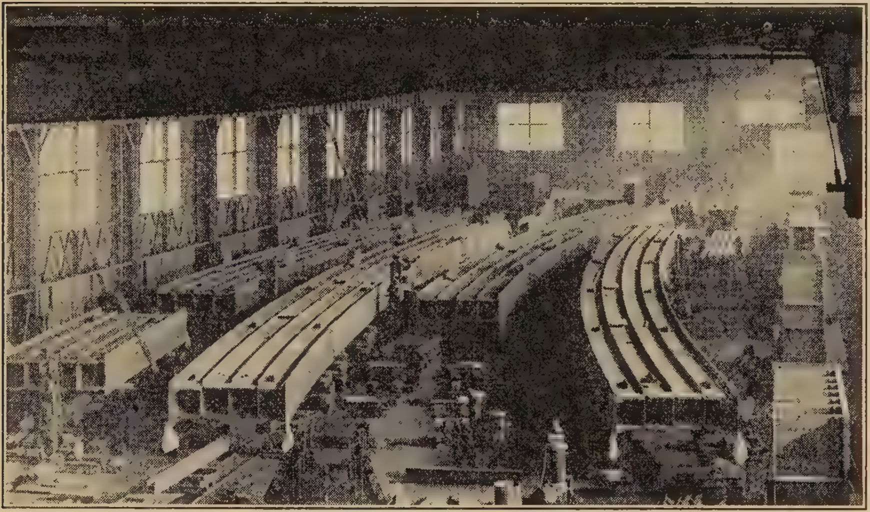

Fig. 21.—View of Four Rib Assemblies in the Assembly Shop

Prior to making the aforementioned two types of assembly—seven-piece and six-piece—the offsets to center line were calculated from as many successive base lines as there would be pieces in the final assembly, each base line running from the left-end center of the first piece laid down to the right-end center of the last piece attached. As successive pieces were attached on the assembly skids, the ordinates from the base thus created were measured and compared with the calculations. Thus, curvature was checked in seven different ways through the seven-piece assemblies and in six different ways through the final, six-piece assemblies. Throughout these successive checks, the measured and calculated ordinates were held to differences not exceeding $\frac{1}{8}$ in. While these checks on curvature were being made, the milled ends of successive sections were kept in close contact and the splice holes thus reamed. The care taken in the laying off, milling, and splice-reaming throughout the fabrication resulted in a gratifying accuracy in the finished structure.

The Erection Problem

To assist in an appreciation of the erection engineering calculations required, Fig. 22 is presented to show the successive cantilever positions, and the following summary of successive operations is given.

First, three rib sections (points 13 to 10, Fig. 6) were erected by cantilevering freely from the anchor bolts, a determinate condition. Next, eight wire tie strands per rib were connected at point 10 and put under a measured, predetermined stress. Henceforth, until closure, the conditions were statically indeterminate. Two more rib sections were freely cantilevered beyond point 10, depending upon the splice bolts and pins for stability; eight tie strands were connected at point 8 and put under predetermined stress. The strands at point 10 were then disconnected from the rib but not from the tieback bent. Two more rib sections were cantilevered beyond point 8, and eight tie strands were connected at point 6; these were the strands originally connected at point 10, with extension "pennants" attached. Four additional strands were attached at point 6, making twelve in all. The tie strands at point 8 remained in place, and the loads were shared between the eight strands at point 8 and the twelve strands at point 6 in predetermined amounts. Three more rib sections were cantilevered beyond point 6, and four tie strands from point 6 were successively connected and stressed at point 3; then the eight strands at point 8 were released from the rib, lengthened with pennants, and reattached and stressed at point 3. The loads were shared between the eight strands at point 6 and the twelve strands at point 3 in predetermined amounts. Two more rib sections were cantilevered beyond point 3, which brought the two half arches, cantilevering from the two shores, within the predetermined 11 in. of meeting at the crown.

At the crown, jacking brackets were bolted to the upper and lower cover plates of each half rib, so that two 500-ton jacks could be inserted above, and two symmetrically below, each rib. After these jacks had been operated to pick up a crown thrust and slack it on to shims, all the tie strands were successively released and removed.

Up to this point, it was necessary to predetermine by calculation, for each successive position, the arch-rib stresses, the stresses in tie strands, tieback bent and anchorages, and, from these latter, the necessary initial lengths of the tie strands. At the successive connections of strands to ribs, there were structural bar-and-pin devices to permit shortening and lengthening the strand length in increments of 1 in. to total adjustments of 12 in. and 18 in., respectively, from the mean, and to permit shortening and lengthening by larger increments to maxima of 24 in. and 30 in., respectively, from the mean. With so limited an adjustment possible in long, flexible ties, it was obviously important to determine the unstressed length with accuracy. Ties too short or too long would have seriously changed the stresses in the arch ribs by straining them too far, or not far enough, against their fixation at the skewbacks.

Scope of Computations

To furnish the erection engineer with the data necessary for the proposed erection procedure, rather elaborate computations were required. The work necessary to obtain this information for each erection stage is outlined herein. The complete tabulation of calculations as prepared by the contractor and checked by the consulting engineers is available at Engineering Societies Library (see Appendix II).

FIG. 22.—ERECTION STAGES AND TOTAL TIE STRESSES FOR ARCH RIB, AT 60° F

The calculation work for each erection stage falls into three divisions, as described under 1, 2, and 3 below. In this description, and in Appendix II, references to sheet or drawing numbers prefixed with ED are to the contractor's erection drawings.

1. (Sheets ED10 to ED15). The part of the rib thus far erected was assumed to be cut loose from any ties and to cantilever from the skewback. Assuming that the steel would hold together and remain elastic under such a

condition, the deflected position was calculated for the points importantly in question—namely, the points of tie attachment and the splice points. Thus, for example, with the rib cantilevered three panels to point 10, the vertical deflection of the free end, in feet, was computed to be:

From bending	0.11406
From thrust	0.00028
From shear	0.00521
Total	0.11955

and the stresses in the rib were found to be just under the allowable. Again, for example, with the rib erected to point 1, but before the jacks and jacking diaphragms at the crown were in place, the hypothetical cantilever deflection was computed to be (in feet):

From bending	49.6117
From thrust	0.0032
From shear	0.1200
Total	49.7349

(and horizontally, 11.9038).

2. (Sheets ED4 to ED8). For a unit vertical force, and for a unit horizontal force, applied at a "tie point" (point of attachment of a wire-strand tie), the displacements, due to the elastic deformations of the rib between that tie point and the abutment, of all rib splice points and all tie attachment points were calculated.

3. In the tie or ties to be attached in the erection stage, forces were first assumed and then changed by the method of successive approximations until their effect, as found from step 2, was: (*a*) To raise the tie attachment points on the rib through approximately the deflected distance found in step 1; (*b*) to stretch the tie system until the end of each tie coincided with its attachment point on the rib; and (*c*) to give safe stresses throughout the rib. An average of four steps in the successive approximations was necessary to get perfect agreement on one erection stage, and this work was doubled since two solutions were made, one using the maximum and the other the minimum expected temperature.

From computations made in this manner, the erection engineer was given not only the information shown in Fig. 22, but also the theoretical elevation of each rib splice point at each erection stage; the stresses in the tie strands; the stress in the first strand to be connected and in the last strand to be disconnected for each forward tie; the effect per inch of change of length of one or all of the adjustment links of each forward tie on tie stress and arch elevation; the influence of change in temperature; and the necessary order for the various steps in each new move.

Displacement Calculations for the Rib

All the theoretical deflections required under step 1, and the displacements due to unit tie force components required under step 2, were computed by the following adaptation of the "slope-deflection" method, taking separately into account deformations due to bending, thrust, and shear.

The change in angles (Fig. 23(*a*)) at m in relation to the adjacent members, due to the bending moment, will be:

$$(\tau_m)' = (M_{m+1} + 2\,M_m)\,\frac{L_m}{I_m} \times \frac{1}{6\,E} \ldots\ldots\ldots\ldots (25a)$$

$$(\tau_{m-1})'' = (2\,M_m + M_{m-1})\,\frac{L_{m-1}}{I_{m-1}} \times \frac{1}{6\,E} \ldots\ldots\ldots\ldots (25b)$$

and the total angle change at m will be:

$$\theta_m = (\tau_m)' + (\tau_{m-1})'' \ldots\ldots\ldots\ldots (26a)$$

These angle changes will accumulate from the supported end, and cause an angle change in the member itself equal to:

$$\phi_m = \sum_{m+n}^{m+1} \theta \ldots\ldots\ldots\ldots (26b)$$

They also will cause deflection at the forward end of the member, with respect to the other end, equal to:

$$u_m = \phi_m\,L_m \ldots\ldots\ldots\ldots (27)$$

and hence total deflections due to bending equal to:

$$\delta_h = \sum u \sin\alpha \ldots\ldots\ldots\ldots (28a)$$

and

$$\delta_v = \sum u \cos\alpha \ldots\ldots\ldots\ldots (28b)$$

Thrust and shear deformation (Figs. 23(*b*) and 23(*c*)) will also add up from the support. The total thrust deflections will be:

$$\delta_h = \sum \frac{T\,L}{A\,E} \cos\alpha \ldots\ldots\ldots\ldots (29a)$$

and

$$\delta_v = \sum \frac{T\,L}{A\,E} \sin\alpha \ldots\ldots\ldots\ldots (29b)$$

and the total shear deflections will be:

$$\delta_h = \sum \frac{s\,L}{A_w\,E_s} \sin\alpha \ldots\ldots\ldots\ldots (30a)$$

and

$$\delta_v = \sum \frac{s\,L}{A_w\,E_s} \cos\alpha \ldots\ldots\ldots\ldots (30b)$$

in which A_w = the web area and E_s = the modulus of elasticity in shear.

To apply Eqs. 25 to 30, it was necessary to divide the rib into the thirteen sections defined by the splice points (so as to determine the successive deflected positions of these particular points for field check), and also to subdivide it further at points where there was a change in moment of inertia, and at points of application of concentrated loads (the tie attachment points).

The calculation record sheets (ED10 to ED15) for the rib deflections required by step 1, under the heading "Scope of Computations," may be typified by Table 5, which is a résumé of sheet ED10, applying to erection stages I and II, Fig. 22.

Fig. 23.—Deformation Diagrams

Sheets ED4 to ED8, covering computations for rib displacements due to unit vertical and unit horizontal force at a tie point, were similar. Because the calculations were made for unit loads instead of for steel-and-traveler dead loads, certain initial column headings differed. For example, in these rib-displacement computations, Figs. 24(*a*), 24(*b*), and 24(*c*), respectively, replaced Cols. 5 to 9, 20, and 28, Table 5. (Note that, in Fig. 24(*a*), 475.00 is the horizontal distance from the midspan to the skewback, SB; and 374.84 is the horizontal distance from the midspan to panel point 10.) Also, the deflections from unit load being very small compared to those for actual loading, the powers of 10 in all columns of sheets ED4 to E8 were changed, and the resulting deflections were obtained in integral numbers of millionths, instead of thousandths, of a foot.

FIG. 24.—EXAMPLE OF ALTERNATE COLUMN HEADINGS FROM SHEETS ED4

From the theoretical deflected position of the rib in any erection stage, from the restoring deflections available from unit vertical and unit horizontal tie pulls, and from the approximate angle of the tie after restoring the arch to almost its proper elevation, the tie stresses could now be approximated. It was found that these agreed sufficiently well with much cruder computations made before compiling the bidding estimate. Since the $1\frac{9}{16}$-in. strands had a guaranteed strength of 310,000 lb each, it was hoped to keep working loads within 100,000 lb, but it was considered proper not to change the assumed number of strands if the final calculations should indicate 120,000 lb. The final maximum (see Fig. 22, stage VII-B) was just over 100,000 lb. Actually, the cable stress for the condition in stage V was also slightly greater than 100,000 lb but only for the minimum temperature condition. The modulus of these strands was assumed as 24,000,000 lb per sq in., that value having given satisfactory results when the strands were previously used as footwalk support ropes at the Tacoma Narrows Bridge in Washington.

DISPLACEMENT CALCULATIONS FOR THE TIES

All calculations for balancing the cable stress and tie positions with the corresponding data for the rib itself were made by an exact method which involved a modified form of the "deflection theory" for suspension bridges. This was necessitated by the extreme flexibility of the interlocked system. The methods and formulas used would be grasped quickly by any designer conversant with cable calculation work, but are of such a highly complex and specialized nature that in their stead the method of approach will be given in general terms.

A diagrammatic sketch of the tieback arch with the loads in position is shown in Fig. 25. These loads comprised: The weight of the arch rib, the uniform weight of the backstay and of the forward-tie strands, the weight of the links at the bent and at the rib, the eccentric weight of the bent with its back-leg, and the concentrated load introduced on the forward-tie strands by the pennant sockets when there were any.

In the first instance, three "basic" cases were computed to determine the length to which the several strands should be socketed. These "basic" cases were those of maximum stress in the strands and, in order of attack, were:

(1) Erection stage IX, ties at T6 and T3, arch erected beyond T3 to crown;
(2) Erection stage V, ties at T8, arch erected beyond T8 to T6; and
(3) Erection stage III, ties at T10, arch erected beyond T10 to T8.

These "basic" cases were computed at +60° F for ordering strand lengths. They and all other cases were computed at +60° F and −10° F for determination of arch position, and for a check against any overstress of ribs or strands within this temperature range.

In the first "basic" case investigated (erection stage IX at 60° F), it was assumed that the bent was vertical. This condition was nearly maximum for stress in the backstays (−10° F would have been maximum), and was used for ordering the backstay strands and the full-length forward ties at T6. It also determined the total length of the T10-plus-pennant ties which were used at T6, and of the T6-plus-pennant and T8-plus-pennant ties which were used at T3.

The second "basic" case determined the order length of the strands used at T8, and the third determined that of the strands used at T10. In these stages the backstay stress was much less than in stage IX, and the bent leaned shoreward.

When the backstay strands were first erected, before any forward ties were in place, the bent had to be supported by a back-leg. To keep the initial stress in the backstay strands within the capacity of the pulling tackle which was used in their initial adjustment, the top of the bent was set back 3 ft. When the load from the T10 cables came on, the bent was pulled forward, of course, releasing the back-leg, and, from that time until final dismantling, it was pin-ended at the base.

In the calculations for the three "basic" positions, the problem was to determine a length of tie such that, when the horizontal and vertical components of the force at the point of attachment F (Fig. 26(*a*)) were applied first to the rib and then to the tie, the resulting location of F as determined from the tie system would coincide with that as determined from the rib.

The first step was to determine a position of the rib for each "basic" case, and to compute *H*-forces and *V*-forces (interrelated by an assumed slope of the link at its connection to the rib) which would raise the free-cantilevered rib to this position. The determination of this position, which was always at or near

[a] These quantities are the final results applicable to SP10, the free end in erection stage I, and will be recognized as including those stated in the text under "Scope of Computations."

"normal" or "geometric" position (namely, that which the point would occupy after completion of the entire structure), involved a consideration of the action of the rib under the then existing loading, and under subsequent loadings, at various temperatures.

In the first "basic" case, the elevations of the tie connection points T3 and T6 were determined by finding their location for erection stage IX (Fig. 22) such that the crown opening would be near "normal" at 60° F and the rib moments would be within safe limits. These tie-point elevations were determined for assumed loads from the cables at assumed slopes, and were essentially unchanged under the exact loads and slopes finally found; it was not essential that the final position in erection stage IX be exactly as stated, since it was important only that the ribs at closure be far enough apart to permit erection of the final members and insertion of the jacks. A final check was made of the crown elevation and opening, of course, after the tie lengths had been accurately determined, and, if it had been found that the elevations of the tie points originally used had led to an impossible closing condition, the tie lengths would have been recomputed for new assumptions of elevations of the tie points.

In a similar manner, the "basic" elevation of T8 was, in the second "basic" case, determined so that, starting from this elevation in erection stage V, the succeeding stages of erection could be completed without requiring that the ties at T8 be readjusted after their initial adjustment had been made. The "basic" elevation of T10 was determined similarly for erection stage III.

It must be noted, however, that the choice of the "basic" elevations thus selected also affected the stresses in the ribs, so that, particularly in the initial erection stages when the rib was very stiff and resistant to change in elevation, it was necessary to investigate and modify the "basic" tie-point elevations to keep the rib stresses within allowable values.

(*a*) BASIC CONDITION (*b*) BALANCING CONDITION

FIG. 26

Assuming a trial value of H, a length of tie was computed which would bring the tie and rib into coincidence at point F, and, for this length, the value of V for the tie was computed (that is, the slope of the link at the rib was computed, thus automatically determining V). By successive approximations, modifying

H and V on the rib each time but holding the elevation of point F essentially constant, tie lengths were finally determined for forces H_b and V_b which balanced the system. These lengths were the "basic" lengths, and the final position of point F so determined was the "basic" position of the point of attachment of the link to the rib.

By using these "basic" results as a starting point, and with the strand lengths now established, the amount of successive approximation computation for the remaining or "intermediate" cases was considerably reduced. These "intermediate" cases comprised erection stages II, IV, etc., and all stages at which strand ties were added, adjusted, or released. With one minor exception, the strand stresses in each "intermediate" case were less than those in the "basic" case to which it was immediately related (as stage II to stage III, etc.).

The method used for calculating the position and H-forces and V-forces for any intermediate condition is shown graphically in Fig. 26(*b*). With the location of point F, and the "basic" forces H_b and V_b known, values of H_r and V_r were assumed which would raise the rib to point A, approximately its normal position. This H_r-force was then applied to the link and cable system (the "basic" position of the cable was actually used so that only a differential force $H' = H_b - H_r$ was applied to this system), and a horizontal deflection Δ was determined so that point F moved horizontally to point F′; V_1 was then the vertical force required to balance the cable. Since points F′ and A did not coincide, point F′ was moved to point F″ by considering the forward-tie assembly rotated about the point of attachment of the link to the bent, and a new and slightly different $(H_1)'$ and $(V_1)'$ were determined. The vertical distance y was then a measure of the error in the assumption originally made, and new assumptions were set up and the process repeated as many times as was necessary to make points F″ and A coincide. After the cable system and rib were mutually in equilibrium, the moments and shears throughout the erected portion of the rib were investigated to assure that there were no overstresses.

The problem of connecting and disconnecting sets of forward ties and of adjusting them to stress or elevation made it desirable to investigate the effect of changing the length of all strands by 1 in., and of changing the length of one strand by 1 in. When more than one set of ties was connected to the rib at one time, as was the case beginning with erection stage V, calculations for the unit change in length of one set of strands included not only the effect on the stress in these strands and the elevation of the rib at their point of attachment, but also the same effects on all other effective sets of strands. These results were tabulated for field use, so that the erection forces had complete information regarding elevations of the rib at all splice and tie points, stresses in the strands, and effect of changing strand length on both elevation of the rib and strand stress, for all erection stages shown in Fig. 22. They also were given a sequence for releasing, partly, the load on the strands by jacking the ribs apart at the crown, casting off some strands, modifying the jack load, and finally casting off the remaining strands. Thus, it was possible to cast off the strands progressively, without any intermediate partly released stages, and without danger of excessive loads on top or bottom shims at the crown, or of excessive stresses on the last strands left in place.

FIELD CONTROL OF TIE AND RIB STRESSES

To measure the stresses in the tie strands, the contractor provided himself with four patented dynamometers, the principle of which is as follows: Holding the end supports (which are about 4 ft apart) upon the stressed rope, a spring is released which imposes a constant force transversely upon the rope, midway between supports. Since the deflection of the rope produced by this transverse force bears an inverse relationship to the longitudinal stress in the strand, the stress in the rope may be read on a properly calibrated dial. At the top of the tieback bent, platforms were installed on which the contractor's engineers could operate these dynamometers, free from the confusion and danger on the bridge.

If the external loads applied to the ribs by the forward ties were known for any erection stage, the stresses in the rib were no longer indeterminate. The aforementioned dynamometer provided a means for determining the actual loads applied to the rib by the forward ties, and thus made it possible, in the initial erection stages, to adjust the strands to a precalculated load so that the rib would not be overstressed. In the initial erection stages it was not practicable to determine the load applied by the ties by measurements of the rib deflection, since the rib was so stiff that large changes in tie loads produced deflections of the rib too small to measure. However, in later erection stages, the opposite effect occurred; the rib was then so flexible that even very small changes in tie loads produced large deflections. Therefore, in these later stages, elevations on the rib were used as the criterion in determining the forward-tie strand adjusted length, rather than the loads as measured by the dynamometer, and these loads were used only as a check.

This condition was actually a fortunate occurrence, as it happened that this strand-load check proved to be somewhat illusory. In the later stages, with the ribs at correct elevations, the sum of the strand forces was read 10% or more above the computed values. It was felt that the computations could not be in error to such a degree. The possibility to be feared was not that the strands would yield at these stresses, but that the dead loads had been underestimated and therefore the stresses in the finished bridge would be greatly in error. The contractor rejected this hypothesis and confidently maintained that the dynamometer readings were in error. Later, when the crown thrust was measured on the jacks and found to be exactly as computed, there was general satisfaction. In the initial stages, where dynamometer readings were used as the criterion, it is believed that they were in error by no more, and probably less, than 5% since the angle of inclination of the ties with the vertical was small, thus reducing the correction factor for slope.

The apparent error in dynamometer readings may have been in the calibration or in the manipulation, or in both. The dynamometers are understood to have been positively calibrated in a vertical rope-testing machine, and in a horizontal strand-pre-stressing machine. Correction charts were provided for inclined strand positions, such as prevailed on this operation, and it is natural to question their accuracy. Also, it was found that methods of manipulation, and the particular points on the strand to which the bearings were applied, changed the readings considerably. It follows that the technique used in taking the readings, which were recorded, may not have been the technique that should have been selected.

The adjustment of the several strands at one tie point was tedious, usually consuming several working days. The accuracy of the strand-length computations was such that there always was more than enough in the pinned links to put the rib at proper elevation. Sometimes one or more strands in a group would be connected at a 1-in. interval longer or shorter than most of the group, so that the measured stresses could be averaged better. To save time, it was considered permissible to let one or more strands take 15% more load than the average of the group, because that did not exceed the 120,000 lb considered proper. Levels taken along the ribs after each adjustment showed the arch-rib contours to be following the prescribed curve within fractions of an inch at all points.

THE ELASTIC CENTROID—ITS APPLICATION TO THE STUDY OF THE ACTION OF THE CLOSED RIB

To study the stresses in the arch ribs, with the half arches erected to the crown but not connected, and the method of controlling these stresses through jacking thrusts, it was convenient to use the previous type of analysis, with modifications. The previous concept of a rib deflected from the skewback as a cantilever was retained, and the imaginary cantilever deflections from bending, thrust, and shear were found as before. However, instead of introducing forces at the forward-tie points to raise the deflected half rib to its proper position, it was necessary to raise each half rib by applying to it, at the crown, a thrust and a moment coming from the opposite half rib. Since loads were symmetrical about the vertical axis through the crown, there would be no transfer of shear. Each half rib was assumed to carry, in addition to its own weight, the erection travelers and equipment in their final position and the jacks, including their supports and appurtenances, but no tiebacks.

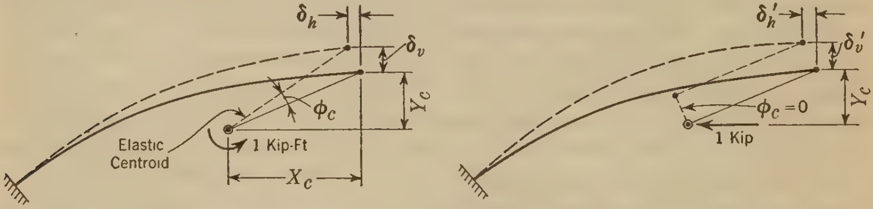
The physical forces available and under control at the crown would be a thrust from two 500-ton jacks above each rib and a thrust from two equal jacks below each rib. These jacks would be equidistant from the rib center line, and the manipulation of one set would be independent of the manipulation of the other. Therefore, both thrust and moment were alterable at will, provided that the effects of opening and closing the upper and lower jack openings, in any combination, could be known in advance in terms of change of thrust and change of moment.

Also, it was necessary to know the effect of jack thrust upon the crown elevation of the arch. Increasing the thrust would spread and raise the half ribs, and such an adjustment might have become desirable if the two arches were somewhat out of level across the bridge. It was not the intention to adjust the crown opening to change the crown elevation of the bridge as a whole, as the ribs were relatively flexible, and any substantial vertical change would require too much change of the crown opening to be practicable.

Another desideratum in the crown adjustment was that the two half ribs should be left in such a relationship, as to distance and angle at the crown, that the prefabricated floor panel 1–1′, several feet above the ribs, should fit without alteration of its over-all length.

To study these effects of jacking thrusts at the crown, the concept of the "elastic centroid" was introduced. The method here used, based on the physical concept of the elastic centroid defined in the paper, is taken from "Die graphische Statik der Baukonstruktionen," by H. Müller-Breslau.[17] The subject of the elastic centroid, also called the elastic center or neutral point, is approached from a somewhat different point of view in texts written in English,[18] but the basic concept is the same.

The elastic centroid of the half arch is a point, located mathematically, where the effect of thrust and moment upon the half arch may be segregated; it is a point in space, but is assumed to be connected to the crown point of the half arch by an infinitely rigid member. A unit moment applied at the centroid produces no translation of the centroid, but does rotate the imaginary connecting arm. A unit thrust (a horizontal force) applied at the centroid produces translation of the elastic centroid (and crown of the arch), but no rotation of the imaginary connecting arm or of the arch itself at the crown. This is shown graphically in Fig. 27.



(*a*) UNIT MOMENT AT CENTROID (*b*) UNIT HORIZONTAL FORCE AT CENTROID

Fig. 27

The problem of determining the thrust, moment, and shear existing at any point in any hingeless arch, of course, is one involving the analysis of an indeterminate structure. The general rule for such analysis is to cut the structure at the point in question, thus dividing it into two determinate structures. By evaluating the forces required to bring the cut ends into coincidence, the internal forces in the uncut structure can be determined.

Closure of the Rainbow arch was made at the crown, and all calculations were based on cutting the structure at that point. Since the structure and erection loads were symmetrical, consideration of shear was eliminated. It was only necessary to determine for one arm the thrust and moment, at the crown, that would return the freely deflected arm to its closed position—erection loads, camber, and temperature being considered.

It is obvious that both the crown moment and crown thrust produce rotation and thrust at the crown. The analysis of these interrelated functions is complex and is greatly simplified by the introduction of the elastic centroid concept in which translation and rotation are segregated. The procedure used in determining the thrust and moment at the centroid, and in translating these functions to the crown, follows:

---

[17] "Die graphische Statik der Baukonstruktionen," by H. Müller-Breslau, Vol. 2, Pt. 2, 1925 Edition, p. 377 *ff.*

[18] "Theory of Modern Steel Structures," by L. E. Grinter, The Macmillan Co., New York, N. Y., Vol. II, 1937, p. 206 *ff.*; also, "Movable and Long-Span Steel Bridges," edited by G. A. Hool and W. S. Kinne, McGraw-Hill Book Co., Inc., New York, N. Y., 1923, p. 440 *ff.*

To establish the location of the centroid, a moment of 1 kip-ft was applied to the arch rib at the crown, and ϕ_c, δ_h, and δ_v were computed for the crown from Eqs. 25 to 28, where (taking into consideration the basic properties of the rib), as defined by Fig. 27(*a*):

$$\phi_c = \frac{222.750}{6\,E\,10^3} = 0.001263 \times 10^{-3} \quad \text{(31a)}$$

$$\delta_h = 0.0566 \times 10^{-3} \quad \text{(31b)}$$

and

$$\delta_v = 0.2854 \times 10^{-3} \quad \text{(31c)}$$

For the purpose of simplifying computations, all calculations involving E or E_s (such as Eq. 31*a*) were made in kip units (E = 29,400 kips per sq in. and $E_s = \frac{E}{2.6} = \frac{29{,}400}{2.6}$ kips per sq in.). After solving Eqs. 31, the centroid ordinates were then (see Fig. 27(*a*)): $X_c = \frac{\delta_v}{\phi_c} = \frac{0.2854}{0.001263} = 226.0$ ft; and $Y_c = \frac{\delta_h}{\phi_c} = \frac{0.0566}{0.001263} = 44.8$ ft.

In skeleton form, Table 6 gives the computations (from sheet ED9) leading to Eqs. 31. A horizontal load of 1 kip at the centroid, using Eqs. 25 to 30, produced bending, thrust, and shear deformations. As defined by Fig. 27(*b*):

$$(\delta_h)' = (2.108 + 0.025 + 0.019)\,0.10^{-3} = 2.152 \times 10^{-3} \text{ ft}$$

$$(\delta_v)' = (6.557 - 0.007 + 0.047)\,0.10^{-3} = 6.597 \times 10^{-3} \text{ ft}$$

Table 7 gives in skeleton form the computations (from sheet ED9) leading to the foregoing numerical results. In the complete table (sheet ED9) from which Table 7 and other similar tables are condensed, the "point" column contains an entry for each splice point, SP13 to SP1, inclusive, and for each intermediate point at which there is a change in the area, and the moment of inertia, of the rib.

If a vertical force P is applied to the half rib at some point A, and if δ_v is the vertical deflection at point A due to a unit moment at the centroid (or by Maxwell's law, the rotation at the centroid due to unit vertical load at point A), then the angular rotation at the centroid due to force P is $P\,\delta_v$. The restoring moment at the centroid to overcome this angular rotation is $\frac{P\,\delta_v}{\phi_c}$ in which, by Fig. 27(*a*), ϕ_c is the rotation at the centroid due to unit moment. These values of δ_v for all critical points on the rib were computed for unit moment at the centroid. The value of ϕ_c is given in Eq. 31*a*.

Similarly, if the same force P is applied at the same point A, and if $(\delta_v)'$ is the vertical deflection at point A due to a unit horizontal force at the centroid (or, by Maxwell's law, the horizontal deflection at the centroid due to unit vertical load at point A), then the horizontal deflection at the centroid due to force P is $P\,(\delta_v)'$. The restoring horizontal force at the centroid to overcome this deflection is $\frac{P\,(\delta_v)'}{(\delta_h)'}$ in which $(\delta_h)'$, by Fig. 10, is the horizontal deflection at the centroid due to a unit horizontal load at the same point. These values of $(\delta_v)'$ were computed for all critical points on the rib for a unit horizontal load at the centroid. The value of $(\delta_h)'$ is 2.152×10^{-3}, as stated.

Thus, for any series of vertical loads acting on the half rib, the foregoing computations offer a rapid and accurate method for determining the moment and thrust, at the centroid, required to bring the crown to a position such that it can be joined to the adjacent half rib. The requirement is, of course, that the crown point have zero horizontal movement and zero rotation. This moment and thrust was:

length along the rib. If δL is the camber change in length of one section of the rib, α the angle of this section with the horizontal, and $(\delta_h)' = 2.152 \times 10^{-3}$, then the thrust due to camber is

$$H_c = \frac{\Sigma \delta L \cos\alpha}{(\delta_h)'} \quad (33)$$

Table 8(*a*) gives, in skeleton form, the computations (from sheet ED9) for the calculation of thrust due to increase of length in cambering, and the vertical displacement (upward) resulting from the elimination of spread by the pressing of one crown on the other.

If t is the change in temperature in degrees Fahrenheit, ϵ the linear coefficient of temperature expansion, l the length of the horizontal projection of the half arch, and $(\delta_h)' = 2.152 \times 10^{-3}$, then the change in thrust due to temperature change t is:

$$H_t = \frac{\epsilon t l}{(\delta_h)'} \qquad \text{(34)}$$

Table 8(*b*) gives, in skeleton form, the computations (from sheet ED9) for calculating the crown displacements, horizontal and vertical, for each degree of change of temperature. Note that Cols. 3 and 9, Table 8(*b*), apply also to erection stages I to IX, inclusive.

From Eq. 32*a*, the moment at the centroid due to final erection loads (ties removed and jacks in place at the crown) was found to be 122,760 kip-ft. From

Eqs. 32*b*, 33, and 34, the thrust at the centroid due to these same loads, at 60° (which is 10° above the normal or camber temperature of 50°, previously stated) was found to be 2,719 + 76 + 15 = 2,810 kips. These are the thrust and moment which, if applied at the elastic centroid of the half rib, would make it possible to join the two adjacent half ribs. Therefore, to determine the corresponding moment and thrust at the crown of the closed arch, it was only necessary to transfer them to that point, using the distance $Y_c = \dfrac{\delta_h}{\phi_c} = 44.8$ ft as the lever arm for H. The nominal moment and thrust at the crown of the closed arch as erected at 60° were found to be: $M = 122{,}760 - 2{,}810 \times 44.8 = 3{,}130$ kip-ft; and $H = 2{,}810$ kips.

Since one pair of the jacks at the crown, which were to be used for weighing the thrust and moment, were located above the rib and one pair below, on 13.92-ft centers, the proportion of this load to be taken by each pair of jacks (at 60° F) was:

$$\text{Top jack load, } + \frac{3{,}130}{13.92} + \frac{2{,}810}{2} = 1{,}630 \text{ kips}$$

Closure Computations

Since there was no assurance in advance that it would be possible to survey the abutments and fabricate and erect the arch without any appreciable errors, it had been decided to fabricate the ribs with a normal opening of 11 in. at the crown, and, after weighing in the proper crown thrust and moment, to measure this actual opening and fabricate a piece that would fit it exactly. This closing piece, referred to as the "keystone piece," was prefabricated 13 in. long on its center line, with its two ends not milled. Provision was made that it could be finally as small as 9 in. on the center line, a variation of ±2 in. from the 11-in. normal.

Prior to closure work in the field, the flexibility of the arch rib itself was investigated completely so that it would be possible to determine the proper correctional movements at the crown to produce theoretical thrust and moment after a weighing had been made.

To determine the effect of unit movements at the crown on the thrust and moment, the results of the elastic centroid calculation were used. Thus, the

horizontal force required at the centroid to deflect the centroid (and the crown) of the half rib a distance of $\frac{1}{2}$ in. (0.0417 ft) horizontally without rotation was found to be, since $(\delta_h)' = 2.152 \times 10^{-3}$, $H = \frac{0.0417}{2.152 \times 10^{-3}} = 20$ kips. Similarly, the moment on the half rib, which would rotate the crown of the rib through an angle whose tangent was $\frac{1}{2}$ in. in $\frac{12.23\text{ ft}}{2}$, or $0.0417 \times \frac{2}{12.23}$, was (from Eq. 31*a*): $M = 0.0417 \times \frac{2}{12.23} \times \frac{1}{0.000001263} = 5{,}400$ kip-ft. This moment, applied at the centroid, would cause only rotation at the centroid, but would produce deflection at the crown. The horizontal component of this deflection would be (from Eq. 31*b*): $\delta_h = 5{,}400 \times 0.0000566$ ft; and, since for this condition only rotation was wanted at the crown, it was necessary to introduce a restoring force (away from the skewback) at the centroid to eliminate this horizontal deflection at the crown. This restoring force was $H = M \times \frac{\delta_h}{(\delta_h)'} = 5{,}400 \times \frac{0.0000566}{0.002152} = 142$ kips.

There were thus two basic conditions—one to produce a $\frac{1}{2}$-in. translation of the crown without rotation, or a 1-in. opening between the two ribs; and the other to produce a rotation at the crown, without translation, of such magnitude that the opening at the top jack would be increased by 1 in., and that at the bottom jack would be decreased by 1 in. This is shown graphically in Fig. 28.

From these basic values, combinations were made which enabled the fabricators to determine readily the expected movement for a given change in jack load, or the expected change in jack load for a given movement. It was obvious from the values in the first three columns of Table 9 that the crown could be translated easily, whereas those in the last three columns show that it could be rotated only with great difficulty. This indicated that it would be a relatively simple matter to attain the proper relationship between the load on the top and bottom jacks—that is, to locate the thrust line vertically on the rib—but that it would be difficult to change greatly the total thrust on the two sets of jacks. Thus, there was little control over thrust, and better control over moment, at the crown.

When the foregoing effects of unit jacking had been calculated, it was a matter of simple geometry to construct diagrams tying the movements to the aforementioned criterion—that the upper ends of spandrel columns 1 and 1′ should be at such a distance as to accommodate the prefabricated panel of floor. It appeared that, because of the extreme flexibility of the half ribs in regard to translation, it would not be practicable to change greatly the total crown thrust, and that something quite close to the thrust, as weighed with nominal 11-in. opening, would have to be accepted. Because of the apparently high stresses read on the tieback strands as erection proceeded, there arose some nervousness regarding what the weighed thrust might prove to be. An increase in thrust of 100 kips would increase the computed skewback moment by 15,000 kip-ft. This would be of little import if it arose from a uniformly distributed underestimate of the vertical loads, which would produce counter moments; it could

be a serious matter if it arose from some other inexplicable cause, and was progressively additive from crown to skewback. The contractor did not fear that this latter hypothesis would be true, and was unwilling to agree that, if the total thrust should read higher than computed, it would be obligatory to reduce it. Fortunately, the computed and the weighed total thrust agreed within 1%; the circumstances are recounted because they brought into full relief the necessity, in closing a similarly indeterminate structure, for maintaining the highest possible accuracy in computing the amount and distribution of all dead loads.

FIELD CLOSURE

Actual weighing of thrust was done on specially constructed "weighing capsules," one of which was inserted in series with each hydraulic jack. They were sealed, high-pressure hydraulic mechanisms, in which extremely small movements of a plunger under load application were transmitted to a Bourdon tube gage by the enclosed liquid. Each capsule was calibrated with its gage to a load of 400 tons, on the 800,000-lb testing machine at Lehigh University in Bethlehem, Pa. The several gage reading-load curves, as plotted, were straight lines, and were extended to 500 tons, the jack capacity.

Check readings of crown thrusts were also made on 10-in. gages on the hydraulic jack feed lines, and these agreed very closely with the readings on the capsules, although neither the jacks nor the gages had been specially calibrated. The accuracy of hydraulic jacks for reading loads has been questioned many times, but experience on this structure indicates that, if the jacks are in good condition and are calibrated with the gages, and if readings are always taken on ascending loads, they will read the actual loads with only mirror errors.

A fuller discussion, with record of individual readings on all capsule gages and all jack gages, was published in 1941.[19] Crown thrusts were read after midnight; temperature readings at several points indicated quite stable temperatures between 60° and 64° F. Readings were taken under four different top and bottom crown opening combinations, and it was interesting to see how closely the relationships between change of opening and change of thrust agreed with the results of the intricate computations herein explained.

No better crown opening was found, all factors considered, than the originally selected nominal value of 11 in. The total thrusts at that opening, corrected to 60° F, were as follows, in kips:

Rib	Sum of two top jacks	Sum of two bottom jacks	Total
North rib	1,716	1,123	2,839
South rib	1,757	1,081	2,838
Theoretical	1,630	1,180	2,810

The total measured thrust was therefore only 1% in excess of the computed value; the point of application, however, was above that indicated by computations. The dead weights which seem most open to question are those of the erection travelers and appurtenances, all located near the crown, where they would operate to raise the thrust line. It appears highly probable that not only the thrusts, but also the moments, throughout the structure are within negligible fractions of their computed values. If an excess moment does exist at the crown, it is quite small, does not increase at other points, and is a small proportion of the total moment, including that from partial live load, at any rib section.

CONCLUSION

If a long, flexible arch bridge of the hingeless type is built with meticulous accuracy in surveying, in fabrication, and in erection, it can be closed on its properly cambered form without need for final adjustments or fear of considerable error in the locked-up stresses from the loads in place at time of closure. If not laid out and built with such meticulous accuracy, it is not probable that such adjustments as can be made at the time of closure would provide sufficient remedies or create full confidence in the stress distribution.

APPENDIX II

For the benefit of any who may wish to make a further and more detailed study of points raised in this paper, the following descriptive index of the information on file at Engineering Societies Library has been prepared.

---

[19] "Weighing Reactions of Rainbow Bridge, Niagara Falls," by Jonathan Jones, *Civil Engineering*, December, 1941, p. 730.

Sheets	Information
ED1	Basic geometry.
ED2	Camber calculations and shop working points.
ED3	Areas, bending properties, and capacities of rib sections and splices.
ED4 to ED8, inclusive	The vertical and horizontal displacements of splice points, tie points, and crown resulting from unit vertical or horizontal forces acting successively at the tie points (see Fig. 24).
ED9	The location of the elastic centroid of the half arch; the vertical and horizontal displacements, for the half arch, of splice points, tie points, and crown, resulting from unit horizontal thrust or unit moment acting at the elastic centroid; these same displacements, for the closed arch, resulting from camber and from change in temperature (see Tables 6, 7, and 8).
ED10 to ED15, inclusive	The vertical and horizontal displacements of splice points, tie points, and crown under erection dead loads, for the various erection stages, considering the erected portion of the arch to be cantilevered from the skewback (see Table 5).
ED16	The resisting moment of the anchor bolts at the skewback.
ED17	The theoretical crown thrust and moment in the closed arch under erection loads; the horizontal and vertical displacements of splice points, tie points TP6 and TP3, and crown under these loads; the moments and thrusts at the splice points for these loads. The erection loads used were based on carefully made preliminary estimates, but were found to be in error by small amounts when final shop bills were completed. The final calculations for theoretical thrust and moment at the crown were made from influence lines constructed from this basic information (see sheets A129, and A137 to A140, inclusive).
ED18	Tabulation of field information for arch elevations, strand stresses, and strand adjustments; index to calculation (A) sheets which are supplementary to these ED sheets.
ED19 and ED20	Wind stresses and displacements during erection.
ED21 to ED23, inclusive	Backstay strand setting and tension charts.

For index to calculation (A) sheets, and their relationship to the foregoing ED sheets, see sheet ED18. The following calculation sheets referred to on sheet ED18 are included with the information on file in the Engineering Societies Library:

A19 to A24, inclusive, with charts; A30 to A135, inclusive.

The following subsequent sheets, not referred to on sheet ED18, are also included:

A137	Final revision in erection dead loads at time of closure at crown.
A138	Effect of these latter revisions in erection dead load on theoretical thrust and moment at crown.
A139	Final calculation of total theoretical thrust and moment at crown.
A140	Theoretical elevations on top of cover plate at splices, at closure.

ERECTION OF STEEL SUPERSTRUCTURE

By E. L. Durkee,[20] M. Am. Soc. C. E.

Synopsis

The erection of the steel superstructure of the main 950-ft span of the Rainbow Bridge is described in this paper. Since it is the longest, single, fixed arch span in the world unusual care was exercised in planning the method of erection as well as carrying out the actual erection operations in the field.

The paper describes the general method of erection and the erection equipment. The most unusual features are the tieback system of cable supports used to cantilever the two half arches from each side out to the center of the span; the method of adjusting these cable supports and of measuring the stresses in them; the method of surveying and controlling the profile of the arch ribs during the various erection stages; the measurement of the crown opening left for the purpose of determining the crown stresses; and the fabrication of a special keystone section to make the actual stresses agree with the computed ones for the dead load of the arch ribs. Also, the erection of the floor steel and the placing of the concrete deck are described.

The general features and the design of the arch are covered in the first paper of the Symposium. The calculation of the erection stresses in the arch and tieback system used for controlling the fabrication and erection of the arch ribs is contained in the third paper.

Introduction

Award of the general contract for the fabrication and erection of the 950-ft main arch span of the Rainbow Bridge, including the concrete deck, was made to the Bethlehem Steel Company early in May, 1940. In the construction operations it was required that all workmen employed should be residents of the country where such operations were being done. It was desirable, however, that the field work be under one management and it was agreed that all construction operations be under the supervision of Bethlehem.

The entire responsibility for the exact position and elevation of the arch was that of the contractor. He was required to check all control lines and grades, including the measurement of the distance across the river between the skewbacks made by the engineers, as well as the exact angle of the concrete skewbacks. The engineers' triangulation of the main span showed a length of 950.016 ft, and the contractor's check measurement gave 950.013 ft based on entirely independent base lines—a difference of only 1 in 317,000.

---

[20] Res. Engr., Erection Dept., Bethlehem Steel Co., Alameda, Calif.

Because of the construction program for the concrete approaches, work on the main span had to be started in the middle of December and was carried on under extremely unfavorable working conditions during the next three months. In spite of this, and the difficulty of securing adequate help, work progressed steadily throughout the winter, without any serious delays and without a single fatality or serious accident of any kind. The work was completed within the allotted contract time and the bridge was opened to traffic on November 1, 1941.

Method of Erection

Cantilever Tieback System.—The arch, obviously, could not be erected on falsework. Although a single bent might have been placed on the steep and rocky shore on either side of the river, it would have been too close to the abutments to have been of much use. To construct bents farther out in the river was impossible because of the sharp angle of the rocky bottom which sloped at about 45° to a maximum depth estimated at 175 ft. Since construction was to be undertaken in the winter and spring, there was also the same danger from ice such as destroyed the Honeymoon span (which the Rainbow Bridge replaced).

An overhead tieback system of support was the obvious solution. Since the arch ribs are entirely self-supporting (there being no spandrel truss system), it was decided to cantilever only the arch ribs and their bracing, which would reduce the dead load to be supported during erection considerably and also permit temporary use of the spandrel columns and floor material in the overhead falsework. This method of erection is not new and has been used in its essential principles in several other arch spans, notably the Hell Gate arch in New York, N. Y., the Sydney Harbour arch in Sydney, Australia, and the Croton Lake arch in Westchester County, New York.

It was found that the first three panels of arch rib, from the abutment to point 10, could be cantilevered on the thirty-two 3-in. diameter upset anchor bolts in each abutment, thus locating the first point of support at point 10. Three other points, at panels 8, 6, and 3, were chosen at which to connect the forward cable ties so as to keep the stresses in these ties and the connection details within reasonable limits considering the weight to be supported and the angle of inclination of the ties. Fig. 29 shows a general view of one half the span cantilevered out to the center with the supporting cable ties and other erection equipment used.

Cable Bents.—To support these ties, a steel tower or bent 130 ft high and 56 ft 2 in. between centers of columns was located on the end of the concrete approach. This height was such as to give a favorable angle of inclination to the forward ties at panel point 3 and keep the stress in, and number of, these ties within reasonable limits. Each leg of the tower was composed of two of the permanent spandrel columns, stitch-bolted together along one face, all riveting in this face being omitted in the shop except for enough rivets with countersunk heads to hold the enclosed box sections together. Each individual column was about 3 ft square, giving a bent column 3 ft by 6 ft. A special base and top section was fabricated to provide for a hinged bearing at the base and suitable details at the top to which to connect the forward ties and backstays.

FIG. 30.—MAKE-UP OF CABLE BENTS

The columns were braced in their narrow direction by three struts each made up of a pair of floor beams from the permanent bridge deck, and each pair of which was braced laterally with temporary angle latticing. The two panels of diagonal bracing completing this bent consisted of permanent lateral bracing also from the deck. An open, unbraced panel of 24 ft was left at the base to permit the passage of the arch-rib sections and other material.

At the top and on each side of each column was a double-deck, steel-framed cage providing two working platforms (see Fig. 31) each 3.5 ft wide by 30.5 ft long. These provided complete access to the various groups of cable strands in the backstays and forward ties both for erecting them and later for measuring the stresses in these strands with the special cable dynamometer. On top of each column was a small, steel jinniwink or A-frame derrick with a single sheave at the peak. This rig was detailed with a central, vertical pin about which it could be swung, enabling the rig to face shoreward for the erection of the backstay cables and riverward for erecting the forward ties.

[a] Longitudinal. [b] Transverse.

Anchorages.—The top of the cable bent was guyed back on the shore side by means of backstay cables connected to concrete anchorage blocks embedded in the solid rock, there being a separate anchorage for each column. Their location, 360 ft and 375 ft in back of the cable bent, was such as to give the same inclination to the backstays on each side of the river. On the Canadian side of the river, the bare rock surface is exposed, as there is no overburden near the rim of the gorge. Here the anchorage blocks were embedded 6 ft to 8 ft in the solid limestone and extended 17 ft to 20 ft above the rock surface. On the New York side of the river, there is an overburden of 18 ft to 20 ft of clay, gravel, and hardpan which had to be excavated down to the rock surface before blasting out the rock itself. It was also necessary to excavate a trench in front of each anchorage block for the passage of the backstay cables.

In plan, each anchorage consisted essentially of a rectangular block of concrete approximately 16 ft by 19 ft, and 26 ft in height, weighing 550 tons or about 1.5 times the vertical component of the maximum pull of 920 tons in each set of backstay cables (see Fig. 32). The front face of each anchorage in the embedded rock was inclined so as to be normal to the resultant of the cable pull and the weight of the concrete, this resultant thrust being downward at an angle of approximately 12°. In the lower half of each anchorage was embedded a set of structural bars projecting just above the rock surface for connecting the links and bars designed to take the pull of the tiebacks. The embedded anchorage bars spread out fanwise so as to distribute their load throughout the entire area of the anchorage.

In Fig. 33 members AF are sets of three angles and members AB and LK are sets of eight bars.

In excavating the north anchorage pit on the west side of the river, the rock at the surface on the front was found to be of inferior quality and several large uncemented areas between the natural bed planes were encountered during the excavation. Rock excavation for the approach structures in front of this anchorage also was extended somewhat farther than expected and was cut up further with both transverse and longitudinal sewer trenches. The anchorages, therefore, were excavated 2 ft deeper than originally intended in the north pit and 1 ft deeper in the south pit to insure that the reaction from the backstays would be carried safely into the rock.

In order to prove the value of the rock and the safety of the anchorage design in general, a jacking test was devised for the north anchorage pit on the Canadian side. The entire front face of the excavation was timbered, and grout was poured between the timbering and the rock to give a uniform bearing. Three hydraulic jacks of 350-ton and 500-ton capacity, laid horizontally in the pit, were used to apply a maximum horizontal thrust of 900 tons to 1,000 tons to simulate the inclined design reaction of 870 tons. The thrust from these jacks was taken by timbering against the rear face of the pit in which a shelf had to be excavated as shown in Fig. 34. Observation points were established on the rock surface in front of the pit and compared with other points set in the rock well to either side of the excavation so as to detect any possible movement. It was intended to apply the test load for at least 12 hours, but weather conditions made this impossible. For the 5 or 6 hours during which load actually was applied, no movement or distress of any kind in the rock in front of or around the anchorage pit could be observed.

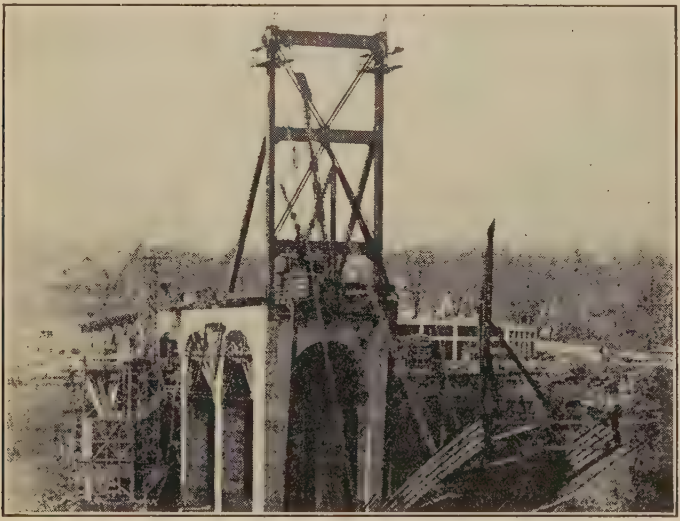

FIG. 31.—VIEW OF CABLE BENT, WITH WORKING PLATFORMS AND JINNIWINKS

As a matter of interest, it may be noted that all anchorage blocks have been left permanently in place. The two on the Canadian side are incorporated in the basement of the approach structure, forming part of the walls. The exterior faces of these anchorages were given the same surface treatment as the other building walls at this level. On the New York side, the anchorage pits

bridge strands each $1\frac{9}{16}$ in. in diameter with a minimum breaking strength of 155 tons (see Fig. 33). Their normal maximum working stress was 50 tons, increased to 60 tons for wind and ice load. Although they had been prestrained by having been used previously as footwalk cables in the erection of the Golden Gate and Tacoma Narrows suspension bridges, they were prestressed to 150,000 lb for 30 min before being socketed at both ends to carefully calculated lengths under a stress of 100,000 lb. These strands were connected to the tower top through an open socket pin-connected to a short heavy link, which in turn was pin-connected to a pair of links which were pinned off to the hammer-head gusset plates forming the top of the column. The sockets at the lower end of the strands were of the closed bearing type. They were nested between groups of links bolted to the embedded anchorage steel projecting from the face of the concrete, and the head of the socket bore against pairs of transverse plates bolted to these links. The only adjustment was by means of shim plates between the bearing sockets and these bars (see Fig. 33).

The cable bent was tipped back from its vertical position approximately 3 ft and supported during this time by means of a pair of stifflegs and sills made up of spandrel columns from the permanent structure (see Fig. 30). The rear end of each sill was blocked up from, and tied down to, the concrete approach by means of embedded steel anchors. The actual lean of the tower top was determined by a plumb bob consisting of a steel piano wire and a short section of railroad rail, the latter immersed in a bucket of oil. The lean of 3 ft was designed to give a stress of approximately 5,000 lb in each backstay cable at 60° F. This was well within the pulling capacity of the single runner line used to adjust these strands which first were hung from the top of the tower and the lower end then hauled back into the anchorage connection.

The correct strand stress for the actual tower lean and temperature was insured by surveying the strands for elevation at the quarter point where a wooden tower was located for this purpose. The minimum thickness of the adjusting shim provided at the anchorage was $\frac{1}{4}$ in. which proved to be sufficient to give practically uniform sag to the four cables in each of the four horizontal layers. After this adjustment, no further attempt was made at any time during the erection to survey or to measure the stress in these backstays, entire dependence being placed on the calculations for stress and on measuring and socketing the strands to the calculated lengths.

Forward Ties or Tiebacks.—Two sets of forward ties were used to support the cantilevered arch ribs alternately at points 10, 8, 6, and 3. They were the same size ($1\frac{9}{16}$ in. in diameter) as for the backstays. At point 10, eight strands were used for each arch rib and were hung in two vertical rows of four each from the two center gusset plates at the top of the cable bent. After these ties were adjusted and the rib cantilevered to point 8, the second set of ties, also eight in number, was connected and adjusted. This second group was hung in two rows of four each from the two outside gussets of the cable bent so that, when erected, they passed outside of the first group still in place at point 10.

While the ribs were being cantilevered from point 8 to point 6, the ties at point 10 were disconnected from the rib and slacked back to the abutment where they were left hanging vertically from the top of the tower. An adjustable working platform was provided which could be raised or lowered to bring the workmen up to the lower end of these strands. Lengthening "pennant" strands then were attached to this first group of panel 10 ties to make them long enough for use at panel 6. For this point, four additional strands also were hung from the two inside gussets at the top of the bent in addition to the eight lengthened strands from point 10, making a total of twelve strands for point 6.

These twelve strands had to be erected by swinging them out through the group supporting the rib at panel 8. When they were finally connected and adjusted, cantilever erection of the arch rib was continued to panel 3 supported on the strands at both panel 8 and panel 6. At point 3 the final group of twelve strands was connected as follows:

ELEVATION OF ADJUSTABLE LINKS

FIG. 35.—ADJUSTABLE LINKS AND SPLIT SHEAVES

The first or uppermost four strands at panel 6 were removed one at a time, slacked back on the arch rib, and lengthened with a pennant. The lengthened strand then was dragged out on the arch rib to panel 3 where it was connected and adjusted. This operation was repeated four times, giving four strands at panel 3, eight at panel 6, and eight still in place at panel 8. These latter then could be disconnected, lengthened, swung out, and connected at panel 3. This gave twelve strands at panel 3 and eight at panel 6, a total of twenty strands per rib, on which cantilever erection was continued to the crown.

The connection of the forward ties to the arch ribs was through a pair of 18-in. heavy T-sections spaced 8 in. on centers and bolted to the top flange of the rib by 1$\frac{1}{4}$-in. diameter high tensile bolts. The arch ribs were reinforced inside by diaphragms which took the load from the T-sections and transferred it to the web plates.

The connection of each forward strand to the T-sections was through an adjustable set of links shown in Fig. 35. The lower end of the strand carried an open socket to which was pin-connected the upper link consisting of two plates 7 in. by 1 in. with pinholes in the lower end spaced 5 in. on centers. Meshing with this upper link was the lower link which consisted of three plates, one 7 in. by 1 in. and the other two 7 in. by $\frac{1}{2}$ in. with pinholes in the upper end spaced 4 in. on centers. The lower end of this link was pin-connected directly to the T-sections. Pinning these two sets of links together through different sets of pinholes gave different over-all lengths of link varying by 1-in. increments from 12 in. shorter to 18 in. longer than the normal length; and by the same or larger increments to maxima of 24 in. shorter to 30 in. longer.

The strand length was adjusted by means of a double set of falls, one on either side of the adjustable links. Each upper, two-sheave block in these falls was supported on the $3\frac{1}{2}$-in. strand socket pin which was extended for this purpose. The lower, three-sheave block was supported on the 4-in. pin connecting the lower link to the T-sections. This pin also was cantilevered out for this purpose. Each set of falls was reeved up with five parts of $\frac{5}{8}$-in. wire rope, the lead lines of which ran directly to the top of the cable bent where they passed over a pair of sheaves and then part way down the bent where they were clamped together to form a bight in which was supported a third or equalizing sheave. This latter sheave was overhauled by a $\frac{7}{8}$-in. wire rope runner line from an engine either on the deck of the approach or on the engine platform. In adjusting a strand, with the adjusting falls in place, a strain first was taken on the equalizing sheave to get the same tension in the two lead lines of the adjusting falls. The two lead lines then were clamped together just above the equalizing sheave so that equal movement was insured in both sets of falls.

The forward ties were erected by a system of horizontal and vertical runner lines, one for each arch rib. The vertical runner line was a $\frac{7}{8}$-in. wire rope run through the jinniwink at the top of the cable bent. The horizontal runner line was also a $\frac{7}{8}$-in. wire rope running from an engine at the abutment out over the arch rib, through a snatch block at the end of the erected steelwork, then back to the abutment where it could be connected to the lower end of the vertical runner line thus forming a "telegraph" system.

The forward ties were shipped on large wooden reels which were unloaded on platforms constructed near the skewbacks. Each strand was unreeled by using the vertical runner line to haul it up to the top of the cable bent where the socket was pinned to the connecting links. To swing a strand out and connect it to the arch rib, the two runner lines were connected through a triangular hitch plate to which the lower end of the strand also was connected. By proper manipulation of the runner lines the strand then was hauled out to the desired point on the rib. Each group of strands was connected at the upper end in two vertical rows whereas the connections at the lower end were in a single row, between the two T-connections. This gave the strands at panel 8 a long, triangular-shaped arrangement with an opening between them of 3 ft at the upper end, tapering to zero near the rib connection.

To erect the strands at panel 6, which had to be swung out through this opening between the strands in place at panel 8, the two runner lines first were hauled up taut so as to bring them above the strands at panel 8. Then they were dropped down through the opening, hooked to the loose strand hanging from the tower top, and pulled back again to a taut position above the panel 8 strands, dragging the loose strand with them. Finally, the runner lines were hauled out to panel 6 where the loose strand was connected and adjusted. The strands at any panel point were removed by a similar use of the runner lines.

Fan Falsework Bent and Platform.—On the river side of the cable bent, and forming an extension to the concrete approach spans, was a steel platform 20 ft long, the outer end of which was supported on two inclined falsework columns themselves supported on a concrete seat just above and in back of the concrete skewbacks for supporting the arch ribs. These two columns, 140 ft long and unsupported for their entire length, each were made from two suitable lengths of the permanent spandrel columns. A special end section (which later was removed and discarded) was detailed, both top and bottom. The upper end of each column was tied back by a steel strut connected to anchor bolts embedded in the concrete approach for the purpose. A floor beam from the permanent structure was framed between the upper ends of the columns. Various other struts and bracing members completed the main platform.

The purpose of this falsework bent and platform was to support a stiffleg derrick for unloading and erecting the steelwork for the arch ribs. This material all was trucked out over the approach and through the cable bent so that the derrick could unload it and lower it into place. A refuge bay 15 ft long was cantilevered out beyond the main fan falsework platform to permit the truck hauling the material to come far enough out so that the center of gravity of the arch ribs would be in front of the cable bent.

ERECTION EQUIPMENT

Yards and Unloading Equipment.—All material for erection in the permanent structure was shipped by railroad to yards on either side of the river. The heaviest pieces to be handled were two 75-ton arch-rib sections (the second rib sections out from the abutment) approximately 53 ft long. Two other arch-rib sections weighed approximately 65 tons and the two steel grillage sections, designed to spread the load of the arch ribs over an area 12 ft by 22 ft on the concrete skewbacks, weighted 63½ tons each, giving a total of six pieces on each side of the river weighing more than 60 tons.

On the Canadian side, an 85-ton stiffleg derrick was set up and operated by a 100-hp, 3-drum steam hoisting engine. Scrap railroad rail was used for counterweight on the end of each sill. This derrick was capable of handling the heaviest, or 75-ton, loads without assistance. It was placed far enough back from the railroad track to permit the trucks and trailers used for hauling to the bridge site to come between it and the track. The material thus could be unloaded directly from cars to the trucking equipment or could be swung around and stored on the ground beside the derrick.

On the New York side it was not possible, in the yard selected (which was long and narrow), to set up a stiffleg derrick of sufficient capacity, or one that could cover the entire yard area. A locomotive crane of 60-ton capacity was provided operating on one track to unload material from the cars which were brought in on a second, parallel track. For the six pieces weighing more than 60 tons it was necessary to bring in a railroad wrecker crane and use both cranes to unload these pieces, one picking each end. Otherwise, the locomotive crane unloaded and loaded all materials. The arch-rib sections could be unloaded and stored alongside the crane track when necessary.

Hauling Equipment and Roadways.—All heavy material was hauled from the railroad yards to the bridge site about a mile distant, by heavy tractors and trailer equipment. All arch-rib sections were loaded on two heavy trailers, one under each end of the rib. A 50-ton, goose-neck type of carry-all trailer was used at the front end and a 100-ton dolly trailer under the rear end. The number and spacing of the wheels in each trailer was such as to spread the load satisfactorily over the pavement. The maximum axle and wheel loads were 24 tons on an eight-wheel axle and 20 tons on a four-wheel axle. Pneumatic tires were used on the carry-all trailer (four wheels) and solid tires on the dolly trailer (eight wheels).

Two separate, heavy-duty tractors were used to haul the trailers, one leading and the other following. The rear tractor was used largely for the purpose of steering, but on the Canadian side of the river it also was necessary to help brake the loads down the steep hill between the yard and the bridge site. The tractors were equipped with air brakes.

On the New York side, the new bridge deck was at the same level as the existing ground surface and the loads could be hauled out over the natural ground directly on to the concrete approach. On the Canadian side, the bridge was approximately 20 ft above the bare rock at the edge of the gorge. A steel ramp 315 ft long with 4% grade was constructed to provide access from the ground surface to the level of the deck. This ramp was made of two-column steel bents spaced from 20 ft to 28 ft on centers with an almost solid floor of 12-in. by 65-lb steel H-beams laid longitudinally to act as stringers. The roadway was formed of 4-in. by 12-in. planks laid transversely across these stringers. A pair of 6-in. by 12-in. timber curbs, spaced 12 ft apart and set 6 in. above the deck, completed the roadway. This ramp was located on the south side of the bridge roadway.

A timber roadway, 12 ft wide between curbs, was provided over the concrete approach on each side of the river. It was located on the south side of the structure, on the Canadian side of the bridge where it formed a continuation of the ramp. On the New York side, the roadway was located on the north side of the approach. This roadway led through the cable bent and out to the fan falsework platform beside the unloading derrick. The 15-ft refuge bay cantilevered beyond the end of the fan falsework columns was designed to support the weight of a tractor only. The remainder of the roadway was designed to carry the heaviest wheel loads. The roadway slab on the concrete approaches had not been poured at this time, as only the main arches, floor beams, and stringers were completed. Hence, the timber roadway was needed over these approach spans.

Unloading Derrick, Traveler A.—For each side of the river, a stiffleg derrick of 85-ton capacity was provided to start the erection and to act as an unloading derrick. It was known as traveler A (see Fig. 29), erected on steel platform beams at the shoreward end of the concrete approach by means of a smaller derrick. In its first position, about 60 ft back from the outer end of the approach, the derrick was provided with a boom 145 ft long by which the first fan falsework columns and platform were erected. Each of these columns weighed 36 tons and was set at a radius of about 65 ft. From this same position, the second operation was to erect the 130-ft high cable bent, the heaviest lift in which was the 27-ton top section. After completing the bent, the traveler backed off and the boom was shortened to 95 ft. Then, the traveler was moved forward to the end of the concrete work, standing in the opening of the cable bent from which the lower panel of bracing was omitted and from where it erected the steel grillage and skewback sections of the arch. Finally, the traveler moved forward to its third position standing directly over the fan falsework columns, 27.5 ft in front of the cable bent. In this position, it was used to erect the first three panels of the arch itself and the arch-rib traveler, after which it acted as an unloading derrick feeding material from the deck down to the arch rib. After the arch ribs were completely erected and swung, the boom was lengthened to 105 ft and this derrick then was used to erect the spandrel columns, girders, and floor starting from the abutment and moving out to panel point 9 where it removed rib traveler B (Fig. 29) and completed the erection of the floor. Traveler A was itself dismantled and removed by a tractor crane brought out on the material roadway for this purpose.

The beams and track stringers forming the deck used to support and move this traveler were all stringers from the floor of the permanent structure. The traveler was operated by a 100-hp, 3-drum, steam hoisting engine.

Rib Traveler B.—To continue erection of the arch ribs beyond the reach of traveler A, a second traveler, moving on the arch rib itself, was provided. This consisted of a stiffleg derrick normally of 40-ton capacity but reinforced to enable it to handle the heaviest remaining arch-rib sections weighing about 53 tons. A 76-ft boom was used. The derrick was supported, in plan, on a triangular-shaped steel underframe (see Fig. 36). This underframe consisted of a front cross girder spanning between the two arch ribs and a single longitudinal girder over one arch rib only, the rear end of which was supported on an adjustable vertical leg which could be pinned off to different lengths and thus could keep the deck of the traveler level for the varying angle of the arch rib as the traveler advanced from the abutment toward the crown. The derrick was powered by a 4-drum steam hoisting engine supported on an engine platform located on the steep, talus slope at the bottom of the gorge, just in back of the skewbacks, and occupying the area under the outermost span of the concrete approach. The framework of this platform consisted of steel columns seated on shelves in the concrete footings, and steel beams and girders. A 4-in. plank deck and a light housing to enclose the engine and protect the operator completed the structure.

In working position on the arch this traveler was pinned to brackets bolted to the top flange of the ribs, which took the entire reaction. To move the traveler, it was jacked up, the bracket pins pulled, and the traveler lowered on to three, two-wheel trucks, one at each corner. A move was made for each panel of the arch erected. At the outer end of each rib was bolted a steel frame or cathead which supported a set of four sheaves. An eight-part set of falls was reeved up between these sheaves and a three-sheave block at each side of the front end of the traveler. The lead lines from these two sets of falls ran back to the hoisting engine at the abutment where lines from two of the drums were removed to accommodate them. A complete move of the traveler, including removal and replacement of the lead lines on the engine, required from 3 to 4 hours.

For the first operation, the rib traveler was used to erect the arch ribs and the bracing between them, advancing from panel point 10 to panel point 2, one panel from the crown. After the erection of the keystone pieces, this traveler moved back down the rib to panel point 8, erecting the spandrel columns, girders, and floor framing behind it from the crown to panel point 7. Standing at point 8, it was dismantled and removed by the overhead derrick, which, in the meantime, had been used to erect the floor and had advanced from the abutment out to panel point 9.

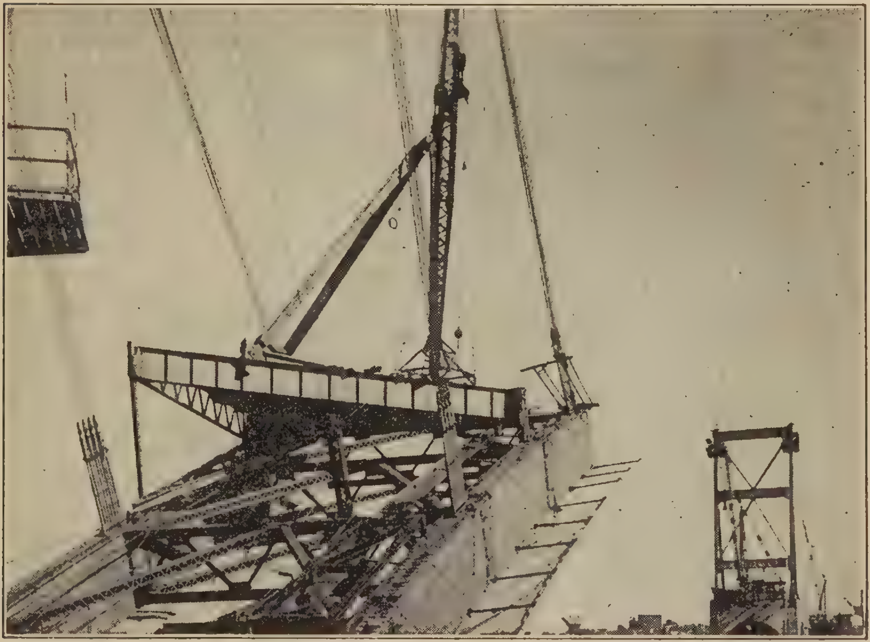

Fig. 36.—View of Rib Traveler B

Material Truck and Track.—All material was brought within reach of the rib traveler by lowering it from the deck with the unloading derrick A and by landing it on the material truck consisting of a steel framework with a single wheeled truck at each corner. The truck was 38 ft long and had an 8-ft gage between wheels. On one side, it ran on a rail supported over the inside web of the arch rib, the two wheels running on this rail being double-flanged. The two inside wheels ran directly on the top flange of a track beam supported on top of the cross struts at each panel point of the arch rib. These wheels had a plain tread with no flange. The truck was moved by a set of six-part pulling falls, the upper three-sheave block of which was fastened to the right-hand front corner of the rib traveler. The triangular shape of the rib traveler underframe enabled the material truck to be brought out immediately behind the front cross girder and within easy reach of the derrick. The arch-rib sections were landed on, and securely belted to, special seats on the truck. They were handled one at a time. All other material, such as struts, bracing, and all floor material, was either bolted or securely lashed to the truck and kept from sliding off endwise by means of special brackets or stops.

Hitches.—Special hitches were provided for the arch ribs and for all other heavy loads as a part of the erection equipment. For the rib sections these consisted of a pair of T-sections bolted to the top flange with high-tensile bolts, and with a hole in the web for a 2¾-in. pin for the connection of the open socket on the wire rope pennants hanging from a triangular hitch plate on the lifting falls.

The center of gravity of each rib section was computed from the shop drawings and the hitch T-sections were so located that the rib would hang free at the same angle as determined by its location in the structure, thus greatly simplifying the entering of each piece into the splice plates at the joint.

Hoisting Engines and Power.—Steam hoisting engines were used on both sides of the river. It had been fully expected that electric power would be used, but it was found disadvantageous for several reasons. On the Canadian side only 25-cycle power was available, whereas the contractor's electrical equipment was all 60-cycle units. Both 25-cycle and 60-cycle power were available on the New York side. The power companies on each side of the river were not anxious to furnish power, however; their lines already were loaded and new lines would have had to be erected, the entire cost to be borne by the contractor. Moreover, the rates for electric power, taking account of the stand-by charges, were found to be high in comparison with the cost of steam power. Therefore, steam hoisting engines were decided upon and used. Four hoists were required on each side of the river, the boilers being operated by fuel-oil burners.

A 3-drum, 100-hp hoist located on the derrick platform was used to operate traveler A. A similar hoist, but with 4 drums and located on the engine platform at the foot of the gorge, was used to operate the rib traveler B. Three lines operated the derrick boom falls, main load, and runner line, and the fourth line operated the falls used to haul the material truck out along the arch rib. A 3-drum, 50-hp hoist also was placed on the engine platform and operated as a skeleton engine, obtaining its steam from the boiler with the hoist used for traveler B. This hoist was used to operate one set of vertical and horizontal runner lines for one of the arch ribs. The runner lines for the second rib were operated by a fourth hoist of either 2 or 3 drums which was placed on the deck of the concrete approach in back of traveler A. This gave a total of 13 drums in use on each side of the river. In addition, 2 of the 4 drums operating the rib traveler served a double purpose in that they were used for moving the traveler as well as operating the main falls and boom falls of this derrick.

Each derrick boom was swung by a bull wheel operated by a steam swinger engine on the traveler platform. The derrick signalman operated the swinger in each case. For traveler A, steam from the derrick engine boiler was used for power. Since the engine for traveler B was not with the derrick, but back at the abutment, compressed air was used to operate its swinger engine.

Signal System and Telphones.—Signals between the signalman on the platform of the rib traveler and the hoisting engineer on the engine platform back at the abutment were relayed by an electric light signal system. A signal box was provided at the derrick with two push-button switches for each drum on the engine. A signal light box faced the hoisting engineer and contained two lights for each drum—one red and one green or amber. The lights were operated by dry cells. The green or amber light was used for "going ahead"—that is for raising a load or the boom and the red light for slacking off or lowering. No light at all stopped all operation. Different speeds of operation could be obtained by flashing the lights on and off, giving very delicate control of the load being handled. Considerable pressure was required to operate the push-button switches, making the system practically foolproof.

On traveler A the signalman was always in sight of the hoisting engineer and no signal system was required. Hand signals, relayed as necessary, also were used for the operation of the runner lines, and adjusting falls were used in the erection and adjustment of the forward ties.

Hand-cranked, dry-cell-operated, field telephones were set up in enclosed boxes for use on the work. One telephone was on the deck, at the fan falsework platform, one at the top of each column of the cable bent, and one on the arch rib at traveler B. These telephones were invaluable for the general interchange of information between the foreman (who was usually on the fan falsework platform where he had full view and command of the entire work) and the pushers or subforemen. This was particularly true in the case of the erection and adjustment of the forward-tie cables, the actual adjustment being made on the arch ribs while the stress was being measured at the top of the cable bent.

Compressors and Pneumatic Tools.—Compressed air for the operation of all pneumatic tools and for operating the swinger engine on the rib traveler was furnished by two, 210-cu-ft capacity, fuel-oil compressors set up on the edge of the gorge near the end of the approach spans. Air was piped down the face of the cliff to the abutments and then out the arch ribs. This line also was used to feed air to the work of erecting the center section of the floor, from the crown back to the quarter point. A second air line was run out over the concrete approaches to the deck of the arch span as this was built out from the abutment until it joined the center section, at which time the line on the arch ribs was removed.

In addition to the usual pneumatic riveting hammers, the following pneumatic equipment was used: All bucking up of field rivets was by means of air dollies of various types. Very few rivets are now bucked up by hand dollies. Fitting-up bolts were tightened entirely by the use of pneumatic impact wrenches which have contributed greatly to decreased costs for this work because of their greater speed over hand wrenches and because they exert a greater force, thus insuring tighter work and consequently fewer loose rivets and cutouts.

Safety Nets.—The specifications required the contractor to use safety nets and barriers to safeguard men against falling into the river, these to be left in place until the completion of the work. A type of net similar to that used in the erection of the floor system of the Golden Gate Bridge was used, and, in fact, five nets still on hand from that work were refabricated for use at the Rainbow Bridge. The remainder of the twenty-five nets were newly fabricated.

The average size of the nets was 45 ft by 85 ft (see Fig. 36). They were constructed of $\frac{3}{8}$-in. manila rope laid to form a 6-in. square mesh, one set of ropes being passed through the other at the intersections and being tied with special twine as well. The sides of the net were finished with $\frac{3}{4}$-in. manila ropes extending 12 ft beyond the ends; and at each end there were additional $\frac{3}{4}$-in. tie ropes 8 ft long and spaced 4.5 ft apart with which to fasten the nets to the supports. The edges of adjacent nets were laced together with separate $\frac{3}{4}$-in. manila lines not a part of the nets themselves.

These nets were supported beneath the arch ribs on 6-in. steel H-beams running outside and parallel to the bottom flange of each rib. The beams were held in position 10 ft outside the rib by angle struts and $\frac{1}{2}$-in. wire rope ties extending from the top flange of the rib out to the end of the struts. A diagonal wire rope guy in the plane of the bottom flange of the rib, one per panel, prevented this assembly from swinging downhill due to the slope of the arch. The struts were hinged at their connection to the bottom flange of the ribs so that the entire framework could be assembled to the rib in the yard and folded up alongside it, where it was fastened until after the rib was erected. Each safety net support projected lengthwise about 8 ft beyond the end of the rib toward the center of the span so that when the net was erected, it extended beyond the end of the steelwork and thus provided protection at the splice where the men were connecting the next rib section.

The nets were folded at the factory and shipped in separate bundles. In erecting them, two lines were passed beneath the arch rib from one net support to the other. The net was unfolded to its full width and one end picked by the rib traveler until the entire net hung vertically; then one end of these two lines was connected to the lower end of the net. As the net was lowered over the side, the two lines hauled the lower end under the two ribs and over to the far support. The tie ropes were first secured to the H-beam support on one side, after which the ties on the opposite side were pulled up, using a line from the tugger hoist to give the proper sag in the net, and then tied off. The adjacent edges of the nets were then laced together with a $\frac{3}{4}$-in. manila rope.

Records were kept of all men who fell, or were knocked off the span, into the nets and it is believed that four lives were saved by their use. One man was actually knocked off the rib by a runner line which sagged and then whipped loose, while the other three men either slipped or fell accidentally. Only one man fell from the deck of the bridge, fortunately near the center of the span, and dropped 40 ft. The man knocked off was standing on the top of the arch rib, and the other two fell from scaffolds at the level of the bottom flange of the arch rib. Fortunately none of these men hit any of the bracing members in their fall and were entirely uninjured. All of them returned to work indicating their confidence in the nets and the job as a whole.

It should be noted that all erection work on the structure, including the concrete deck, was completed without a single fatality or a single serious injury. This is an excellent safety record in view of the locality and the time of year during which the work was undertaken, and the difficult and hazardous nature of the work itself.

Stair Towers, Ladders, Etc.—Access to the engine platforms and skewbacks at the foot of the gorge on each side of the river was by means of a vertical, timber, stair tower approximately 100 ft high down the vertical face of the cliff, followed by a set of steps on the surface of the talus slope. The stair towers were braced from the face of the cliff by struts and guy wires attached to anchors embedded in the rock. These stair towers and steps were constructed by the foundation contractors and then taken over by the superstructure contractor for his work.

Steel ladders were employed to provide access from the deck to the top of the cable bent, running up the inclined stiffleg and then vertically up the column the remaining distance to the platforms at the top of the tower. A steel ladder was provided from the foot part of the way up each fan falsework column to give access to the adjustable working platforms hung at the lower end of the forward ties as they were hanging from the top of the cable bent.

From the skewbacks out to approximately panel point 8, the slope of the arch ribs was so great that a timber ladder arrangement was laid on the top flange of each rib, the cross pieces consisting of 1-in. by 3-in. strips. In addition to this, a 3-ft wide timber walkway with cleats was provided alongside the material track beams. This walkway extended from panel 11 to the rear end of the traveler at panel 2, and enabled the men to keep off the ribs themselves while the forward cable ties were being erected and adjusted.

Short, 12-ft timber ladders were hung over the sides of the arch ribs at various points to give access from the top flange to manholes in the side of the ribs and to the scaffolds hung under the bottom flange at the splices.

At the crown of the arch, opposite the jacking brackets, a timber platform supported on steel beams was constructed, 12 ft wide and 56 ft long, covering the entire distance between the ribs. Large scaffolds were constructed beneath the jacking brackets on the bottom flange of each rib with steel ladders between them and the upper platform. This gave complete and easy access for the erection and adjustment of the jacking equipment and for the measurement of the crown opening during the jacking operations. The upper platform provided a convenient space for the storage of miscellaneous jacking equipment and other tools required at the crown at this time.

ERECTION OF ARCH RIBS

General Method of Erection.—Since the 12-ft deep, box-girder, rib sections formed the sole supporting member for the span, it was logical to erect them only, together with the lateral bracing between them, as the first operation. This reduced by about one half the total weight of steelwork to be supported until the ribs were connected at the crown and made self-supporting. It also permitted the use of the steel not first erected as temporary falsework, traveler track, etc. Approximately 1,000 tons of spandrel columns, girders, and floor beams from the permanent structure were used temporarily for such purposes.

Grillages.—The first piece erected on each concrete skewback was the 63.5-ton steel grillage section made up of plate girders and forming a cellular construction 6 ft deep, 12 ft wide, and 22 ft long. These pieces were designed to distribute the reaction of the arch ribs over the necessary bearing area of concrete. The center third of the top surface of each grillage was milled to a true plane to take the bearing of the steel skewback section, and four corner-bearing surfaces also were finished on the bottom face of each grillage. The original intention was to finish the entire bottom surface to rest directly on the corresponding bearing surface on the concrete skewback itself. This was judged by the contractor to be too difficult of attainment and the following alternative method of securing the proper bearing and alinement was used.

The inclined surface of the concrete was kept about 5 in. below the bottom of the steel grillage except for a 1-ft square pad at each corner. These four pads were to be finished to correct slope and elevation by the foundation contractor. Suitable center lines on each abutment were provided by the engineers and corresponding lines were scribed on the 4-in. slab forming the bottom face of the steel grillage. In order to prove the slope and elevation of these four concrete pads, two triangular-shaped steel frames were built with suitable lateral bracing between them and erected on each abutment, supported on the four concrete pads. They were so designed that, if the pads were finished correctly, the top or horizontal legs of this framework would be in a true horizontal plane, and horizontal and transverse center lines scribed on the steel framework would correspond with the center lines on the concrete work. The original finishing of these concrete pads was neither carefully done nor properly checked and considerable refinishing and adjustment was necessary. As a final check, the milled top bearing surface of each steel grillage also was checked after the grillages had been erected. Instead of a fixed concrete pad, it would have been cheaper and more accurate to provide an embedded, threaded bolt at each corner, with a nut to support and adjust the grillage, and then to survey directly on top of the grillages themselves.

For erection, each grillage was picked up by a special hitch bolted to the top and bottom flange of one of the transverse girder webs. This hitch projected above the grillage and had a pinhole for a pair of short links connecting to the triangular hitch plate on the derrick falls. The hitch was so placed that the grillage hung at approximately its correct inclination in the structure. To guide the grillage in place over the thirty-two 3-in. diameter anchor bolts and to protect the thread on these bolts during this operation, a pilot was provided for each bolt. This consisted of a piece of 4-in. pipe, to one end of which was welded a solid, cone-shaped, steel nose. The pipe simply slipped over the thread on the anchor bolts and did not screw on, so that the pilots could be placed and removed readily.

After the grillages had been set and adjusted and before erection could continue, it was necessary to fill with grout the 5-in. space under the grillage and to fill with concrete the center, vertical row of cells in the grillage, beneath the steel skewback, to give proper bearing for the thrust of the arch ribs. After erection was completed, the remaining cells were also filled, and the entire grillage surrounded with concrete, thus completely enclosing it and making it a part of the concrete skewback.

Steel Skewbacks.—The second steel member to be erected was the steel skewback section 22 ft deep on the lower side and tapering to the 12-ft depth of the arch rib framing into it on the upper side. This member was a box section, 3 ft wide between the web plates the same as the arch rib, designed to spread the load from the rib over the 22-ft depth of the steel grillage. It was approximately 12 ft in height and weighed about 47 tons. The skewback bolted directly to the steel grillage and in addition was secured by double nuts on the end of each of the thirty-two anchor bolts.

Arch Ribs 13 to 10 and Tiebacks at Panel Point 10.—The three arch-rib sections from the skewback out to panel 10, together with the bracing between them, were erected by cantilevering them out under their own weight, still using the unloading derrick or traveler A to handle them. These three sections weighed, respectively, 65 tons, 75 tons, and 58 tons, each. This resulted in a maximum computed stress in the anchor bolts of not quite 20,000 lb per sq in. (erection stage I).

During this operation, the first set of eight forward-tie ropes had been unreeled and hung from the top of the tower. These were swung forward, using the runner line system and connected to the T-sections at point 10 using the outermost pinholes of the adjustable links so that they still hung slack. After all eight were connected, the adjusting falls were applied to the uppermost strand which was pulled to a stress of approximately 50 tons and pinned off. The falls then were applied to the second strand which was adjusted similarly and which, of course, reduced somewhat the stress in the first strand. The strand stress was measured by the use of a dynamometer, applied at the upper end of the strand. The stress in each successive strand adjusted was reduced slightly in an endeavor to secure approximately equal stress in all eight strands when the final one was adjusted. It was necessary for the total stress in the eight strands to equal as closely as possible the calculated stress of 331;500 lb at 60° F (erection stage II), and also for the individual strand stresses to vary by as little as possible. Three adjustments of the strands were necessary to attain this result. The entire operation of erecting and adjusting this group of strands required 2.5 days.

The sole criterion for adjustment of the arch at this erection stage was the total stress in the eight ties at panel 10 which was calculated to pick up the end of the ribs an amount approximately sufficient to reverse the cantilever stress. Subsequent cantilever erection from points 10 to 8, of course, would increase the stress in the ties at point 10 and bring the arch ribs down toward their normal position. No survey for profile of the ribs was made at this stage, the measured tie stresses being regarded as critical. The ribs were so stiff that, if they were not adjusted to a correct profile, an excessive stress would have had to be applied in order to bring them to that profile even though the variation at point 10 was only a small fraction of an inch.

With the strands at panel 10 properly adjusted, the rib traveler was erected at point 10, using the overhead derrick for the purpose. The material track and truck also were erected at this time.

Arch Ribs 10 to 8 and Tiebacks at Point 8.—Standing at point 10, the crew on rib traveler B proceeded to erect the next panel of arch ribs and bracing from points 10 to 9 after which it was moved to panel 9; then the crew erected the next panel of the arch from points 9 to 8. This completed erection stage III in which the theoretical total stress in the tiebacks at point 10 was now 493,500 lb at 60° F. No check was made of the strand stresses at this time or of the elevation of the arch rib. The tiebacks for connection at point 8 had been hung in the meantime from the tower and were now swung forward and connected to the T-sections first loosely and then pulled to proper adjustment with the adjusting falls in accordance with the figures furnished by the engineering department for erection stage IIIA.

The total theoretical strand stress at point 8 was now 454,100 lb which reduced the stress in the tiebacks at point 10 to 69,900 lb. This reduced stress permitted the easy removal of the strands at point 10 by the adjusting falls which were used to disconnect them, one at a time, and swing them back to the abutment, still hanging from the tower.

The removal of the strands at point 10 completed erection stage IV and increased the stress in the strands at point 8 to a total of 485,600 lb. No readings of the strand stress were made at this stage. It was assumed that, if the previous adjustments had been made correctly, the stresses at erection stage IV could not be greatly in error. Neither were the arch ribs surveyed for profile at this stage since they were still so stiff that the total strand stress at point 8 was considered to be the proper criterion.

Arch Ribs 8 to 6 and Tiebacks at Point 6.—Arch-rib traveler B was moved immediately to panel point 8 from which position it was used to erect the ribs and bracing from panels 8 to 7, and then moved to panel 7 and erected the ribs from panels 7 to 6. This completed erection stage V, for which the total theoretical stress in the eight tieback strands at point 8 was 772,100 lb. A set of strand readings made at this time for the Canadian side gave a total stress of 786,600 lb for the north rib and 775,900 lb for the south rib, or a variation of less than 2% from the theoretical. The maximum variation in an individual strand stress was considerably higher, one strand being 19% above the average but all others being within 8% of the average. The average variation in strand stress was about 5%. The one highly overstressed strand was slacked off 1 in. as a precaution, but no other adjustment was deemed necessary.

On the New York side of the river, the total measured strand stress at this stage was 20% high for the south rib and 12% high for the north rib, with a maximum variation for a single strand of −10% from the average. Although the total measured stress was considerably higher than the computed stress, there was some question as to the accuracy of the dynamometers being used to measure these stresses, and, for a number of reasons, the readings seemed high, probably by at least 10%. Therefore, no adjustment was made.

Meantime the eight strands released from panel 10 and left hanging from the tower had been lengthened with pennant strands and made ready to be swung forward and connected at point 6. Four additional strands also were added to this group, making a total of twelve. Because of the arrangement of the strands at the tower top, where they were connected in four vertical rows, these twelve strands for panel 6, which were in the two inside rows, had to be swung out between those at panel 8 which were in the two outside rows. Each strand was swung forward and loosely connected at point 6 until all twelve strands were in place, after which they were adjusted individually to the proper tension. This gave a total of twenty strands now supporting each rib, twelve at point 6 and eight at point 8, and completed erection stage VI.

The first survey for the actual elevation of the arch ribs was made at this stage. The elevations were obtained for each panel point by means of a 200-ft steel tape with a specially constructed target and weight hung from the lower end, the total weight being such as to give the correct pull in the tape. The transit used for leveling was set up near the skewback on the side to be surveyed and the height of instrument was obtained from a near-by bench mark. Instead of depending upon the level bubble to obtain a level line, a specially constructed level board was set up on the far side of the river and the instrument was adjusted so as to read the same elevation on the far side of the river as given by the bench mark on the near side of the river. Two such level boards were used, fastened to the concrete abutments, and only a very slight adjustment of the level bubble was required to give the same reading on the two boards.

Theoretical elevations were computed for each erection stage from points 6 to 10 and for each panel point in the arch rib, the point chosen being on top of the splice plate over the milled joint. The tape was kept wound on a small reel. To obtain an elevation the tape was unreeled, and the target and attached weight were lowered over the outside face of the rib, through the safety net, holding the tape at the proper point on the rib. When the target had been properly lined in vertically, a reading was made on the tape at the top edge of the splice plate. Adding this reading plus the distance from the end of the tape to the center of the target, to the height of instrument, the elevation of the panel point was obtained. It was found that these surveys were made best early in the morning, between 6 a.m. and 9 a.m., at which time there was a nearly constant temperature in the steelwork and usually a complete absence of wind. Even a light breeze was enough to set the target swinging sufficiently to make accurate readings difficult and a moderate or heavier wind made them impossible to obtain. In a light wind, however, the target reading usually could be caught at the bottom of its swing and consistent results obtained.

The first survey of the ribs on the Canadian side of the river for erection stage VI gave results nothing short of remarkable. Of the fourteen panel points surveyed, eight agreed exactly with the theoretical elevations, reading to the nearest 0.01 ft. Of the remaining six points, two were within 0.02 ft, two were within 0.04 ft, and the other two varied by 0.05 and 0.07 ft. The point with the latter variation was at the extreme end of the rib, and the error was never explained satisfactorily. It may have been due to an inaccuracy in the reading, to a minor error in the calculations, or possibly to some local variation in the steelwork itself. No adjustment was made.

On the New York side of the river, the first survey for elevation at erection stage VI showed a maximum variation from theoretical elevation of +0.07 ft at panel 10 and −0.09 ft at panel 6 for the south rib, with corresponding figures of +0.06 ft and −0.05 ft for the north rib. The plotted profiles showed the arch to have slightly too great a curvature due apparently to too great a stress in the strands at point 8 and not enough in those at point 6. Three separate sets of strand adjustments and profile surveys had to be made, after which the measured profiles agreed with the theoretical within 0.04-ft maximum variation. The average variation was only 0.02 ft. It was interesting to note that, at this erection stage, the arch rib was sufficiently limber to respond readily to changes in shape caused by variations in the tieback stresses at panels 8 and 6. The measured strand stresses at this time were higher than those computed by 5%, 6%, 11%, and 16% for the four sets of tiebacks.

Arch Ribs 6 to 3 and Tiebacks at Point 3.—Rib traveler B was moved forward successively to panels 6, 5, and 4, and from these positions the crew erected panels 6–5, 5–4, and 4–3. This completed erection stage VII, with both sets of tiebacks still connected at points 8 and 6. No profile surveys were made for this stage, but complete sets of strand stress measurements were made. These indicated that the tieback stresses at point 6 were somewhat higher, and those at point 8 somewhat lower, than the computed stresses. As the individual strand stress was well within the allowable limit, no adjustment was made.

The next step was the connection of the forward ties at panel 3—one of the most critical and difficult steps in the entire erection procedure. The first four strands at point 3 were obtained from the group at point 6 by: Disconnecting them one at a time; slacking them back on the arch rib; removing the adjustable links; lengthening the strand with a pennant; reconnecting the links; and pulling the lengthened strand forward and connecting it at panel 3. Then, the strand was carefully adjusted to its full stress before the next strand was disconnected at point 6, lengthened, and moved forward. The erection and adjustment of the first four strands at panel 3, with eight strands still in place at panels 6 and 8, was necessary before the strands at panel 8 could be released, and completed erection stage VIIA. A complete survey of the strand stresses was made for this stage to make sure that none of the strands was overstressed, and that the total measured stress was reasonably close to the computed stress.

The remaining eight strands at panel 8 then were disconnected as a group and swung back hanging free from the tower where they were lengthened by pennant strands. This left the arch ribs in erection stage VIIB, supported on four strands at panel 3 and eight strands at panel 6. An entire set of strand stress measurements also was made for this stage. The stress in the strands at point 3 was shown to be somewhat less than the theoretical, and in those at point 6, somewhat greater than the theoretical. As further cantilever erection would decrease the stress in the ties at point 6, and, as their actual stress at this stage was not critical, no adjustment was made.

The eight lengthened strands then were swung forward to panel 3 where they were connected and adjusted, completing erection stage VIII. At this time a complete survey of the arch ribs again was made both for rib profile and strand stresses. Two adjustments were made on each side of the river, before the third and final surveys showed the ribs to be within a maximum variation of $\frac{5}{8}$ in. from the theoretical profile and the measured strand stresses within reasonably close agreement with the computed ones. In general, the average strand stress was found to be from 10% to 20% higher than the computed, with a maximum variation for a single strand of as much as 50% for the strands with low stress, and 25% to 30% for the strands which were highly stressed. In no case, however, was any individual strand stress found to be greater than the specified design limit. The readings are believed to have been high because of errors in the dynamometer and because the readings were taken relatively close to the socketed ends of the strands where they connected to the tower. Experiments showed that the measured stress decreased the farther away from the end of the strand the measurement was made. In addition to this, the angle at which the instrument had to be used also tended to increase the reading as proved by experiment. The effect of curvature in the cables due to the sag from their own weight was eliminated generally by applying the dynamometer from the side—that is, in the vertical plane of the cable—but in some few cases, the instrument had to be rotated in order to clear adjacent strands, thus causing somewhat higher readings. It is believed the measured strand stress was from 10% to 20% higher than the actual stress.

Arch Ribs, Panel 3 to Crown.—With the final adjustment of the strands in erection stage VIII, traveler B was moved forward to panel 3 in which position the crew erected panels 3 to 2. Then it was moved forward to panel 2 and used to complete the erection of the arch ribs and bracing to the crown where the special jacking brackets on the top and bottom flanges were erected. This completed erection stage IX, the last main erection stage before swinging the two half arches one against the other. Because of the careful control of the profile during previous erection stages, the opposite ribs closed in almost perfect alinement and elevation with respect to each other across the 11-in. gap left at the crown. No adjustment whatever in the elevation or alinement was neces-

Fig. 37.—Elevation of the Arch Rib at the Crown, Showing Jacking Devices

sary although the ribs were so sensitive at this stage that considerable relative movement was observed from the handling of even light loads by the travelers. Swinging the traveler booms from one side to the other also would produce discernible changes in the elevation. Such relative movements were eliminated by the erection of the special shear devices and temporary lateral bracing erected at the crown for this purpose (see Figs. 37 and 38).

A complete and final survey of the arch ribs was made for erection stage IX, both for rib profile and strand stresses. The actual profile of both ribs, on both sides of the river, was found to be slightly high, by as much as $\frac{5}{8}$ in. to $\frac{3}{4}$ in., between the abutments and panel 7 or 8 where it coincided with the computed profile. From there to the crown it gradually drooped, deflecting to a maximum of 0.16 ft or not quite 2 in. below the computed elevation. The weight of traveler B and the other erection equipment near the crown must have been underestimated. As the cantilevered length was greater than 500 ft and the ribs were only 12 ft deep and supported on only two sets of elastic cables, the structure was extremely flexible in this condition and small loads would cause great changes in profile.

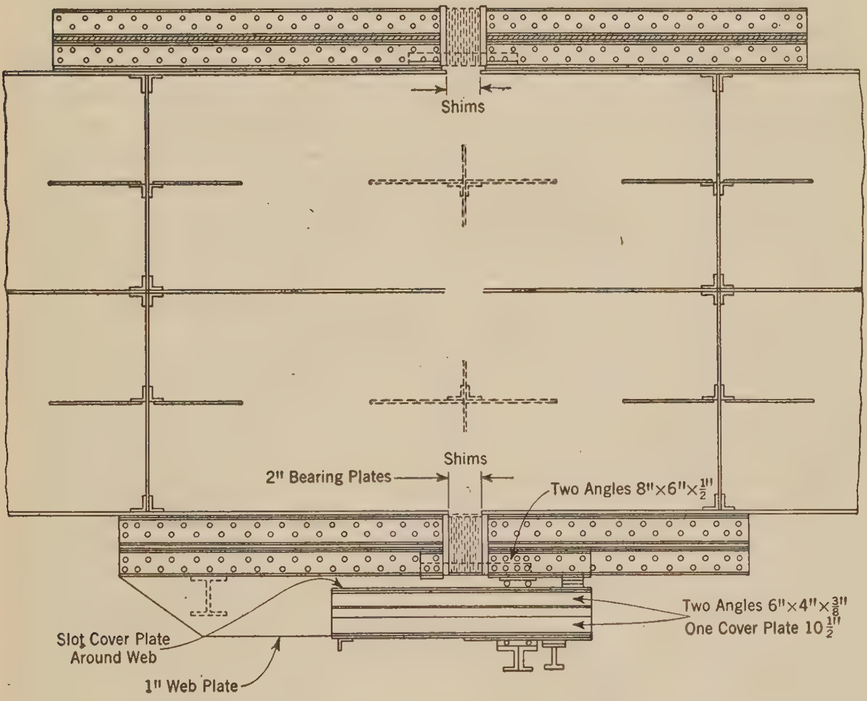

Fig. 38.—Section on the Center Line of the Arch Rib Showing Jacking Devices

The measured strand stresses at panel 3 were roughly from 30% to 50% higher than the computed stresses, and at panel 6 they varied from 6% too high to 20% too low. Even allowing for the dynamometers giving measured stresses from 10% to 20% too high, they still would be greater than the computed stresses, which bears out the assumption that the erection loads near the crown must have been heavier than estimated.

Fitting Up and Riveting.—Each arch-rib section, when it was erected by cantilevering out from the preceding section, was fitted up in the connecting splice with sufficient pins and bolts to carry the weight of all cantilevered steelwork plus the weight of the rib traveler and other erection equipment. All splices were milled, and the splice plates and rivets were designed to carry only about 60% of the total stress. Computations were made for each joint showing the number of pins and bolts required to carry the erection stresses. In general, sufficient pins were employed to carry the entire erection stress without any dependence on the bolts, which were used mainly to pull the various parts into close contact for riveting. The pins for carrying the erection tension stress were all located in the top-flange splice plates and splice angles. Because of the 12-ft depth of the arch ribs, surprisingly few pins were required to carry this stress.

The cantilever erection stress tended to open the milled joints at the top flange by the amount of play of the pins in the holes, but the bottom flange was brought into tight contact and good bearing. The bottom-flange splice plates and angles were riveted in this condition as soon as possible after the rib was erected. Only a small amount of fitting up was performed in the web splice plates at this time.

After erection had reached the point where a set of forward ties was to be attached and after the ties had been connected and adjusted, the cantilever stress in the two or three forward-rib sections was reversed. This reversal of stress actually put the top flange in compression and thus closed the milled joint. As soon as this occurred and the joint was in good bearing, the top-flange splice plates and angles were fitted up and riveted. The holes in the web splice plates were fitted up and riveted as convenient after both the bottom and top flanges had been riveted.

The lateral bracing between the arch ribs was fitted up as soon as erected but was not riveted immediately. Close watch was kept of the lateral alinement of the arch as cantilever erection progressed, and none of the bracing was riveted until it was certain that the alinement was perfect. Both half arches tended to drift slightly to the south, up to a maximum of about $\frac{5}{8}$ in. to $\frac{3}{4}$ in. A stiff south wind was sufficient to bring the ribs back to alinement, however, and no unusual difficulty was experienced in forcing them back to line by means of temporary cable diagonals tightened with turnbuckles. Riveting of this bracing was kept at least three or four panels behind the erection, however, regardless of the alinement, and the 12-ft deep struts were not riveted until it was determined that the two ribs were within $\frac{3}{8}$ in. of the same elevation.

When the arch ribs were closed at the crown and swung and the last panels of lateral bracing erected and fitted up, the entire arch was found to be in perfect lateral alinement within $\pm \frac{1}{16}$ in. All surveys for lateral alinement were made by means of an engineer's transit set up near the top of the cliff on the center line of the bridge. A foresight was obtained on a bench mark on the far side of the river, and the span lined by means of targets painted on the center of the top cross strut at each panel point.

CLOSURE OF ARCH RIBS

Jacking Operations at Crown.—The arrangement of the jacking brackets, the hydraulic jacks, and the shims is shown in Figs. 37 and 38. Two 500-ton hydraulic jacks were provided for both the top and the bottom flange for each rib, giving a total jacking capacity of 2,000 tons per rib. The computed rib thrust was about 1,400 tons, of which 800 tons was in the top flange and 600 tons in the bottom flange, due to the dead-load moment at the crown.

As soon as the jacks were fitted up, those at the top flange were operated to increase the top flange opening to 18 in. The bottom-flange jacks were not operated, but the bottom opening automatically increased to approximately 17.5 in. during this procedure and was shimmed snug. During the entire jacking operation, shims were placed in the space provided between the jacking brackets for this purpose, and the load was carried on these shims at all times except during actual jacking movements.

The purpose of this preliminary jacking apart of the ribs was to release the stress, partly, in the forward ties that were still supporting the ribs at panels 6 and 3, particularly at the latter point where the individual strand stresses were about at their maximum and were beyond the capacity of the adjusting falls. The reason for not putting any stress in the bottom flange of the ribs at the crown at this time was that releasing the strands at point 6 would allow the ribs to deflect and thus automatically would induce stress in the bottom flange at the crown, provided the ribs were just in contact at the beginning.

Eight of the twelve strands at point 3 next were completely disconnected, one strand at a time, using the adjusting falls, and the strands were swung back and left hanging from the tower. This caused the cable bent to lean back somewhat and also increased the stress in the remaining four strands at points 3 and 6. In addition, of course, there was an increase in the crown thrust which was taken through the top and bottom shim packs.

At this time, the remaining four strands at panel 3 were left in place to provide the necessary forward pull at the top of the cable bent while the eight strands at panel 6 were removed. Since removal of those strands would increase the stress in these four remaining strands at point 3, the latter first were lengthened by about 30 in. each in small increments so as to avoid overstressing any one strand during this operation. The bottom-flange shims were reduced at this time to $16\frac{7}{8}$ in., thus keeping the bottom-flange load down so that it would not exceed the flange stress that would exist in erection stage X after all cable ties were removed.

Next, the remaining eight strands at panel 6 were completely disconnected, swung back clear of the arch, and left hanging from the tower. Similarly, three of the four remaining strands at panel 3 then were removed and swung back clear of the arch, leaving only one strand per rib still connected at panel 3. In this condition, the top of the cable bent had leaned back very nearly to its original erection condition, about 3 ft out of plumb, thus reducing the stress in the backstay cables so that they readily could be disconnected with a single runner line. Blocking and lashing was placed at the rear end of the sill and stiffleg to support the tower after the last forward ties were removed. The last strand at point 3 then was disconnected, thus completely freeing and swinging the arch ribs which were now entirely self-supporting. The jacks at the crown again were operated and the crown opening reduced from 18 in. in the top and 16 $\frac{7}{8}$ in. in the bottom to the normal opening of approximately 11 in., top and bottom.

Measurement of Crown Opening.—The 11-in. normal opening at the crown between the arch ribs had been left so that the stresses in the arch ribs might be measured at this point by means of hydraulic jacks and thus compare the actual with the design stresses. The closing keystone piece was prefabricated 13 in. long and provision made so that it could be cut down to a minimum length of 9 in. if circumstances required. By varying the top and bottom lengths of this keystone section, an angular rotation and moment also could be induced at the crown and thus the location of the center of pressure could be changed. A complete description of these calculations is given in the third paper of the Symposium.

In order to compute the crown stresses at this stage of the erection accurately, it was necessary that the dead loads of the erection equipment be known with great accuracy. The weights of the major pieces of erection equipment already had been computed and their effect calculated. All miscellaneous equipment (including drift pins, fitting-up bolts, small tools, timber platforms, and walkways, etc.) was surveyed and its weight computed. Preliminary calculations had shown that the weight on the north rib on the New York side of the river, and on the south rib on the Canadian side, would be somewhat heavier than on the other ribs. It was desirable to have equal weights on the two ribs to avoid two sets of calculations. For this purpose, concrete counterweight blocks weighing 5,000 lb each had been cast and erected at each panel point from points 3 to 10, inclusive, on the south rib on the New York side of the river, and on the north rib on the Canadian side. The traveler booms were swung around to a specified location to produce the desired reaction on the two arch ribs.

In addition to four new 10-in. test gages inserted in the hydraulic pumps, a weighing capsule, which was inserted in line with each jack between the plunger and the jacking bracket, also was provided. These weighing capsules contained an enclosed liquid under initial pressure. They were extremely sensitive to increase of pressure which was measured on accurately calibrated gages. In the actual weighing operations, however, it was found that there was extremely close agreement in the loads measured both by the weighing capsules and by the ordinary hydraulic gages.

The weighing and measuring operations were performed between midnight and 6 a.m. in order to avoid the effects of temperature changes. The crown opening first was set at its theoretical value of 11 in. $+\frac{3}{32}$ in. at the top flange and $-\frac{3}{32}$ in. at the bottom flange, and the jack stresses were recorded. The crown opening was measured between the milled surfaces at each corner of the flanges by means of machinist's scales, reading to the nearest $\frac{1}{64}$ in. Three other sets of readings for different crown openings also were made in order to check better the relation between the actual and computed stresses and also to determine the most favorable dimensions of the keystone piece. Finally, it was decided that the normal 11-in. opening would produce stresses as close to the computed ones as possibly could be desired. Briefly, the total crown thrust was 1% higher than the computed thrust for each arch rib, although the center of pressure was about 4 in. too high for the north rib and 6.5 in. too high for the south rib. The latter variation was probably due to some inaccuracy in the weight and location of the erection equipment. Since the computed thrust due to dead load of steel must be subject to an error of at least 2% to 3% and since the estimated weight of the erection equipment was undoubtedly in error by at least 5%, it can be appreciated readily that the agreement of the measured and computed thrusts within 1% was nothing short of remarkable. On the other hand, reference to the change in crown opening for various changes in the crown thrust indicates that the two half arch ribs are extremely flexible with regard to translation or change in the crown opening. They are much stiffer with regard to an angular change (that is, a change in moment); hence the conclusion that, for a long flexible hingeless arch fabricated and erected with a high degree of accuracy on accurately surveyed skewbacks, it should not be necessary to provide any closing or keystone piece with the idea of varying the dimensions of such a piece to obtain the computed stresses. Only relatively small changes in the thrust result from relatively large changes in the crown opening.

Keystone Pieces.—The two keystone pieces, one for each arch rib, were an ordinary section of arch rib, 11 in. in length on the neutral axis as finally fabricated. They were slightly wedge-shaped, each face being on a radial line of the rib. The splice plates at the crown were continuous between the two ribs and across the keystone section. All holes in these splice plates were reamed to metal templates in the shop, setting them from the milled ends of the ribs and of the keystone pieces as finally finished. There were a total of forty-six splice and filler plates for each keystone piece.

The keystone pieces were erected by swinging them into place sideways into the opening between the arch ribs which was increased to about 11.5 in. to give clearance. A special hitch was provided on the outside of the piece, near the top flange, and a line connected to the inside face at the bottom flange assisted in swinging the piece into place sideways into a vertical position. The splice plates were fitted up to the rib on one side before carefully lowering the jacks to bring the other side into bearing and correct alinement. No particular difficulty was encountered in this operation, and good holes, together with perfect alinement between the opposing ribs, were obtained.

Removal of Erection Steel.—As soon as the crown opening had been measured and while the keystone pieces were being finished in the fabricating shop, all temporary erection steel used in the tieback system was removed. The forward cable ties hanging from the front face of the tower were disconnected and rereeled. The backstay cables were disconnected from the anchorages, lowered from the top of the tower, and also rereeled. The lower strut and panel of bracing in the cable bent was removed, allowing traveler A to back up to a position about 60 ft behind the tower where the boom again was lengthened to 145 ft. Then, the cable bent, together with the stifflegs and struts used to support it, was dismantled, and all material was returned to the yards for refabricating into permanent columns for use in the final structure. The fan falsework platform and columns also were removed and returned to the yards for refabricating. The traveler boom then was shortened to 95 ft, and the traveler advanced to the end of the concrete approach spans ready to start erection of the floor steel. All of this work was completed by the time the keystone pieces were received and erected.

Erection of Floor Steel

Survey of Arch Ribs and Adjustment of Column Shims.—Immediately after the cable tiebacks had been removed and the crown opening measured, the arch ribs were placed in their normal position with an 11-in. crown opening (the same condition as would exist if the keystone pieces actually were in place). A survey then was run over the arch ribs to determine the relative difference in elevation of like-numbered panel points in the two ribs. The absolute elevation was not desired and was not determined at this time, but it was necessary to know whether one rib was higher than the other so that a correction could be made in order to bring the floor beams level. Difference in elevation was determined by setting up a transit on the arch rib near each panel point and reading the elevation of that point on each rib. This survey showed the north rib to be slightly higher than the south rib throughout its entire length, by a maximum of $\frac{7}{8}$ in. on the Canadian side of the river and $\frac{3}{8}$ in. on the New York side. The difference in elevation at the crown was about $\frac{3}{4}$ in. Both ribs had a very uniform curve or profile from end to end.

The columns had been fabricated with $\frac{1}{2}$ in. of normal shims (made up of one $\frac{1}{4}$-in. shim and two $\frac{1}{8}$-in. shims) between the base plate and the cover plate on the rib. By shifting the proper amount of shims from the north to the south rib, the floor-beam connections at the top of the columns could be brought to the same elevation at any one panel point. On the New York side of the river, a $\frac{1}{8}$-in. shim was removed at each panel point from points 9 to 3, inclusive, on the north rib and added to the south rib. For the three points, 2, 1, and 2, at the crown and for points 9, 10, and 11 on the Canadian side of the river $\frac{1}{4}$ in. of shims was shifted from the north to the south rib. For points 3 to 8, inclusive, on the latter side $\frac{3}{8}$ in. of shims was shifted making a relative difference in elevation of $\frac{3}{4}$ in. for the column bases at those points. A $\frac{1}{8}$-in. shim was interchanged at point 12 on the Canadian end of the bridge, and no change was made in points 10, 11, and 12 on the New York end. No explanation is offered for this relatively large difference in elevation between the two ribs which was somewhat surprising after they had followed their theoretical profiles so closely during the various erection stages.

Erection Procedure.—Actual erection of the floor steel was begun as soon as the keystone pieces had been inserted and while they were being fitted up and riveted. At the abutment, traveler A erected the first pair of spandrel columns, which were spliced at the center, for their full height of 142 ft by simply standing them on the arch ribs without any guys or bracing between them. Each column immediately was stayed at the top by erecting the spandrel girder next to the abutment, followed by the floor-beam framing between these columns. These two spandrel girders were supported on sliding seats on the abutment. At this time, they were pulled back several inches to give clearance for erecting the closing floor panel and temporarily anchored in that position to give longitudinal stability to the floor structure being built from the abutment.

At the crown of the arch, travelers B erected the floor steel in front of them, panel by panel, moving backward down the arch rib as each panel was completed. All material for these travelers was fed to them by traveler A and by means of the material truck, as during erection of the arch ribs.

Removal of Travelers; Fitting Up and Riveting.—After traveler A had erected two panels at the abutment, the traveler track was extended and the traveler moved out to panel 11 where it erected two more panels to point 9 and then moved to that position. Traveler B meantime had moved back to panel 7, its final position, from which point its 76-ft boom just could fill in the members in panel 5–6. When this operation was completed, traveler B was dismantled and removed by traveler A which proceeded to fill in the two remaining panels of floor from points 6 to 8.

When the last pair of spandrel girders was erected in panel 6–7, the temporary connection of the two spandrel girders at the abutment was released. These two girders then were jacked forward to close the opening in panel 6–7 and to permit the girders in that panel to be fitted up.

In spite of the fact that there was no sway bracing between the spandrel columns, no difficulty was encountered in keeping them plumb and in holding the entire floor system to correct lateral alinement. This must be attributed very largely to the excellence of the shop work in fabricating the columns and the floor steel.

Fitting up and riveting of the floor steel and bracing followed the erection as closely as possible and was completed within ten days after traveler A had been dismantled and removed by a small tractor crane.

Handrailings.—The two roadway railings and the single sidewalk railing had been erected by the travelers with the other floor steel. With the floor entirely fitted up and known to be in correct alinement, fitting up of the railing-post connections and alinement of the railing itself were begun. The details of the railing-post connections were such that it was practically necessary to fit them up and rivet them before the concrete deck and sidewalk could be poured. In general the railing-post connections were fabricated with small-sized holes and were fitted up with small bolts until proper alinement was attained. The connections then were reamed out to full size and riveted. The subsequent operation of pouring the concrete deck, and the resultant deflections of the arch rib, produced no noticeable change in the alinement of any of the three railings.

CONCRETE DECK

The work of forming and pouring the concrete deck and sidewalk slabs was sublet to other contractors, one for the Canadian and one for the New York side. Wooden forms were used throughout, supported on timber joists which were carried in wire hangers resting on top of the stringers.

The main roadway slab reinforcement consisted of prefabricated, welded, bar joists. All longitudinal bracing consisted of plain bars wired to the trusses at the intersections. Ordinary two-way bar reinforcing was employed in the sidewalk slab.

Each contractor used a mixing plant set up near the shore end of the concrete approach. On the Canadian side of the river the mixed concrete was wheeled out over a runway to the center of the bridge where pouring operations were started. On the New York side all concrete was pumped out over the span through an 8-in. pipe line. Concreting was started at the center of the span in one roadway only and proceeded simultaneously in both directions. The sidewalk slab was poured at the same time as the south roadway slab. In order to prevent excessive deflections in the arch ribs, it was specified that not more than four panels of the roadway be poured on one side of the approach than on the other.

The concrete subcontractors also poured the concrete encasing around the steel grillages at the skewbacks, thus completely filling and enclosing these members and making them a part of the concrete abutments.

PAINTING

Two field coats of aluminum paint were applied to the structure over two coats of proprietary brands of a red lead and iron oxide type of paint.

Application of the first field coat was started before the arch ribs were closed at the crown and continued during the erection of the floor steel and the pouring of the concrete deck. The second field coat was not applied to any exterior surface until the concrete deck immediately above had been poured and the forms removed. All the floor steel received its first coat of paint before the concrete was poured. During concreting operations streams of water were played on the steel to clean it of concrete splash, but, because of an insufficient number of streams and lack of pressure, considerable cleaning had to be done by hand after the concrete had dried before the second field coat could be applied.

Both field coats of paint were applied by brush and no spray painting was done. The aluminum paint used was purchased in the summer of 1940 before its use was prohibited.

Conclusion

Field work was begun on the Canadian side of the river on December 15, 1940, and on the New York side on December 26, 1940. The first permanent steel, consisting of the steel grillage, was erected on the Canadian side on February 14, 1941, and on the New York side on March 6. The last four main-rib sections were erected at the crown on May 19, and the measurement of the crown opening was made on the night of May 26–27. The keystone pieces were received June 11 and erected June 12. Erection of the floor steel was begun on June 13 and completed on July 17. The contract date for starting work on the concrete deck was July 21. The concreting was completed on the Canadian side on September 9 and on the New York side on September 15.

The safety nets were left in place until all concrete work and painting (with the exception of painting the top flanges of the arch ribs) was finished. Removal of the safety nets was completed on October 9, and the final painting was completed on October 24.

The bridge was opened to traffic on November 1, 1941, at which time paving of the approaches and the finishing of the toll booth and quarters for the customs and immigration officials still had not been completed.

DISCUSSION

Egidio O. Di Genova,[21] Assoc. M. Am. Soc. C. E.—An assertion, repeated several times in this Symposium, implies that the elastic theory is not entirely valid for the Rainbow Arch Bridge. The writer's extended studies of the elastic theory lead him to the conviction that the following statement in the first paper (12 lines preceding Eq. 1) at least is out of place:

> "The preliminary calculations for the two-hinged arch rib were sufficient to show that the elastic theory was inadequate for the design of such a structure."

If the writer understands this statement correctly, he believes that it is incorrect. The two-hinged arch is different from the hingeless arch, and it is impossible to draw parallel comparisons between the two. In general, in any elastic system the writer has found that the resultant elastic deformations (and therefore the internal stresses), computed by means of the so-called elastic theory, and the findings obtained by other systems of computations are closely alike, with one exception: When all the possible internal stresses are considered (that is, compression, shear, and flexural moments, generated by an externally applied system of forces), slightly larger results are obtained; but, if the structure is computed by the elastic method without taking in consideration shear and axial stresses, the difference does not exist, or it is of a very small relative order such as can be expected within the common range of approximations.

The elastic theory in itself has certain limitations in relation to the magnitude of the elastic deformations, but those limitations must be considered in relation to the linear variation of strain and stress of the material used, and also in relation to the relative size of the structure.

On an arch of 950-ft span and 150-ft rise, 12 in. (or even 18 in.) of elastic deformation, for a steel structure, is relatively small, and the limits imposed by the theory of elasticity are still satisfied.

The writer has the impression that the geometrical simplicity of this arch, the continuous uniformity of its cross section, the very sturdy condition of fixed restraint, etc., define an ideal case for useful practical application of the theory of elasticity.

Although this theory is not applied to any minor engineering problem, nevertheless the use of it by well-trained engineers in this field and for important works is worth a lot. All engineers know that, in theoretical studies inherent in the elastic behavior of materials, the elastic theory is a very important instrument for developing ideas, but there are also many cases in which its application to practical problems is just as important as the more theoretical applications and the Rainbow Bridge, in the writer's opinion, is one of them.

This writer insists on the idea that the basic principles governing the elastic theory must be understood clearly, and a consistent system of computation must be followed implicitly. Tables and methods of application must be used wisely so as to reflect the theory accurately, or there is likely to be considerable confusion in the mind of the computer; if this advice is not followed, the chance of errors is greater, especially if certain sets of formulas are applied blindly.

---

[21] Civ. Engr., Board of Water Supply, New York, N. Y.

The writer admits that it is very difficult to establish a logical system of computations for such an important structure as the Rainbow Bridge. Nevertheless, the various means of checking one's work offered by the elastic theory (as for example: The cut-and-try method; the method of virtual work; the ellipse-of-elasticity method; etc.), which are integral parts of that theory, can be used to best advantage on a project that is as important as the Rainbow Bridge. The results obtained are certainly worth the extra cost, and no competent person can ever charge that they are erroneous, unless some serious error is made.

After a preliminary proportioning of the structural elements, the use of the various analytical and graphic solutions offered by the elastic theory is a blessing. Even if the expense of constructing a model is considered desirable, the theory itself will prove valuable.

The elastic theory, like many other means of analysis, is not magic; the engineer should always remember that in final results he receives from an analysis only the findings inherent in the assumptions made. For example, in the design of the Rainbow Bridge, the effect of vertical loads and the deflections of the arch ribs could have been analyzed by the elastic theory, whereas the laterals, the deck, and the spandrel columns could have been analyzed in some other way. In the preliminary analysis of the bridge, it seems natural that the spandrel columns, for example, should be replaced by their reactions in order to simplify the computation of the arch itself.

The application of the elastic theory requires a little more than just a handbook. It calls for personal ability and engineering art—qualities that cannot be taught easily by any standard handbook.

It is also true that, after all, the origin of any system of computations is essentially based on the elastic theory. At times some standardized system of analysis, made easy for a practical man, is a wonderful thing indeed, for the diffusion of knowledge; but, as a class, professional men of higher standards and reputation must remember that the basic culture of an engineer must be on a plane above the superficial knowledge of a plain mechanic, in the same proportion as the skill of the physician is to that of the registered nurse. To this end, the writer takes this opportunity to express the hope that one more year may be added to the present university engineering course so as to spur the profession to attain a keener technical, cultural, and moral point of view and that engineers of the future will use it to sponsor a more extensive and rational study of the elastic theory.

CHARLES MACKINTOSH,[22] ESQ.—This analysis of the Rainbow Arch Bridge is a valuable work because the writers have reemphasized the fact that any slender arch must be considered as an unstable body since twice the load produces more than twice the stresses. An attempt has been made to reduce the cumbersome procedure required for finding the final moments in the arch. In developing an approximate method of finding the moment, a formula is suggested which is quite satisfactory for the particular arch under consideration with the particular loads to which it was subject. However, these recommended formulas are not applicable to many other loads and shapes of arches.

---

[22] Structural Engr. (Mackintosh & Mackintosh), Los Angeles, Calif.

If the arch were of such shape that the moment due to the dead load was high, Eq. 16 would not be satisfactory. According to this formula, for instance, if there were no live loads or impact loads, the arch moments would not be increased by the slenderness of the arch section. Perhaps Eq. 16 would be satisfactory for the general case if all of the moments were grouped together ($M_{DL, LL, I, w, t}$) and these moments, in turn, were multiplied by a factor using the combined moments in the denominator similar to Eq. 16, as previously written.

Thus

$$s_y = N \frac{\Sigma T}{A} + N \frac{\Sigma M}{S} \left[\frac{1}{1 - N \, \Sigma T \, \dfrac{\Sigma u}{\Sigma M}} \right] \text{............} (35a)$$

To include the effect of the inaccuracy in fabricating the arch to the prescribed outline, ΣM should include $\Sigma T \times e'$, in which e' is the tolerance allowed as the authors have indicated in Eq. 17. If no factor of ignorance is present in determining e', the ratio $\frac{e'}{N}$ may be used. Eq. 21 would also be unsatisfactory in any case where M_{DL} is large. This may be treated as suggested herein.

In the course of designing many long-span slender roof arches, the writer has found that a rapid and convenient approximation is given by an adaptation of the usual beam-column formulas[23] as follows:

$$s_y = N \frac{\Sigma T}{A} + N \frac{\Sigma M}{S} \left[\frac{1}{1 - N \dfrac{\Sigma T}{\Sigma T_{cr}}} \right] \text{.............} (35b)$$

in which

$$T_{cr} = \frac{\pi^2 E I}{L^2_i} \left[1 - \left(\frac{\alpha}{\pi} \right)^2 \right] \text{..................} (36)$$

In Eq. 36, L_i = estimated length of arch between points of inflection, and α = central angle between points of inflection. For flat arches the correction for curvature $\left[1 - \left(\frac{\alpha}{\pi} \right)^2 \right]$ is small and may be neglected.

Such methods offer a facile check for stresses in "lamella roofs" and in arched roofs with ribs of wood, concrete, or steel under uniform loads and one-side snow loads and wind loads.

[23] "Theory of Elastic Stability," by S. Timoshenko, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1936, pp. 27–45 and 225–230; "Formulas for Stress and Strain," by Raymond J. Roark, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1938, pp. 120–121; "Strength of Materials," by S. Timoshenko, 2d Ed., D. Van Nostrand Co., Inc., New York, 1940, Vol. 2, p. 218; and "Airplane Structures," by A. S. Niles and J. S. Newell, John Wiley & Sons, Inc., New York, 1938, Chapter 14.

C. M. GOODRICH,[24] M. AM. SOC. C. E.—In the discussion of the design of the Rainbow Bridge "elastic theory" is frowned upon, and a "deflection theory" is preferred. Elastic theory deals with deflections, and is based on the law of conservation of energy, a law not lightly to be repealed or suspended. If one made a blunder in a mathematical problem, or failed to find a solution in one particular way, the remedy would be more mathematics. In the case of the arch the remedy is more elastic theory, unless indeed the elastic limit is threatened.

In suspension bridges what is here termed "the elastic theory" is based on the assumption that the stiffening truss rises and falls in a gracefully parabolic manner, which does not accord with elastic theory. It would perhaps be more nearly correct to call it the "inelastic method."

In the very common case of a boom the dead load causes a deflection and a consequent series of moments and deflections due to the axial load; often the biggest effective load on a long boom is due to the swinging and the series of moments and deflections that come from that; the writer proportions also for an inaccuracy of 1/750 the length in each of two directions. A boom 180 ft long was once used to erect the towers for a lift bridge; such a boom deserves respectful consideration. Only three times has the writer gone through the somewhat tedious operation suggested; and the experience of others no doubt will be similar. This case is clearly one of limit design, like the arch.

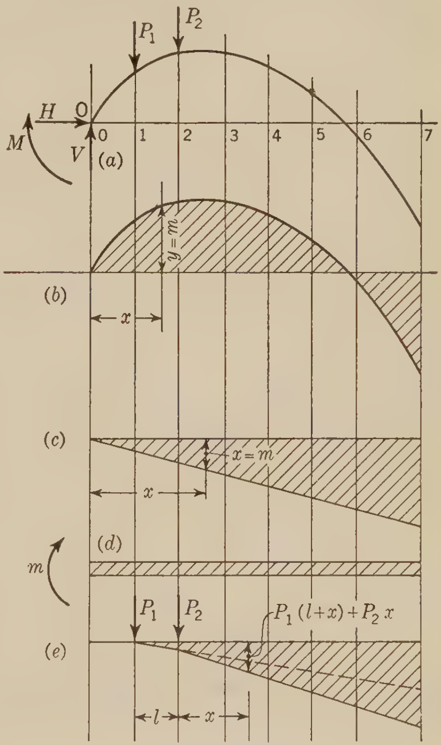

FIG. 39

If "Stern's Theory"[9] contains something more than computing an arch by bits and pieces in the long-familiar way, or the investigation and cure of critical deflection, if any, it would be useful to have the procedure explained.

According to the authors of the third paper (see "The Elastic Centroid—Its Application to the Study of the Action of the Closed Rib"), the method of the elastic centroid, as used by them, was taken from a 1925 edition of Müller-Breslau's book.[17] The writer's first acquaintance with this Müller-Breslau method was shortly after 1910, when the late David A. Molitor, M. Am. Soc.

---

[24] Cons. Engr., The Canadian Bridge Co., Ltd., Walkerville, Ont., Canada.

C. E., published[25] a very clear and complete explanation of its use for fixed arches. His work contains also an interesting case of its use in a problem with two redundants. The elastic centroid is also called "center of instantaneous revolution," since it is determined by the moment applied at the base. A still more appropriate name is perhaps "imaginary hinge"; this is the name for like devices used in several problems by August Föppl.[26]

Such fixed arches may be figured by a modest extension of the two area-moment theorems, announced in 1873 by the late Prof. C. E. Greene, M. Am. Soc. C. E. One need only bear in mind that in most cases $\int \frac{m\,M}{E\,I}\,ds$ may be represented conveniently by an area $\int \frac{M}{E\,I}\,ds$, when the expression means the statical moment of a series of areas about either of two axes; or, when m is a unit moment, the sum of these areas.

The arch may be divided into any number of segments n, preferably agreeing with the changes in arch section (see Fig. 39(a)). Taking moments about a horizontal axis through point O:

$$0 = -H\sum_{0}^{6} k\,A\,\bar{y} + H\,k_{6,7}\,A_{6,7}\,\bar{y} + V\sum_{0}^{7} k\,B\,\bar{y}$$

$$+ M\sum_{0}^{7} k\,l\,\bar{y} - \sum_{1}^{7} C\,k\,\bar{y} \ldots\ldots\ldots\ldots\ldots\ldots (37a)$$

in which (in addition to the Symposium notation): $k = \frac{\lambda}{l\,I}$; A and B are the m-areas in section n due to the horizontal and vertical unit dummy loadings, respectively; $\bar{y}$ = vertical distance from a horizontal line through O to that point in the arch intersected by a vertical through the centroid of the moment area with which y is used; l = length of the horizontal projection of section n; λ = axial length of section n corresponding to l; and C = the M-area in section n due to P loads. Taking moments about a vertical through point O:

$$0 = -H\sum_{0}^{6} k\,A\,\bar{x} + H\,k_{6,7}\,A_{6,7}\,\bar{x} + V\sum_{1}^{7} k\,B\,\bar{x}$$

$$+ M\sum_{0}^{7} k\,l\,\bar{x} - \sum_{1}^{7} C\,k\,\bar{x} \ldots\ldots\ldots\ldots\ldots\ldots (37b)$$

in which $\bar{x}$ = the horizontal distance from O to a vertical through the centroid of the moment area with which it is used. Finally, summing areas:

$$0 = -H\sum_{0}^{6} k\,A + H\,k_{6,7}\,A_{6,7} + V\sum_{0}^{7} k\,B + \sum_{0}^{7} M\,k\,l - \sum_{1}^{7} C\,k \ldots (37c)$$

---

[25] "Kinetic Theory of Engineering Structures Dealing with Stresses, Deformations and Work for the Use of Students and Practitioners in Civil Engineering," by David A. Molitor, McGraw-Hill Book Co., Inc., New York, N. Y., 1911.

[26] "Vorlesungen über technische Mechanik," by August Föppl, Leipzig, 1902–1912.

In computing the deflection (say at point 2, Fig. 39(a)), consider the tangent at that point to be unchanged, and compute the movements of points 0 and 7 relative to point 2. For a horizontal movement at 0 relative to 2:

$$E\,\rho = -H\sum_{0}^{2} k\,A\,\bar{y} + V\sum_{0}^{2} k\,B\,\bar{y} + M\sum_{0}^{2} k\,l\,\bar{y} - C_{1,2}\,k_{1,2}\,\bar{y}\ldots(38)$$

The equations for the other side would be similar except that the x-values would be measured from the right and the y-values from point 7. For the two-hinged arch, omit the M_0-terms and Eq. 37c. For temperature use $E\,\rho$ in Eq. 37a instead of 0.

Clearly the foregoing method is adapted to finding the first and second shape changes, or to checking the result of an assumption. This ignores, of course, the effects of shear, of possible variations in material and workmanship, of the yielding of steel concrete and rock in the bases, of splices, and of connecting members. Mr. Molitor considered the base as yielding. It would be interesting to know what, if any, measurable displacement occurred in the length of the Rainbow Bridge arch.

The writer would have preferred straight segments in the arch, as being cheaper and without unrelieved stresses; he believes the esthetic effect would have been equally good, due to the fact that the eye sweeps over such a figure in a curve, as shown in psychological laboratories by tracing the movements of the eyeball. A camelback with say three straight segments in the top chord is ugly; with say seven or more it is pleasing, because the eye passes over the top chord in a curve. The mass of the arch is of modest size relative to the mass of the roadway as seen at an angle; the connections between the two are too slight to effect an esthetically satisfying unity.

T. KENNARD THOMSON,[27] M. AM. SOC. C. E.—It is a pleasure to read in the first Symposium paper (heading, "Preliminary Studies") that the engineers realized that such a structure should "blend with the natural beauty and grandeur of the Niagara gorge." The Rainbow Arch Bridge is the fifth to be erected at approximately this site—probably the only case of so many renewals of an iron or steel bridge in America. The first three were undoubtedly iron bridges and the last two steel:

No. 1—A suspension bridge, 10 ft wide, was opened for traffic on January 2, 1869.

No. 2—A suspension bridge replaced No. 1, with a width of 17 ft. This bridge was finished on December 15, 1888, and blew down on January 9–10, 1889.

No. 3—No. 2 was rebuilt also as a suspension bridge, 17 ft wide, in 1889.

No. 4—A steel arch replaced No. 3, and was completed in August, 1897, and destroyed by ice on January 27, 1938.

No. 5—The Rainbow Arch Bridge, as described by the authors, was opened for traffic on November 1, 1941.

---

[27] Cons. Engr., New York, N. Y.

The late John A. Stewart, in 1911, acting on his own initiative, invited a group of Americans and Canadians to celebrate the 100th Anniversary of the Treaty of Ghent—100 years of peace between the two countries. He had many prominent men on his Commission, including: Joseph H. Choate, Jacob H. Schiff, Gutzon Borglum, the great sculptor, Sir Edmund Walker, president of the Canadian Bank of Commerce (who was the most outstanding Canadian banker of his time), and many others. He also honored the writer by asking him to serve and to design two bridges for the event. The first World War put an end to the proposed celebration.

One of these bridges, designed by the writer, was to be built between Buffalo, N. Y., and Fort Erie, Ont., Canada, and the other was to replace No. 4, at the site of the Rainbow Arch Bridge. At that time bridge No. 4 was known to be inadequate and unsafe, and the thought was that a bridge built to celebrate 100 years of peace should endure for several hundred years—which no steel bridge, at this site, can ever do, unless a far better paint is developed to resist the spray from the falls, the ice, etc. The writer proposed a heavily reinforced concrete arch, with granite facing (see Fig. 40). The Buffalo Bridge, built by others, also had the same location, number of spans, and similarity of outline as the writer's plan of 1911.

When the writer spoke to Sir Edmund Walker about these proposed bridges, he said that he would not be in favor of bridges; they were too utilitarian; but, when he was shown photos of paintings of the writer's two bridges, he said at once, "Oh, that is different—they are beautiful." When Mr. Stewart showed the two paintings—one 5 ft and one 8 ft long—to Mr. Schiff, he at once told Mr. Stewart: "You cannot get up plans like those without money," and voluntarily gave Mr. Stewart his personal contribution, a check for $5,000.

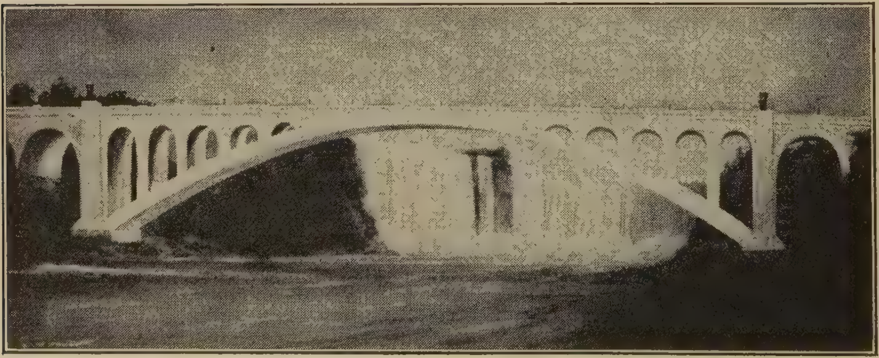

Fig. 40

At a subsequent luncheon, attended by about forty people, one of the most prominent of the New York architects said that suitable architectural plans should be prepared (he would like to have made them). When asked what he thought such plans would cost, he replied, "About $50,000." He was then shown photos of these two paintings, and he exclaimed: "Oh, you have the plans already," and lost interest in the subject. This is a good example (many others could be cited) of how men in other professions are much more adept in knowing what to charge for their services than most engineers are. It also shows that it is well worth while to have simple but beautiful outlines for all engineering structures.

Simplicity of design gives beauty without expense; whereas much intricate filigree work is very expensive and not so beautiful, as exemplified in many cathedrals.

C. M. Spofford,[28] M. Am. Soc. C. E.—The Rainbow Arch Bridge is a beautiful structure, perfectly adapted to its location. Great credit is due to the engineers and architects who evolved the design, to the men who built the bridge so successfully and expeditiously, and to the writers of the papers in this Symposium for their comprehensive description of the design and construction.

Although the laboratory work on the two-hinged segmental arch is valuable in itself, its publication as a part of the Symposium is doubtless due to the fact that it was of assistance to the designers in determining whether or not to use two-hinged arches or perhaps to confirm their opinion that a two-hinged arch would not be satisfactory for this bridge.

The use of the expression "classic arch theory" seems ill-advised, especially as applied to a two-hinged parabolic arch. The writer knows of no classic arch theory for two-hinged arches. Such an arch has only one indeterminate statical force; namely, the horizontal component of either reaction. An expression for this can be readily developed by the conventional method of assuming one of the hinges to be on rollers and equating the expression for its horizontal deflection under any load, with the deflection of the same point due to a horizontal unknown force applied at the hinge. Certain assumptions may be made in a preliminary computation, a simple equation developed, the deflection of the arch computed, and the computation revised, if it seems advisable, by dividing the arch into sections and using summations instead of integrations. The experimental results would have been more useful to arch designers had they been expressed in terms of the horizontal component of a reaction.

In designing two-hinged parabolic arches, both for bridges and buildings, the writer has found no serious technical difficulties, especially when advantage is taken of the properties of the position line and the kernel points.

More experimental work might well have been done to determine the three unknowns of a hingeless arch instead of making the "limited observations upon this type of arch" of which no record appears in the Symposium.

Congratulations should be extended to the engineers of the Bethlehem Steel Company for their unusually thorough investigations and for their great care in the erection procedure. The thanks of the profession are due especially to the authors of the papers on fabrication and erection for their thorough treatment of these phases of the construction. It is worthy of note that safety nets were used and that no fatalities occurred during the construction of the bridge—an unusual record. Another interesting feature is that the erectors used capsules in order to establish the total crown forces and concluded that hydraulic jacks are reasonably accurate when applied forces are measured on the increasing side of the reaction. It is hoped that in the closures a detailed description of these capsules will be given. The writer's experience with hydraulic jacks for determining reactions has not been entirely satisfactory. He notes with interest that the jacks were calibrated in a testing machine which had been previously calibrated by the use of proving rings and assumes that it was not found convenient to use proving rings for this bridge. The writer has used proving rings on various statically indeterminate structures.[29]

---

[28] Hayward Prof. of Civ. Eng., Emeritus, Mass. Inst. Tech., Cambridge, Mass.; Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

The flexibility of the arch ribs is not surprising; the same thing was noticed by the writer during the construction of a plate girder roof arch—a horizontal adjustment at one end of which was made without difficulty by several laborers pushing the arch end horizontally.

An unusual feature of this bridge is the use of steel keystone pieces and the method of introducing them into the arch ribs. This is the first time, so far as the writer knows, that such a device has been used, although one important reinforced concrete arch bridge, designed by the writer's firm, was erected as a three-hinged arch and made two-hinged by closing the center hinges after erection.

One of the factors that is always of great interest to engineers is that of cost—either the total cost divided between foundations and superstructure, or, if let at a unit price basis, the pound price of both silicon and carbon steel. It is hoped that the authors, in their closures, will give such information.

The writer assumes that consideration was given by the designers to the advisability of using a light-weight floor and that such a floor—either light-weight concrete with bituminous surfacing or steel grating—was found uneconomical. It would be interesting to have this matter presented in the authors' closures.

L. J. MENSCH,[30] M. AM. SOC. C. E.—The Rainbow Bridge is one of the world's outstanding bridges, and the practical bridge engineer will greatly appreciate receiving information as to the high points of its design, fabrication, and erection. The many illustrations, the history of the design, Table 1, and the summary of quantities are very interesting and one nearly lost feature of the art has been disclosed; namely, the advisability, from the fabricating standpoint, of designing the center line of the arch rib as a series of multicentered circular arcs. The first masonry and the first metal arches were built of single-centered arcs. About 200 years ago French engineers introduced three-centered arcs, and about 50 years ago five-centered arcs made their appearance.

---

[29] "Weighing Bridge Reactions with Proving Rings," by C. M. Spofford and C. H. Gibbons, *Engineering News-Record*, March 28, 1935, p. 446.

[30] Civ. Engr. and Contr., Chicago, Ill.

In this bridge there is an eleven-centered arch. It is questionable whether so many centers were really necessary. Although a bridge engineer will note with respect the mathematics and the practical features of the erection problems, he probably would have liked more information on the evidently highly successful job of surveying the bridge site before and during erection and also more details on the concrete deck, the forms used to avoid an accident similar to that which occurred on the Golden Gate Bridge,[31] the kind and spacing of the expansion joints, the kind of railings used, the system of lighting, and other smaller but important features of a successfully constructed bridge. No statement has been made regarding the stiffness of the bridge under traffic—a question of greatest interest for an arch rib with a depth of one eightieth of the span.

According to the Symposium authors, the unusually shallow ribs necessitated the abandonment of the "elastic theory" and the substitution of the "deflection theory." The writer supposes that the "elastic theory" is the mathematical theory of elasticity, except that certain "elastic theory" requirements are not considered:

(1) The effect of unit stresses in excess of the true elastic limit;
(2) Poisson's effect;
(3) Shear deformation;
(4) Vibrations due to loading conditions;
(5) Changes of temperature during critical loading;
(6) Variation of the modulus of elasticity in the various parts of the structure; and
(7) Deformation of the center line of the arch rib for the equation of moments and in the elastic equations.

These phenomena are clearly and completely appraised in the oldest treatise on metallic arched bridges, analyzed by the strict mathematical theory of elasticity.[32] Early writings also emphasize the computation of deflections of the arch due to rib shortening, compression, change of temperature, shrinkage (in wood arches), and faulty joints. J. A. C. Bresse warned his students not to use ribs so shallow as to cause excessive deflection due to a moving load. No real, valid reason has been given in this Symposium why this sound warning has been disregarded. For comparatively large deflections, the problems are treated in textbooks on elasticity under the heading, "Elastica," an expression first used by Leonhard Euler.

The writer holds some reservations as to the validity of Eqs. 18 to 21. For example, Eqs. 18 and 19 contain only two indeterminate quantities—H and M_{oa}. The symbol M'_a refers to a statically determinate moment of the exterior forces in a simple beam and is not concerned with the missing indeterminate value of the reaction at the left springing. To ignore the latter will intensify the conditions in Fig. 12.

To design a bridge, its span, rise, width, dead load, and live load must be known. Often there is a choice of span and rise—greater spans may reduce the cost of the foundation, and greater rise may save in the weight of metal in the arch ribs. Suppose some preliminary designs have prescribed span and rise and number of ribs. The dead load of the roadway does not vary much from 150 lb per sq ft regardless of span. The weight of the ribs may be approximated from handbooks on bridge design. A nearly correct formula for the horizontal component of the thrust is given by:

---

[31] *Engineering News-Record*, February 25, 1937, p. 313; March 11, 1937, p. 377; and April 22, 1937, p. 590.

[32] "Recherches analytiques sur la flexion et la résistance des pièces courbes," par J. A. C. Bresse, Paris, 1854.

$$H = \left(w_1 + \frac{\Delta w_1}{6}\right) \frac{L^2}{8 f (1 + k)} \quad \text{(39)}$$

in which w_1 = the dead load per linear foot on the rib at the crown; Δw_1 = increase in dead load per linear foot at the springing, due to the spandrel columns and the greater weight of rib; f = the rise of the arch; and k = a numerical factor between 0.01 and 0.03 that enters the formula to account for the shortening of the arch under load.

If the permissible stress in direct compression is assumed as one half the maximum permissible stress, then Eq. 39 may be used for a close approximation of the area of metal required in the rib at the crown. The depth of the rib is governed by the live load and deflection caused by it. Modifying and simplifying the prior work of M. Bresse,[32] the writer has derived the following fundamental formulas[33] for the three statically unknown values generated by a concentrated load P at any point along the elastic arch:

Vertical component of thrust, V, at the left abutment—

$$V = \frac{P}{L^3} (L - L_a)^2 (L + 2 L_a) \quad \text{(40a)}$$

horizontal component of the thrust, H—

$$H = \frac{15 P L_a^2 (L - L_a)^2}{4 L^3 f (1 + k)} \quad \text{(40b)}$$

and moment at the left springing, in a counterclockwise direction[33]—

$$M_{oa} = \frac{P L_a (L - L_a)^2 \left(L - \frac{2.5}{1 + k} L_a\right)}{L^3} \quad \text{(40c)}$$

In Eqs. 40, in addition to the notation of the Symposium, L_a = the distance from the left end of the arch axis to the load P.

These formulas were derived originally for a very flat circular arch of constant section, and similar ones can be obtained for a parabolic arch of constant ratio $\frac{ds}{I}$. They may be used safely for arches of the Rainbow type.

For a circular flat arch, or for a parabolic arch of constant $\frac{ds}{I}$,

$$k = \frac{45 I}{4 A f^2} \quad \text{(41a)}$$

For the Rainbow arch, $\frac{ds}{I}$ is not constant and Eq. 41a becomes,

$$k = \frac{12.4 I}{A f^2} \quad \text{(41b)}$$

---

[33] "The Reinforced Concrete Pocket Book," by L. J. Mensch, Neal Publishing Co., San Francisco, 1909, p. 154 and Fig. 68, p. 155.

The bending at any point x, y of the arch can be computed by Eqs. 40, thus: When the distance x from the left end to point x is less than L_a,

$$M = V\,x - H\,y - M_{oa} \quad \text{(42}a\text{)}$$

and, when x is greater than L_a,

$$M = V\,x - H\,y - M_{oa} - P\,(x - L_a) \quad \text{(42}b\text{)}$$

By solving these equations for every tenth point of the arch, for example, influence lines[34] can be constructed for determining the critical loading for eleven points on the arch. In the case of a uniform load the moment at the left springing can be found either by integrating Eq. 40c between the limits $L_a = 0$ and $L_a = 0.4\,L$, or by computing the area of the influence line between those limits. For this case,

$$M_{oa}\,(\max) = 0.0174\,w\,L^2 \quad \text{(43}a\text{)}$$

Of course, Eq. 43a is strictly correct only for a constant value of $\frac{ds}{I}$. If $\frac{ds}{I}$ decreases to $\frac{1}{5}$ at the springing, the maximum value becomes

$$M_{oa} = 0.0257\,w\,L^2 \quad \text{(43}b\text{)}$$

By interpolation for the Rainbow arch where $\frac{ds}{I}$ decreases to $\frac{1}{1.5}$,

$$M_{oa} = 0.0185\,w\,L^2 \quad \text{(43}c\text{)}$$

Adding 10% for impact stresses, $M_{oa} = 0.0204 \times 1{,}380 \times 950^2 = 25{,}400$ ft-kips for the Rainbow arch, compared with 28,850 ft-kips reported in Table 1, line 5. This difference may have been caused by assuming a concentrated load of 26,700 lb acting about 150 ft from the springing. The moment then is $0.07 \times 26{,}700 \times 950 = 1{,}775$ ft-kips, which, increased by 10%, makes the total moment 27,353 ft-kips. The latter value checks very closely the 28,850 ft-kips given in the Symposium. It is generally believed that the greatest moment and the greatest deflection from a distributed load occur at the quarter point of the span. A concentrated load at the three-tenth point produces a slightly greater moment in the arch, and a distributed load over the half span produces a larger moment at the three-tenth point than at the quarter point. Furthermore, the deflection is greater at the three-tenth point than at the quarter point.

For many years it was standard practice (and it is still a recommendable procedure) to design an arch bridge of the Rainbow type for a movable load on the half span from the springing to the crown, except that the crown section was designed for a uniform load extending over a distance $L/6$ on both sides of the crown. For a uniform load on the half span, the three statically indeterminate quantities can be obtained by integrating Eqs. 40 between the limits $L_a = 0$

---

[34] "The Reinforced Concrete Pocket Book," by L. J. Mensch, Neal Publishing Co., San Francisco, 1909, Figs. 69 to 75, pp. 155 and 157.

and $L_a = \frac{L}{2}$. Thus,

$$V = \frac{13}{32} w L \quad \text{(44a)}$$

$$H = \frac{w L^2}{16 f (1 + k)} \quad \text{(44b)}$$

and

$$M_{oa} = w L^2 \frac{1 + \frac{11 k}{3}}{64 (1 + k)} \text{ (tension in the top of the arch)} \quad \text{(44c)}$$

The moment at the right springing is

$$M_s = - \frac{w L^2 \left(1 - \frac{5 k}{3}\right)}{64 (1 + k)} \text{ (with tension at the bottom)} \quad \text{(45a)}$$

and the moment at the crown is

$$M_c = \frac{w L^2 k}{48 (1 + k)} \quad \text{(45b)}$$

The equation for the deflection of the elastic line may be obtained from the fundamental equation of flexure,

$$\frac{d^2 \delta_v}{dx^2} = - \frac{M}{E I} \quad \text{(46)}$$

in which, for a uniform load on the half span,

$$M = V x - H y - M_{oa} - \frac{w x^2}{2} \quad \text{(47)}$$

and, by double integration,

$$E I \delta_v = \frac{w}{192} \left[- 13 L x^3 + \frac{8 L x^3 - 4 x^4}{1 + k} + L^2 \left(\frac{1.5 x^2 + 5.5 k x^2}{1 + k} \right) + 8 x^4 \right] \quad \text{(48)}$$

For the point $x = 0.75 L$,

$$\delta_v = \frac{w L^4 (1 - 3.5 k)}{6{,}144 E I (1 + k)} \quad \text{(49)}$$

and the movement is upward. It is important to know whether there are any moments acting in the arch rib when the bridge is uniformly loaded over the entire span. Integrating Eqs. 40 between the limits $L_a = L$ and $L_a = 0$:

$$V = \frac{w L}{2} \quad \text{(50a)}$$

$$H = \frac{w L^2}{8 f (1 + k)} \quad \text{(50b)}$$

$$M_{oa} = \frac{w L^2 k}{12 (1 + k)} \quad \text{(50c)}$$

and the moment at the crown is

$$M = \frac{w\,L^2\,k}{24\,(1 + k)} \quad \text{.......... (50}d\text{)}$$

Also, at the crown:

$$\delta_v = \frac{w\,L^4\,k}{384\,E\,I\,(1 + k)} \quad \text{.......... (51)}$$

In 1919 discussing a paper on this subject by the late George F. Swain, Past-President and Hon. M. Am. Soc. C. E., the writer presented[35] a new derivation of the Bresse equations, for the deflection and rotation of any element of a curved member, as follows:

$$\theta = \int_0^x \frac{M\,ds}{E\,I} \quad \text{.......... (52}a\text{)}$$

$$\delta_h = -\int^x \frac{T\,dx}{E\,A} - y\int^x \frac{M\,ds}{E\,I} + \int_0^x \frac{M\,y\,ds}{E\,I} \quad \text{.......... (52}b\text{)}$$

and

$$\delta_v = \int_0^x \frac{T\,dy}{E\,I} - x\int_0^x \frac{M\,ds}{E\,I} + \int_0^x \frac{M\,x\,ds}{E\,I} \quad \text{.......... (52}c\text{)}$$

in which *ds* is an increment of length measured along the center line of the arch rib.

Eqs. 52 demonstrate that the deformations are linear functions of the exterior forces and reactions, showing that the law of superposition is valid for the deflections as well as for the stresses. M. Bresse uses them to determine the statically unknown reactions. Subsequent writers have introduced other methods such as the theory of virtual velocities, theory of least work, ellipse of elasticity, Maxwell's equations, Müller-Breslau's equations, slope deflection, etc., all of which lead to equations that must be simplified considerably before they reduce to the simple forms possible by the Bresse equations directly.[32] If the proper value of *M* is introduced, the writer's derivation of the Bresse equations[32] is valid for a simple beam, a continuous beam, a rigid frame, a three-hinged arch, and an arch with two hinges or no hinges.

Contrary to the implied limitations expressed by the Symposium authors, Eqs. 39 to 51 are quite sufficient for the design of an arch of the Rainbow type, and the results agree well with those given in Table 1. To particularize:

(1) From Eq. 39 and Fig. 12 the thrust at the crown is found to be $H = \dfrac{\left(7{,}250 + \dfrac{3{,}350}{6}\right) \times 950^2}{8 \times 150\,(1 + 0.011)} = 5{,}810$ kips for the dead load, as compared with 5,911 kips in Table 1.

(2) The bending moment from the dead load, at the crown, by Eqs. 50, is $M = \dfrac{\left(7{,}250 + \dfrac{3{,}360}{6}\right) \times 950^2 \times 0.011}{24\,(1 + k)} = 320$ ft-kips, as compared with 434 in Table 1.

---

[35] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), Eqs. 17, 18, and 19, p. 660.

(3) The maximum bending moment from live load, at the crown, by Eqs. 44 to 50, is $M = 0.0057 \times 950^2 \times 1{,}380 = 7{,}100$ ft-kips. From Eq. 42*a*, $M = 26{,}700 \times 950 \times 0.047 = 1{,}200$ ft-kips. Adding to the sum (7,100 + 1,200) 10% for impact gives 9,130 ft-kips, as compared with 8,700 in Table 1.

(4) The mechanics for analyzing the effect of a temperature drop in a fixed arch was presented by the writer[36] in considerable detail, in 1929. The analysis offered at that time yields, for the parabolic arch,

$$H_t = \frac{45\, E\, I\, c\, t}{4\, f^2\,(1 + k)} \qquad (53)$$

in which c = coefficient of temperature expansion. The moments at the springing and crown, respectively, are:

$$M_s = H_t \frac{2\, f}{3} \qquad (54a)$$

and

$$M_c = H_t \frac{f}{3} \qquad (54b)$$

For the Rainbow arch the coefficients of H_t in Eqs. 54*a* and 54*b* are 0.7 and 0.3, respectively. The deflection of the crown due to a drop of temperature is obtained easily by means of Eq. 52*c*, and very closely by the relation

$$\delta_v = c\, t\, f + c\, t \frac{L^2}{4\, f} \qquad (55)$$

For the Rainbow arch, when $c\, t = 0.0004$, $\delta_v = 8$ in. Assuming a temperature drop of 60° F and substituting other necessary values,

$$H_t = \frac{13.25 \times E \times 12{,}000 \times 144 \times 0.0004}{150^2 \times 144\,(1 + 0.011)} = 84 \text{ kips},$$

as compared with 93 kips in Table 1; and $M_c = 84 \times 0.3 \times 150 = 3{,}780$ ft-kips, as compared with 4,255 in Table 1.

(5) The effect of an error of 1 in. should be $\frac{1}{4.55}$ of the effect of a drop in temperature of 60° F, as the latter would cause a potential shortening of $0.0004 \times 950 \times 12 = 4.55$ in.

(6) The maximum moment due to live load occurs at the three-tenth point, between points 5 and 6, Fig. 6. By Eqs. 40 to 47, $M = 0.0096 \times 1{,}380 \times 950^2 = 11{,}950$ ft-kips; and, by Eq. 42*a*, $M = 0.0596 \times 26{,}700 \times 950 = 1{,}455$ ft-kips. Adding 10% for impact to the sum, $M = 14{,}745$ ft-kips as compared with 13,470 ft-kips for point 5 in Table 1.

(7) The moment due to live load at the left springing agrees very well with Table 1, as demonstrated previously. It remains only to compare the temperature effects. From Eqs. 54, $M_s = 84 \times 150 \times 0.7 = 8{,}820$ ft-kips, as compared with 8,918 in Table 1.

(8) In view of the very flexible arch rib, the deflections due to dead load, live load, and drop of temperature are of great interest. Deducting the weight

---

[36] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1252.

of the rib (because of the method of erection), the dead-load deflection at the crown is computed by Eq. 51 as $\delta_v = 4.2$ in.; and, assuming a length of 270 ft loaded across the crown, the live-load deflection at the crown,[35] $\delta_v = 3.8$ in. For the temperature drop δ_v was found equal to 8 in. and the shortening of the arch rib due to live load was 0.55 in. The total $(4.2 + 3.8 + 8 + 0.55)$ is 16.55 in. By Eqs. 44, 45, and 48, the live-load deflection at the three-tenth point, $\delta_v = \frac{1{,}380 \times 950^4 \times 12^3 \,(1 + 6.8\,k)}{5{,}920\,E\,I\,(1 + k)} = 7$ in. when the half span is loaded and a constant $\frac{ds}{I}$ is assumed. Because of the larger moment of inertia near the springing the actual deflection should be 20% less. With live load in the half span, the deflection δ_v at the three-tenth point caused by the shortening of the arch is equal to $\delta_v = 0.7 \times 0.55 = 0.39$ in., approximately. The corresponding dead-load deflection δ_v caused by the shortening of the arch is equal to $\delta_v = 0.7 \times 4.2 = 2.9$ in., approximately; and the temperature deflection, $\delta_v = 4.19$ in., or a total of about 14.48 in. Although, possibly, these deflections may be reduced 20% on account of the increased stiffness of the rib toward the springing, they are nearly twice as large as those assumed by the authors on the basis of the deflection theory.

A particularly valuable part of this Symposium is the inclusion of Table 1, which enabled the writer to compare the results of the "elastic theory," as propounded by M. Bresse, with the "deflection theory," defended by the Symposium authors.

O. H. AMMANN,[37] M. AM. SOC. C. E.—The designers and constructors of the Rainbow Arch Bridge deserve credit for having produced a most excellent structure, both esthetically and technically. The arch type of bridge, like its predecessor, undoubtedly suggested itself as the natural solution because of the steep rocky sides of the river gorge. The banks are of sufficient height to permit the bridge floor to be entirely above the arch ribs—an arrangement which is esthetically most ideal for any arch structure.

The appearance is enhanced by utmost simplicity of the structural design, more particularly the selection of slender solid-plate arch ribs in place of deep arch trusses which have heretofore prevailed in arches of this magnitude. The adoption of solid-plate arch ribs in this bridge was undoubtedly made possible and economical by the recent advances in theory and structural design as well as in methods of fabrication and erection, and, therefore, evidences a further milestone in the art of bridge construction.

The design of the graceful imposing arch span proper is kept strictly to structural necessities, free from ornamental or architectural embellishments. The short approaches surmounting the rocky slopes are appropriately designed to appear as massive arch viaducts; their contribution to the monumental appearance of the structure undoubtedly justified the additional expense involved when compared to light steel structures exemplified in some similar cases.

---

[37] Cons. Engr., New York, N. Y.

Under the given conditions the adoption of the hingeless type of arch rib was unquestionably most appropriate. A two-hinged arch of satisfactory performance could have been designed but, as is indicated by the authors' comparative figures, such an arch with slender solid-plate ribs would have been considerably less economical than the hingeless type.

The arguments might be advanced that the two-hinged arch is statically indeterminate in a lesser degree and that yielding of the foundations, or inaccuracies in workmanship and erection, especially at the rib splices, might cause more serious secondary or supplementary stresses in the hingeless arch. Neither of these arguments could be of practical importance in this case. The determination of stresses, even in complex statically indeterminate structures, has advanced to a stage which, for an important structure, does not admit greater simplicity of analysis as a valid argument. Provided there is no external yielding, the stresses in any well-designed and well-built statically indeterminate structure can be determined with the same degree of reliability as those in a statically determinate system. As regards the effects of yielding, the solid rock foundations, and the high degree of accuracy of fabrication and erection which is now attained in steelwork of this nature by experienced and well-equipped constructors, preclude supplementary stresses of practical significance.

In view of the slenderness of the arch ribs, which was undoubtedly dictated by the practicable make-up of the solid-plate section, the deformations under load could be expected to be appreciable and to warrant investigation of the stresses by a more accurate analysis than the so-called "elastic theory," more particularly since in an arch the differential stresses from the deformation are additive.

The designers have made such an investigation, at least for certain points, and have developed an analysis and approximate formulas for more accurate stresses which, as far as they have been applied, appear to be adequate for this particular structure. It seems to the writer, however, that the permissible limits should be assigned to the accurate stresses and not to the ones determined by the inadequate "elastic method." It is true that in this particular case the more accurate stresses, as far as calculated by the designers, are still within safe limits, but it would seem that, in general, and particularly in comparative designs based on the same specifications, the prescribed permissible stresses should apply uniformly to stresses determined by an adequately accurate method. The differential stresses cannot be classified as "secondary" stresses in the commonly accepted sense.

In this connection, the writer has long held the view that the term "elastic theory," by which the analysis of stresses in an assumed rigid system has become known, is incongruous and misleading. If a special term for it appears desirable it should be the "theory of the rigid system"; and what has become known and referred to in the first paper of the Symposium as the "deflection theory" should be termed, in distinction, "theory of the flexible system." Fundamentally, there is no distinction between the two, except the degree of accuracy, both being based upon the laws or the hypothesis of elasticity. For most common structures in which the changes in the form of structure under loads are negligible, the theory of the rigid system is sufficiently adequate. For more flexible structures there are different "theories of the flexible system" depending upon the degree of accuracy desired or justified. Any desired degree of accuracy may be attained by a method of trial and correction, by more or less elaborate cut and dried formulas, or by model tests. The authors, very wisely, have resorted to all three methods in an effort to check the results, at least at certain critical points.

The research work on two-hinged arch models described in the second paper of the Symposium, and the method of analysis derived therefrom, should prove of aid to the designer, especially in connection with rough preliminary studies. It is the kind of research that deserves to be encouraged in connection with the design of any unusual structure. The results obtained demonstrate again the reliability of stress determinations by means of models and their usefulness in checking the adequacy of theoretical analysis.

It is only regrettable that circumstances probably did not permit the work to be extended to include a complete check of stresses on a model representing the hingeless arch of the Rainbow Bridge as actually built, and it is to be hoped that opportunity for such a study will present itself in the future.

The writer cannot agree with the conclusion expressed by the authors of the second paper that two-hinged arches should be of sufficient stiffness to make the application of the "elastic theory" entirely proper. As long as the accurately determined stresses from the maximum specified loads are within the prescribed limits the design should be considered satisfactory. Accepted practice does not determine the design load by applying a uniform factor of safety to a hypothetical yield load, but rather limits the accurate unit stresses under maximum design load to certain safe stresses based upon the qualities (especially the yield point) of the material.

The third and fourth papers of the Symposium reflect the elaborate and thorough studies and preparations made by the constructors to insure accuracy in workmanship and perfect control of the stress conditions during erection.

Louis Balog,[38] Esq.—The papers on the Rainbow Arch Bridge record considerable progress in the design and construction of long-span arch bridges. The designers of the bridge present, in the first paper, a method of analyzing flexible arches that yields correct results, and they also derive practical design formulas. The results of the experimental investigations given in the second paper check the designers' analysis and are useful for preliminary design of flexible two-hinged arch ribs. In Appendix I of the first paper, methods for the consideration of deflection effects are discussed. In addition to those mentioned a method developed by Fr. Dischinger[39] is of interest. It applies to beam-columns and arch ribs, primarily those having a parabolic axis and a varying cross section expressed by

$$I_c = I_x \cos\theta \text{.........................} (56)$$

The increase of the elastic-theory moments is expressed by a rapidly converging geometric series:

---

[38] Cons. Engr., New York, N. Y.

[39] *Der Bauingenieur*, Vol. 18, August 20, 1937, pp. 487–520.

$$M = M_E \left(\frac{\nu + \beta}{\nu - 1} + \frac{\beta_1}{\nu} + \frac{\beta_2}{\nu^2} + \frac{\beta_3}{\nu^3} + \cdots \right) \ldots\ldots\ldots\ldots (57)$$

in which (in addition to the notation of the Symposium): β is a numerical coefficient; and

$$\nu = n \frac{E\,I}{H\,a^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (58)$$

In Eq. 58: a is half the span length; and n is a numerical buckling coefficient.

For ribs that are not too flexible the consideration of the first term in the parentheses at the right side of Eq. 57 is sufficient to estimate the increase of the elastic-theory moments. For a hingeless rib the following approximate formulas are obtained for the half span uniformly loaded:

Moment at springing—

$$M_S \approx M_E \left(\frac{\nu - 0.382}{\nu - 1} \right) \ldots\ldots\ldots\ldots\ldots\ldots (59a)$$

moment at the quarter point—

$$M_{0.25} \approx M_E \left(\frac{\nu - 0.014}{\nu - 1} \right) \ldots\ldots\ldots\ldots\ldots\ldots (59b)$$

and, moment at the three-eighth point—

$$M_{0.375} \approx M_E \left(\frac{\nu + 0.121}{\nu - 1} \right) \ldots\ldots\ldots\ldots\ldots\ldots (59c)$$

For use in Eqs. 59 (see Eq. 58), $n = 20.19$. Introducing the data given in Table 3 for the hingeless rib: $\nu = 20.19 \dfrac{29{,}400 \times 88.2 \times 144}{6{,}460 \times 475^2} = 5.18$; and, by Eqs. 59*a*, 59*b*, and 59*c*, respectively, $M_S = 1.148\ M_E$; $M_{0.25} = 1.236\ M_E$; and $M_{0.375} = 1.268\ M_E$. These approximate values are from 2% to 6% different from the dead-load plus live-load moment values given in Fig. 12 and Table 3, indicating the correctness of the moments used in the design.

For a two-hinged rib the approximate moment at the quarter point, when the half span is loaded, is

$$M_{0.25} \approx M_E \left(\frac{\nu + 0.032}{\nu - 1} \right) \ldots\ldots\ldots\ldots\ldots\ldots (60)$$

in which (see Eq. 58), $n = 9.87$. Introducing the data given for the two-hinged rib in Table 2: $\nu = 9.87 \dfrac{29{,}400 \times 120.24 \times 144}{7{,}551 \times 475^2} = 2.95$; and substituting in Eq. 60: $M_{0.25} = 1.53\ M_E$. This value is 10% less than the correct value of the dead-load plus live-load moment given in Table 2. On account of the flexibility of the two-hinged rib the approximation is not as close as that for the more rigid hingeless rib.

By presenting comparative data for the two-hinged arch and for the hingeless arch, the designers have directed attention to the superiority of the more statically indeterminate structure. The hingeless rib of greater rigidity was designed with considerable saving in metal. The efficient section of this rib resulting from the use of stiffened webs of minimum section should also be noted.

The study of the four papers on the Rainbow Arch Bridge reveals the care and understanding with which this outstanding structure was designed and built.

William G. Rapp,[40] Assoc. M. Am. Soc. C. E.—In its entirety this Symposium is an excellent contribution to the limited existing literature on design, engineering, fabrication, and erection of monumental structures such as the Rainbow Arch Bridge. In particular, a distinct service has been rendered to that part of the engineering profession engaged in the actual prosecution of work in the field—to those engineers on whose shoulders falls the duty of seeing that the structure as designed and fabricated is erected properly, safely, and efficiently. Such practicing engineers must meet unexpected and vital problems with immediate answers, an art that can only be achieved by actual, tedious, and arduous experience, or by the study of papers such as that portion of the third Symposium paper dealing with "Erection Controls" and the entire fourth paper, "Erection of Steel Superstructure."

To the designer, the design of a bridge of this caliber is often an important and seemingly difficult task. Decisions as to type, sizes, etc., are necessary before any further steps can be taken. The engineering work following the basic design decisions is just as important and often just as difficult. Fabrication, similarly, presents important problems, although these can generally be overcome.

The final and most difficult decisions of all, however, are those which must be made by the erector: By the office engineers, who must prepare complete plans for the subsequent erection of the structure, and by the resident engineer, together with all those associated with him at the site. In the preliminary office study: Methods, equipment, stresses and strains in the structure, scheduling, planning and foreseeing all the minor and major details of erection from start to finish; and, for the resident engineer: Unexpected terrain, unforeseen weather, unpredictable working personnel, or difficult field connections—all these problems must be mastered or the design, the engineering, and the fabrication will have been wasted. The structure must be built and too little help has been given, in the past, toward disseminating theoretical and practical information—studies, analyses, and records of actual construction at the site. The more aid that can be given in this phase of engineering, the better the finished project will reflect the original ideas of the designing engineer. Also, the more publicity given to actual field erection problems or difficulties, the better the designing, detailing, and fabricating engineers will be able to solve these problems, by preventing the conditions which too often exist as a result of lack of information on this phase of construction.

Leon Beskin,[41] Assoc. M. Am. Soc. C. E.—The purpose of the following comment is to correct some errors in the first two papers of the Symposium and to show that very simple formulas are available for design and even for definite analysis of flexible arches. The results thus obtained give the same degree of accuracy as the lengthy calculations indicated in the Symposium, and make tests useless.

[41] Senior Stress Analyst, Consolidated Vultee Aircraft Corp., Allentown, Pa.

Deflection Effects and Design Formulas.—It is regrettable that the expression "elastic theory" has been used in the first Symposium paper to indicate a method of stress analysis in which deflections are supposed to be infinitely small. This expression is certainly a misnomer according to all conventional definitions (see A. E. H. Love[42]). S. Timoshenko studies the "deflection theory," in his "Theory of Elastic Stability."[43] The expression "deflection theory" seems acceptable, but as a subdivision of the elastic theory, and not in opposition to it; the expression "beam-columns" is also widely used.

The statement that several deflection theories are available for arch ribs throws an incorrect light on the problem. Written in differential terms, the problem is elucidated completely, and the theory is unique. Methods of integrating the differential equation may differ, generally because terms are neglected in order to simplify the calculations. The fact that results may differ shows that simplifications made are not justified and lead to inaccurate or erroneous results.

Under the action of axial forces and lateral loads curved beams deflect differently from beams submitted to lateral loads only. Many years ago, the late Milo S. Ketchum,[44] Hon. M. Am. Soc. C. E., presented a formula for the combined effects of bending and axial loads in the elastic range. Some formulas developed subsequently herein will show the simplicity of the problem, even if a fairly close approximation (say, within 1%, generally) is required. They avoid unnecessary loss of time in design and they demonstrate the effect of deflections on stresses as soon as the working stress under axial load, the span, the depth and type of beam, and the end conditions are selected. From those formulas a "factor of amplification," c, can be determined which represents the ratio of actual deflections to deflections calculated for a beam without axial load, and also the ratio of moments in both conditions. That factor is defined as

$$c = \frac{1}{1 + \frac{s_a\,(L_1)^2}{\pi^2\,E\,k^2}} = \frac{1}{1 - \frac{T}{T_c}} = \frac{1}{1 + \frac{T\,(L_1)^2}{\pi^2\,E\,I}} \cdots\cdots\cdots\cdots (61)$$

in which, in addition to the notation of the Symposium: s_a = unit stress due to axial load; k = radius of gyration of the arch; T_c = thrust that causes buckling; and L_1 = effective free length of span. The latter is the total length for a hinged beam under an applied active axial load. It is also the length of the arc between the crown and the skewbacks for a hinged arch under the action of applied transverse loads applied on half of the span and thrust or 0.7 of that length, approximately, if the ends are fixed.

Definition of the Factor of Safety N by Eq. 1.—The persistent use of factors of safety that differ for each type of load is regrettable. Reducing the factor of safety for wind and temperature to 1 is equivalent to reducing those loads in the ratio of the factor of safety used for the other loads. As wind and temperature loads are somewhat arbitrary, the use of a variable factor of safety is a useless complication, especially when various factors of safety are used for different combinations of loads.

Equations of Equilibrium for Curved Beams.—The factor $\frac{T}{r_o E A}$ in Eq. 2 is obviously erroneous, and must be omitted, since under uniform axial stress, with necessary radial loads to maintain it in equilibrium, the radius of the ring does not change. On the contrary, if there is a strain e_1 along the radius, the latter changes by $e_1 r_o$.

If stresses along the radius are negligible, the quantity e_1 is equal to $-\frac{\mu T}{E A}$ (in which μ = Poisson's ratio), and the corresponding factor is $+\frac{\mu T}{r_o E A}$. If the terms due to shear are taken into account, Eq. 2 must be written:

$$\frac{d^2u}{ds^2} + \frac{u}{(r_o)^2} = -\frac{M}{E I} - \frac{1}{E_s A_w}\left(W_n + \frac{T}{r_o}\right)' + \frac{\mu T}{E A r_o} \quad \text{......(62)}$$

in which W_n is the component of the load normal to the arc, per unit length of arc.

Eqs. 3 are obviously incorrect because the tangential component v of the deflection is omitted. That component is not negligible, since it produces secondary bending in a two-hinged arch when the moment M'_a is proportional to y, and no camber for dead load is provided.

The term $\frac{u}{(r_o)^2}$ cannot be neglected in a refined analysis (see the comparison between the "exact" procedure and the approximate method presented by Mr. Hardesty, et al.) Comparing the value of $\frac{u}{(r_o)^2}$ to that of $\frac{M}{E I}$ in the nondeflection theory, the ratio is

$$\frac{u:(r_o)^2}{M:(E I)} = \frac{12 \times 14:(827)^2}{23{,}000:(29{,}400 \times 120)} = 0.036 \quad \text{............(63)}$$

A direct estimate of that ratio can be made, assuming that the moment M and the deflection u are sinusoidal functions along a circular arch, of the type $\frac{R_{td} \sin \alpha \pi}{\alpha_s}$. Then,

$$\frac{d^2u}{ds^2} + \frac{u}{(r_o)^2} = \frac{1}{(r_o)^2}\left(\frac{d^2u}{d\alpha^2} + u\right) = \frac{R_{td}}{(r_o)^2}\frac{d^2u}{d\alpha^2}\left[1 - \frac{(\alpha_s)^2}{\pi^2}\right] \quad \text{......(64)}$$

in which R_{td} is the ratio of thrust to dead load; and α_s is the slope angle at the skewback. Thus, the relative influence of the second term is $\frac{(\alpha_s)^2}{\pi^2}$, which has the value 0.038 for $\alpha_s = 35°$.

Both methods demonstrate that an error of 4% occurs in the value of the moment, when the term $\frac{u}{(r_o)^2}$ is neglected. When the amplification due to deflection is introduced (as shown subsequently), the error, which is unconservative, is increased to 6%; thus, the "exact method" applied by Mr. Hardesty, et al., is no more accurate than the approximate method.

The secondary moments due to the effect of change in length of the arch under dead load are eliminated by the introduction of a camber. The moments thus eliminated are actually of the same order of magnitude as the moments omitted with the factor $\frac{u}{(r_o)^2}$. The exact value of the horizontal component of the thrust is:

$$H = \frac{\int y\,M'_a\,ds{:}(E\,I) - \int \sin\alpha\,dM'_a{:}(E\,A) + \int \sin\alpha\,dM'_a{:}(E_s\,A_w)}{\int y^2\,ds{:}(E\,I) + \int \cos^2\alpha\,ds{:}(E\,A) + \int \sin^2\alpha\,ds{:}(E_s\,A_w)} \ldots (65)$$

Assuming that the ordinates of the arch are proportional to the curve of moment due to dead load, $M'_a = H_o\,y$, and, with an error of the second order of magnitude, assuming a constant cross section:

$$\frac{H}{H_o} = 1 - \frac{\int dx{:}(A\,E)}{\int y^2\,dx{:}(I\,E)} = 1 - \frac{15\,k^2}{h^2} \ldots\ldots\ldots\ldots (66)$$

The difference between H and H_o produces moments in the arch, which are equal to

$$M = M'_a - H\,y = \frac{M'_a \times 15\,k^2}{h^2} \ldots\ldots\ldots\ldots\ldots (67)$$

For the arch investigated (approximately): $k^2 = 28$; $h = 150$; and, at the crown, $M'_a = \frac{9.5 \times 950^2}{8} = 1{,}050{,}000$. Thus, $M = 2{,}500$. At the quarter point, the value of M is approximately 1,900, which represents 5% of the total moment at that point, and is somewhat smaller than the error of 6% made when neglecting the factor $\frac{u}{(r_o)^2}$. This shows the regrettable fact that, although the authors have been careful to eliminate some secondary bending by special erection methods, moments of equal importance, due to other factors, have been completely omitted from the analysis.

The methods of successive approximation used by the authors to account for the effect of deflections can be simplified by direct integration of the equations of equilibrium, as this is generally done in problems of beam columns. Using Eqs. 5 and 6 (in which the product $\Delta H\,\eta$ is of second order and can be omitted), and substituting the approximations, $\Delta H = 0$, $v \sin\alpha_s = 0$, the equation of equilibrium is:

$$-\frac{E\,I\,d^2u}{ds^2} = M_{ae} + T\,u \ldots\ldots\ldots\ldots\ldots\ldots (68)$$

As a first approximation, the moment M_{ae} due to live load is given by a sinusoidal line. Then the integration is immediate, and with $M_{ae} = \frac{M_o \sin 2\,\pi\,s}{L'}$:

$$E\,I\,u = \frac{M_o \sin 2\,\pi\,s{:}L'}{1 + \frac{T\,(L')^2}{4\,\pi^2\,E\,I}} \ldots\ldots\ldots\ldots\ldots\ldots (69)$$

Thus,

$$M_{af} = \frac{M_{ae}}{1 + \frac{T\,(L')^2}{4\,\pi^2\,E\,I}} = c\,M_{ae} \qquad \text{(70)}$$

Eq. 70 explains why "it was noted that the variation in Δm_1 * * * was similar to the variation in M_e * * *" (see paragraph containing Eq. 8). Furthermore, the value of the quantity $\frac{\Delta m_{a1}}{M_{ae}} = \frac{T_a\,u_{ae}}{M_{ae}}$ is thus determined. Eq. 13 contradicts the fact that M_{ae} and Δm_{ae} are proportional; an average value of T must be used in Eqs. 13 and 14, instead of a variable value.

The coefficient of amplification c (Eq. 61) gives accurate results for a final analysis. For instance with: $T = 7{,}588$; $M = 24{,}950$; $E = 29{,}400 \times 144$; $I = 120$; and $L' = 1{,}020$; Eq. 37 yields $c = 1.64$ and $M = 40{,}900$. This value of M differs by 150 (0.4%) from the value calculated by the authors. If the correction for $\frac{u}{(r_o)^2}$ is introduced, the amplification coefficient is

$$c' = \frac{1}{1 + \frac{(L')^2}{4\,\pi^2} \cdot \left[\frac{T}{E\,I} - \frac{1}{(r_o)^2}\right]} \qquad \text{(71)}$$

Thus the moments are increased by 6% above the values calculated by the authors. This clearly shows that the so-called "approximate methods" are quite sufficient for practical purposes. Otherwise all terms must be taken into account and the computations will be complicated by the need for solving a differential equation of second order. To avoid it, an error of 6% is introduced; in view of that error, all the refinements introduced by Mr. Hardesty, et al., become meaningless.

A method of integration that is always powerful for problems of this type involves the use of developments in trigonometric series. M. Hupner[45] has developed the theory of buckling in hinged and fixed arches and presents general formulas for the amplification of deflections. Values of Δm_a and M_{ae} are proportional when the curve of M_{ae} is a sinusoid. This property is only approximate for other laws of variation of M_{ae}. When $M_{ae} = M_o \left(\frac{\sin 2\,\pi\,s}{L'} + \lambda\,\frac{\sin 4\,\pi\,s}{L'}\right)$ (in which λ is a constant), the amplification factor at the crown is:

$$c_1 = \frac{c}{1 + \lambda}\left[1 + \lambda\,\frac{\pi^2\,E\,I + T\,(L')^2{:}4}{\pi^2\,E\,I + T\,(L')^2{:}16}\right] \qquad \text{(72)}$$

For $\lambda = \pm\,0.1$ and $c = 1.64$, the values of c_1 are, respectively, 1.59 and 1.70. If the moment M_{ae} is constant on each half span, with opposite values on the two halves, the factor of amplification is 1.80, corresponding to $c = 1.64$; for a parabolic distribution of moments, it is 1.658, which shows that a sinusoid gives a very accurate value of the coefficient of amplification for that case.

---

[45] "Application des Séries Trigonométriques à l'étude du flambement des arcs," par M. Hupner, *Annales des Ponts et Chaussées*, November, 1935, p. 754.

In reference to Eq. 16, the following can be noted:

(*a*) An average value of T must be used instead of T_a, in the denominator.

(*b*) That average value must include the thrust due to wind and temperature.

(*c*) There is no reason to omit the coefficient N for wind and temperature effects.

(*d*) The separation of moments into those due to dead load and those due to live load for the application of the coefficient of amplification is theoretically incorrect but is certainly acceptable. Theoretically the moments must be developed into components to which various coefficients of amplification must be applied:

$$s = \frac{T_a}{A_a} + \frac{M_{1a}}{S_a} + \frac{M_{2a}}{S_a\left(1 - \frac{T}{T_c}\right)} + \frac{M_{3a}}{S_a\left(1 - \frac{T}{4\,T_c}\right)} + \cdots \ldots\ldots (73)$$

In Eq. 73 the buckling value of the average thrust T_c is approximately equal to $T_c = \frac{4\,\pi^2\,E\,I}{(L')^2}$.

A more exact method of computation is indicated subsequently herein (see Eq. 83). For practical purposes all terms after the third, in Eq. 73, can be omitted, and the total moment M can be divided into a part that is not affected by the coefficient of amplification, and a part that is affected by that coefficient. This shows that an expression of the type:

$$s = \frac{T_a}{A} + \frac{M_{1a}}{S_a} + \frac{M_{2a}}{S_a\,(1 - T{:}T_c)} \ldots\ldots\ldots\ldots\ldots\ldots (74)$$

seems acceptable.

The condition $N\,T < T_c$; or, as written in the Symposium (see paragraph following Eq. 16), $N\,T_{0.25}\left(\frac{u_{0.25\,E}}{M_{0.25\,E}}\right) < 1$ theoretically applies, not only to arches carrying no moment, but also to all arches symmetrically loaded; the condition is actually unnecessary, either because of initial inaccuracies or because of unsymmetrical loading (only canal bridges would not give unsymmetrical loading).

It is possible to apply the foregoing methods of calculation to the case of a hingeless arch. Considering the half arch as a uniformly loaded beam, hinged at the crown and fixed at the skewback, the moment (with the origin at the crown) is:

$$M = -\,w_a\left[\,(1 - \cos s{:}j)\,j^2 - \frac{\sin s{:}j}{\sin p}\,j^2\,J\,\right] \ldots\ldots\ldots\ldots (75)$$

and the maximum occurs for $s = s_o$ such as

$$\tan\frac{s_o}{j} = \frac{J}{\sin p} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76)$$

in which $j^2 = -\,\frac{E\,I}{T}$; $p = \frac{L_c}{j}$; and L_c is the half length of the arch or a corrected length taking into account the variations of moment of inertia. The load w_a is the antisymmetrical part, equal to one half of a live load distributed on half the span. The quantity J is equal to:

$$J = (1 - \cos p) - p^2 \frac{\tan \frac{p}{2} - \frac{p}{2}}{1 - p \tan p} \dots\dots\dots\dots\dots (77)$$

The maximum moment has the value

$$M = w_a j^2 \left(1 - \frac{1}{\cos s_o : j} \right) \dots\dots\dots\dots\dots (78)$$

An approximate value of the maximum moment is (T_c = buckling thrust of a hinged arch):

$$M = \frac{9}{128} w_a (L_c)^2 \frac{1}{1 - 0.5\, T : T_c} \dots\dots\dots\dots\dots (79)$$

When the arch is reinforced toward the skewbacks, the corrected length L_c is shorter than the actual development of the half arch and can be determined approximately by considering the angular deflection near the skewbacks. The equivalent length giving the same rotation as the actual length is $L_c = \int \frac{I_o}{I}\, ds$ in which I_o is for the basic section. For the Niagara Bridge it is approximately 470 ft. Thus the critical thrust is $T_c = - \frac{88.2 \times 29{,}500 \times 144 \times \pi^2}{470^2}$ $= - 16{,}700$. With $T = - 6{,}460$, the value c is 1.24. The total moment for $\overline{DL} + \overline{LL}$ is then 11,948 × 1.24 + 2,138 = 16,950, which differs by 2% from the value 16,628 calculated in Table 3. The error in the final stress due to the simplified calculation would be less than 1%. Thus, very simple calculations give accurate values of moments. If a higher degree of accuracy is sought, then the expressions developed in the Symposium are no more adequate than the foregoing simplified expressions.

Conclusions from the First Symposium Paper.—Conclusions 1 and 2 are incorrectly formulated, since the factor to be considered is the dimensionless quantity $\frac{T}{T_c} \left(\text{or } \frac{T\,u}{M} \right)$ and not the factor $T\,u$. This factor has been well known for many years. Conclusion 2, as applied to heavy dead loads, is often incorrect. Let s_a = stress due to axial load, s_c = stress due to the axial load that produces a given buckling, and s_b = the stress due to bending, without amplification. It can be shown that, for $\frac{s_a}{s_c} + \frac{s_b}{s_a} < 1$, an increase of dead weight effects a decrease of the influence of the coefficient of amplification on the total stress. Moreover, an increase of dead weight generally means an increase of the depth of the arch; thus, s_c is increased and the coefficient of amplification is reduced, which adds to the effect indicated. Considering the two arches analyzed from that point of view, an increase of dead weight on the hinged arch may cause a small increase of the flexibility effect on the total stress (increase limited to 2% for an increase of 40% of dead weight), whereas the fixed arch is in the zone in which an increase of dead weight causes a decrease of the flexibility effect.

Much simpler design formulas than those indicated are available for many conditions of beam-columns and such formulas can be applied to arches without any difficulty.

Moments in Flexible Two-Hinged Arches.—The methods of analyzing problems of stress distribution by tests are generally more costly and require more time than mathematical approaches to the same problems. In the case of flexible two-hinged arches, the mathematical treatment is so simple and so commonly known that tests do not add any real knowledge and, if not interpreted with the use of the theory, may even be misleading. The interpretation of the tests made on two-hinged arches is an example of such a case.

It is here assumed that the moments due to dead weight have been eliminated by a change of span compensating for the shortening of the arch. Only in that manner can a pressure line coincide with the neutral line of the arch; but it is to be noted that the distribution of dead load is then far from an actual distribution, since the load must be inversely proportional to $\cos^3 \alpha$. For the three arches examined, this signifies that the ratio of dead load at skewbacks and at crown is equal, respectively, to 1.8, 2.6, 7.7. As it is improbable that actual variations of dead load will be greater than 40% between crown and skewbacks, the tests do not seem to represent actual conditions. On the other hand, in order to compare more accurately the results of tests and the theoretical results indicated hereafter, it would be desirable to know the exact law of variation which was used for dead load.

The moment at any point of an arch is equal to the moment of a non-flexible arch multiplied by the coefficient of amplification; using Eq. 14*a*, $M_{af} = \dfrac{M_{ae}}{1 - T_a\, u_{ae}:M_{ae}}$. The ratio, $\dfrac{M_{ae}}{u_{ae}}$, is a constant, equal to the critical thrust T_c, and T_a can be replaced by $R_{td}\,\overline{DL} + 0.5\, R_{tl}\,\overline{LL}$. That expression is exact (changes of length omitted) for a uniform load extending over one half of the span. For other distributions of live load, the factor 0.5 would be changed. It can be shown that (approximately) the ratio of thrust to live load R_{tl} is equal to $R_{td}\left[1 - \dfrac{2\,(\alpha_s)^2}{7}\right]$. Calling $\overline{DL}_o$ the dead load corresponding to the critical thrust T_c, and introducing a coefficient of moment m (ratio of moment to live load) such that $M_{ae} = m\,\overline{LL}$, the value of M_{af} is:

$$M = \frac{m\,\overline{LL}}{1 - \dfrac{\overline{DL} - \overline{LL}\,[0.5 - (\alpha_s)^2:7]}{\overline{DL}_o}} \quad \dots\dots\dots\dots\dots (80)$$

replacing $\overline{LL}$ in terms of $\overline{DL}$ and $R\left(=\dfrac{\overline{DL}}{\overline{LL}}\right)$:

$$M = \frac{m\,\overline{DL}}{R\left(1 - \dfrac{\overline{DL}}{\overline{DL}_o}\right) - \dfrac{\overline{DL}}{\overline{DL}_o}\left[0.5 - \dfrac{(\alpha_s)^2}{7}\right]} \quad \dots\dots\dots\dots (81)$$

Thus, the curve representing M as a function of R is a hyperbola. Eq. 81 contains two constants m and $\overline{DL}_o$ instead of the four constants of Eq. 24, since the factor $\frac{(\alpha_s)^2}{7}$ generally may be neglected. Such constants can be computed easily, and the final expression of the moment becomes

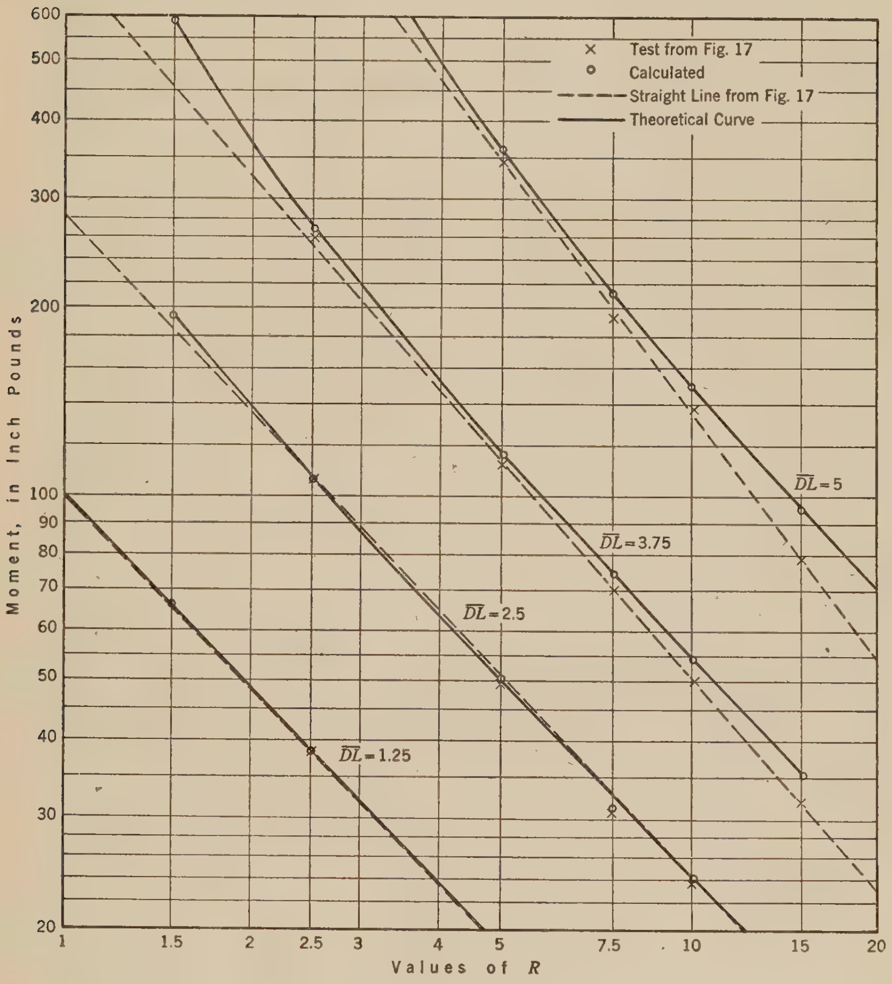

FIG. 41.—LOG-LOG PLOT OF MOMENTS

$$M = \frac{L^2\,\overline{LL}:64}{1 - \frac{(L')^2}{4\pi^2 (r_o)^2} - \frac{(L')^2 r_o}{4\pi^2 E I}\left[1 + \frac{(\alpha_s)^2}{6}\right]\left\{\overline{DL} + \overline{LL}\left[0.5 - \frac{(\alpha_s)^2}{7}\right]\right\}} \quad \ldots(82)$$

The quantity $1 + \frac{(\alpha_s)^2}{6}$ takes into account the average value of the thrust in the arch. Since $\frac{L'}{2\,r_o} = \alpha_s$, Eq. 82 can be written:

$$M = \frac{L^2\,\overline{LL}\,[1 + 0.1\,(\alpha_s)^2]:64}{1 - [1 + 0.6\,(\alpha_s)^2]\left\{\overline{DL} - \overline{LL}\left[0.5 - \frac{(\alpha_s)^2}{7}\right]\right\}L^2\,r_o:(4\,\pi^2\,E\,I)} \;\ldots(83)$$

Fig. 41 affords a comparison between the calculated values and those read from Fig. 17 of the moments. The relative average difference is + 4.5% between the theoretical values and the tests. The average difference would be less if the dead load varied less than indicated by the law $\frac{1}{\cos^3 \alpha}$, and would change its sign for a relative variation equal to half of that given by such law.

As the relation between M and R is represented by a hyperbola, on a log-log diagram, the hyperbola becomes a curve with two asymptotic directions, one parallel to the M-axis and corresponding to buckling, and the other at an angle − 45° with the axes. The straight lines in Fig. 17 are the parts of the transformed hyperbolas which are far from the region of maximum curvature. Thus, they have no significance and do not even represent the asymptotic direction at 45°, since they show the beginning of the amplification effects. On the other hand, moments must become infinite when the loads approach buckling values. For instance, for $\overline{DL} = 5$ and 3.75, buckling occurs when $R = 1.5$ and 0.6, respectively. Therefore, it seems that Eq. 24 has no practical value, since its validity is limited to the range of the tests while Eq. 83 is valid for any values; and moreover it is more complicated and requires more computation than the theoretical expression, Eq. 80. It is to be noted that, in Eq. 24, the loads are in kips per foot and moments are in thousands of foot-kips. The authors have realized the advantage of the coefficient of amplification (called by them "percentage increase") but have made no attempt to introduce it on a rational basis and relate it to the critical thrust. With the use of the theory it is much easier for the designer to examine the influence of changes in shape of the arch and distribution of the load, and tests are unnecessary. Also, the main factors, span L, rigidity $E\,I$, dead load $\overline{DL}$, live load $\overline{LL}$ enter into a theoretical formula in a much more expressive manner than in a formula of the type of Eq. 24, which gives no measure of the relative influence of the various parameters.

The theoretical formula, Eq. 83, reduced to

$$M = \frac{L^2\,\overline{LL}}{64 - (2\,\overline{DL} - \overline{LL})\,L^4:(\pi^2\,h\,E\,I)} \;\ldots\ldots\ldots\ldots\ldots(84)$$

will enable the designer to visualize the influence of the main factors, especially the rise of the arch.

Conclusions, Second Symposium Paper.—The conclusions advanced in this second paper of the Symposium do not throw any new light on well-known results. Tests of the kind made (conclusions 1, 2, and 3) are of little interest, since simple and reliable theories are available, and from such theories definite arches can be selected directly, either for bridges or for hangar roofs. A hingeless arch generally will prove less costly than a two-hinged arch, but there is no special reason to avoid the latter in cases where the coefficients of amplification are small (say, less than 2) when it is difficult to fix the ends. In airplane design, for instance, high coefficients of amplification are accepted.

It is obvious that methods which do not take into consideration beam-column effects are unreliable (conclusion 4), but it is to be hoped that no designer will calculate flexible structures without considering buckling and prebuckling effects—that is, the coefficients of amplication.

There is no doubt that correctly chosen average values of radii and moments of inertia (conclusion 5) will enable the designer to make use of formulas or test data related to circular arches; but no difficulty is encountered in making direct calculations for any type of arch.

It is well known that the relationship between load and stress in beam-columns is not linear (conclusion 6). This fact is taken into account in various specifications for margins of safety—for instance in the Army-Navy-Civil Specifications for Aeronautics (see ANC-5), and also in many recent foreign specifications applied to civil engineering (French Air Department, Air Bases Division, dated about 1934 or earlier).

Since arches buckle in two waves and a change of length introduces a moment corresponding to one wave, the two phenomena are independent, and the nondeflectional theory is valid for temperature stresses (conclusion 7). However, the change of thrust due to temperature will change the coefficient of amplification; and thus there is an influence of temperature on buckling and on live-load moments. That effect, which is small for a bridge, is applied in automatic devices used in temperature control; and it cannot be disregarded entirely.

Nothing fundamentally new has been advanced in the analysis of the Rainbow Arch Bridge (conclusion 8).

It would be very desirable to know precisely what are the "inconsistencies with the elastic theory" (conclusion 9) which occur in the fixed-end type of arch.

Fabrication and Erection Controls.—Unusual care has been taken in the fabrication and erection of the Rainbow Arch Bridge (third Symposium paper), and the engineers who directed that work can consider it as a genuine achievement. It also appears that their computations have been made with all desirable accuracy.

It seems useful to note (see heading, "Application of Data to Niagara Rainbow Arch Bridge") that the elastic centroid concept, which the authors of the third paper took from the 1925 Edition of Müller-Breslau's book,[17] was taught by Maurice Lévy[46] in France as early as the end of the last century in École Centrale des Arts et Manufactures. The correct expression, as used in treatises on mathematics, is "orthogonalisation" and not segregation; and the elastic centroid method is only a special case of the methods of "orthogonalisation" of the unknowns in systems of linear equations.

Moments can be applied at the crown instead of the centroid, since the axis of a moment can be freely displaced without changing the equilibrium.

The elastic center can be determined by a straightforward method (column analogy), which is still valid when deflections due to normal and shearing forces are taken into account.

[46] "La Statique Graphique et ses Applications aux Constructions, 1886–1888," Gauthier-Villars & Co., Paris.

Neil Van Eenam,[47] M. Am. Soc. C. E.—The problems of research, design, fabrication, and erection involved in the construction of the new Rainbow Arch Bridge are presented in a clear and thorough manner in this Symposium. Until recent years, no solid rib arch would have been structurally and economically feasible, or even possible, for the 950-ft span over the Niagara gorge, because of the excessively thick web plates that would have been necessary. Now, methods are available for stiffening the web plates longitudinally so that plates of reasonable thickness may be employed. On the Rainbow Arch Bridge, longitudinal stiffeners have been used to the best advantage by making them serve an architectural as well as a structural purpose.

The investigation of deflections and of secondary stresses is an outstanding example of the thoroughness of the design. The authors deserve great credit for calling attention to the inadequacy of the elastic theory when deflections are appreciable. This word of caution in regard to the magnitude of the secondary stresses applies with equal force to the design of arch ribs of moderate span, particularly when two-hinged or three-hinged ribs are to be of shallow depth.

The Rainbow Arch Bridge is pleasing and graceful in appearance, and, because of the absence of bracing, it offers only slight obstruction to the view. If the rigidity of the spandrel columns is such that the lateral bracing may be omitted safely, the engineers have succeeded remarkably in building a monumental structure that harmonizes with the landscape.

C. H. Gronquist,[48] Assoc. M. Am. Soc. C. E.—Only at rare intervals does there come to the bridge engineer a problem so satisfying to the engineering mind and heart as the bridging of the Niagara gorge. That the designers and builders of the Rainbow Arch Bridge have produced a solution which is eminently right is evident. The papers in this Symposium present more than adequately the record of this achievement of the authors.

A project which makes similar appeal to the bridge engineer is the Henry Hudson Bridge at Spuyten Duyvil in New York, N. Y. This 800-ft arch was built in 1936 as a four-lane bridge, and prior to the construction of the Rainbow Arch Bridge held the distinction of being the longest steel fixed arch bridge. The general designs of the two bridges are essentially alike, although an upper deck accommodating three lanes was added to the Henry Hudson Bridge in 1938 to transform it into a six-lane bridge, and there are many differences in important features of detail design. Although the design and erection of the Henry Hudson Bridge have been described elsewhere,[49,50] a brief comparison of the two structures should be included in the discussion of this Symposium.

The rib of the Henry Hudson Bridge, like that of the Rainbow Arch Bridge, consists of a silicon steel box girder of constant depth, except for a short section adjacent to each skewback. Unlike that of the Rainbow Arch Bridge, the rib section of the Henry Hudson Bridge (which is 12.6 ft deep and weighs 2,400 lb per ft) is composed of two separate girders 3 ft 8 in. center to center, connected by heavy lacing at both flanges and at mid-height.

[47] Highway Bridge Engr., U. S. Public Roads Administration, Washington, D. C.

[48] Associate Engr., Robinson & Steinman, New York, N. Y.

[49] "Designing the Longest Fixed Steel Arch," by D. B. Steinman and C. H. Gronquist, *Engineering News-Record*, August 13, 1936, p. 232.

[50] "Special Problems of Hingeless Arch Erection," by W. K. Greene, *ibid.*, November 12, 1936, p. 669.

The skewback section of the rib and the anchorage to the abutment are generally similar for the two bridges, and flexible connections were used at the top and bottom of the spandrel columns for both bridges to reduce temperature and participation stresses in the columns and deck framing. Lateral bracing between the spandrel columns in the Henry Hudson Bridge is laid out in conformance with the bracing in the steel towers surmounting the skewbacks and the bents of the approach spans, which were of steel construction for reasons of economy.

The Henry Hudson Bridge was erected simultaneously from both ends of the span by cantilevering over steel falsework bents supported by cage-braced steel piles driven to rock. The falsework bents were located near the eighth points and quarter points of the arch, and at the quarter-point bents the ribs were reinforced by toggles consisting of eyebar chains and a bent which later became the end spandrel bent of the bridge. The grillages were erected on steel supports set on the concrete of the skewbacks in such manner as to permit jacking the grillages in any direction to secure their accurate location.

Careful check was made of the actual distance between grillages before erecting the skewbacks, and from these data, and the length of the shop rib assemblies, it was determined that the crown closing piece for the Henry Hudson Bridge, nominally 30 in. long, should be fabricated $\frac{1}{2}$ in. short. A practically perfect check of the elevation of the crown of the arch after closure confirmed the efficiency of the closure scheme. This is made further evident by considering that 1-in. error in length of the rib of the Henry Hudson Bridge (1-in. error in length of the span was assumed in the design), corresponding to 15° F change in temperature, would have changed the elevation of the crown 1.5 in., whereas the change in thrust would have been 28 kips, or only slightly more than 1% of the thrust at the time of closure. From the foregoing it is apparent that check of elevation of the axis is at the same time the most sensitive as well as the most simple check on the calculated stress in the rib at closure, and that, if proper precision is used in field layout and shop fabrication, no adjustment need be made at closure. The latter is essentially the conclusion of the authors of the third Symposium paper, to which the writer would take exception only by stating that, if the span between grillages is known to be correct and if it is determined by measurement of length and elevation of rib at closure that the steel is not of correct length, such error should be compensated for by adjustment at closure.

Jacking arrangements at the crown were similar for the two bridges, except that for the Henry Hudson Bridge only one 500-ton jack was used at each flange, the width of opening between the half arches was 30 in., and a small pin was introduced in the bottom flange, where, on release of the jacking force, contact between the two half ribs would be made first. The crown jacks, which were interconnected and operated from a single pump to maintain non-eccentric axial load until initial closure was made, were first brought to capacity load. Because closure was made on a July day when the temperature rose to 90° F, it also was necessary to jack at the quarter-point bents, while maintaining constant load on the crown jacks.

The problem of determining the effect of deflection on the stresses in a slender arch is unquestionably of prime importance. In an effort to circumvent the laborious cut-and-try procedure for obtaining the final moments and deflections termed "exact" by the authors of the first Symposium paper, the writer, some time before the publication of this Symposium, derived a formula for the so-called "deflection-theory" correction of the usual elastic-theory moment and deflection that can be applied as soon as the moment of inertia of the rib at the crown has been estimated.

The usual assumption is made that the arch axis is parabolic and that the moment of inertia of the rib varies with the secant of the slope of the axis. Vertical deflections may then be computed by considering the rib as a horizontal beam of constant moment of inertia equal to that at the crown. Half-span live load on such a two-hinged arch produces deflection in two segments with zero moment and deflection at the crown. Neglecting the effect of distortion and shortening of the rib, the vertical deflection at either quarter point will be:

$$\eta_e = \frac{\dfrac{p\,L^2}{64}}{4 \times 9.6\,\dfrac{E\,I}{L^2}} = \frac{M_e}{P_{e-v}} \quad \text{.....................(85)}$$

The numerator of Eq. 85 is the value of the moment at the quarter point of the arch. The denominator is the buckling load of the rib, for elastic curve deflection, taken as a horizontal strut of length $L/2$ between the end hinge and central point of contraflexure. Since there is zero deflection at the point of contraflexure, the half arch under this loading is analogous to a simple beam with a full-span uniformly distributed load. The center deflection for a fully loaded simple beam is also equal to the moment at the center divided by the buckling load of the beam, for elastic curve deflection, taken as a column of length L.

Written in terms of the quarter-point moment, the horizontal deflection at the loaded quarter point, neglecting the effect of distortion and shortening of the rib, is:

$$\rho_e = \frac{\dfrac{p\,L^2}{64}}{\dfrac{50}{41} \times 9.6\,\dfrac{E\,I}{h\,L}} = \frac{M_e}{P_{e-h}} \quad \text{.....................(86)}$$

in which the denominator is again a buckling load, dependent on the rise h as well as on the span L of the arch.

For loading of this type, producing negligible deflection at the crown, the value of $H_w + H$ is practically unaffected by deflection, and the correction in moment due to vertical deflection is merely $(H_w + H)\,\eta$. To obtain the correction in moment due to horizontal deflection, it is assumed for simplicity that all points on the arch have the same horizontal deflection and that the position of the live load changes by that amount. Then at the quarter point the correction in moment is $\frac{\rho\,(w + p)\,L}{4}$. This assumption errs on the side of maximum deflection effect. The total final moment at the quarter point is:

$$M_f = M_e + (H_w + H)\,\eta + \frac{\rho\,(w + p)\,L}{4} \qquad \text{(87)}$$

If it is assumed that the deflection correction in deflection is in the same proportion as the deflection correction in moment, the expressions for final deflection become $\eta = \frac{M_f}{P_{e-v}}$ and $\rho = \frac{M_f}{P_{e-h}}$; or

$$\eta = \frac{M_e + \frac{\rho\,(w + p)\,L}{4}}{P_{f-v}} \quad \text{and} \quad \rho = \frac{M_e + (H_w + H)\,\eta}{P_{f-h}} \qquad \text{(88)}$$

in which

$$P_{f-v} = 4 \times 9.6\,\frac{E\,I}{L^2} - (H_w + H) \quad \text{and} \quad P_{f-h} = \frac{50}{41} \times 9.6\,\frac{E\,I}{h\,L} - \frac{(w + p)\,L}{4} \qquad \text{(89)}$$

The final buckling loads as corrected for the effect of deflection are reduced from the values computed by the usual elastic theory by the amount of the horizontal thrust and the vertical shear term.

Solving Eqs. 88 simultaneously to obtain the values of the vertical and horizontal deflection at the quarter point:

$$\eta = \frac{M_e}{P_{e-v} \times \frac{P_{f-h}}{P_{e-h}} - (H_w + H)} \quad \text{and} \quad \rho = \frac{M_e}{P_{e-h} \times \frac{P_{f-v}}{P_{e-v}} - (w + p)\,\frac{L}{4}} \qquad \text{(90)}$$

Substituting Eq. 90 in Eq. 87, the ratio of the final moment to that by the elastic theory is:

$$\frac{M_f}{M_e} = 1 + \frac{H_w + H}{P_{e-v} \times \frac{P_{f-h}}{P_{e-h}} - (H_w + H)} + \frac{(w + p)\,\frac{L}{4}}{P_{e-h} \times \frac{P_{f-v}}{P_{e-v}} - (w + p)\,\frac{L}{4}} \qquad \text{(91)}$$

If only the effect of vertical deflection is considered, Eq. 91 reduces to

$$\frac{M_f}{M_e} = 1 + \frac{H_w + H}{P_{f-v}} = 1 + \frac{H_w + H}{4 \times 9.6\,\frac{E\,I}{L^2} - (H_w + H)} \qquad \text{(92)}$$

With Eq. 92 written in terms of total thrust $(T_w + T)$ at the quarter point, and the buckling load computed for the length of the rib from the end hinge to the crown, the ratio of the final positive or negative moment and deflection to that obtained by the elastic theory, on the basis of radial deflections, is obtained. Thus:

$$\frac{M_f}{M_e} = 1 + \frac{T_w + T}{P_f} \quad \text{(93)}$$

in which

$$P_f = \frac{4 \times 9.6\, E\, I}{L^2 \left(1 + \frac{16\, h^2}{3\, L^2}\right)} - (T_w + T) \quad \text{(94)}$$

Radial deflections are computed from the moment at the quarter point:

$$u_e = \frac{M_e}{P_e} \quad \text{and} \quad u = \frac{M_e}{P_f} = \frac{M_f}{P_e} \quad \text{(95)}$$

The buckling load of Eq. 94 is the critical buckling load for the arch, neglecting the minor reduction due to the effect of curvature. This equation, therefore, should be used for stability computations in determining the factor of safety of an arch against buckling under all possible loads, as in Eqs. 16 and 17.

The foregoing relations have been previously developed for the stability of struts subjected to lateral loads,[51, 52] and their application to arches has been indicated.[43] Eqs. 14 will be found to reduce to the form of Eq. 93, since $P_e = \frac{M_{ae}}{u_{ae}}$; and also to the form of Eq. 92, if the horizontal thrust and vertical deflection only are substituted in Eqs. 14.

Applying Eqs. 91 to 95 to the two-hinged design for the Rainbow Arch Bridge for a half-span load of 1.5 kips per foot of rib:

$$\frac{M_f}{M_e} = 1 + \frac{7{,}350}{20{,}850 \times \frac{37{,}850}{40{,}350} - 7{,}350} + \frac{2{,}500}{40{,}350 \times \frac{13{,}500}{20{,}850} - 2{,}500} = 170.6\%;$$

$$\frac{M_f}{M_e} = 1 + \frac{7{,}750}{10{,}650} = 172.8\%; \qquad M_e = \frac{1.5 \times (950)^2}{64} = 21{,}150 \text{ ft-kips};$$

$$M_f = 1.728 \times 21{,}150 = 36{,}500 \text{ ft-kips};$$

$$\eta_e = \frac{21{,}150}{20{,}850} = 1.01 \text{ ft}; \qquad \eta = 1.706 \times 1.01 = 1.73 \text{ ft};$$

$$\rho_e = \frac{21{,}150}{40{,}350} = 0.525 \text{ ft}; \qquad \rho = 1.706 \times 0.525 = 0.90 \text{ ft};$$

$$u_e = \frac{21{,}150}{18{,}400} = 1.15 \text{ ft}; \qquad u = 1.728 \times 1.15 = 1.98 \text{ ft};$$

---

[51] "Buckling of Elastic Structures," by H. M. Westergaard, *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 576.

[52] "Airplane Structures," by A. S. Niles and J. S. Newell, 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1943.

and $$[(\eta_e)^2 + (\rho_e)^2]^{0.5} = 1.14 \text{ ft}; \qquad (\eta^2 + \rho^2)^{0.5} = 1.95 \text{ ft}.$$

A satisfactory check is observed between deflection-theory corrections obtained on the basis of vertical and horizontal deflection components and radial deflection. The results are likewise in good agreement with those of the authors of the first Symposium paper by their approximate method. Considering only vertical deflections: $\frac{M_f}{M_e} = 1 + \frac{7{,}350}{13{,}500} = 154.5\%$. Therefore the effect of including the influence of horizontal deflection is to increase the deflection-theory correction from 54.5% to 70.6% or 72.8%.

Maximum positive moment by the elastic theory is produced at the quarter point for 0.43-span load rather than half-span load, and the horizontal distance to the point of contraflexure is 0.47 L rather than 0.5 L. Using this length in computing the buckling loads:

$$\frac{M_f}{M_e} = 1 + \frac{7{,}250}{23{,}400 \times \frac{40{,}230}{42{,}700} - 7{,}250} + \frac{2{,}470}{42{,}700 \times \frac{16{,}150}{23{,}400} - 2{,}470} = 158.2\%;$$

$$\frac{M_f}{M_e} = 1 + \frac{7{,}700}{12{,}900} = 159.6\%; \qquad M_e = \frac{1.5 \times (950)^2}{60} = 22{,}550 \text{ ft-kips};$$

and $M_f = 1.596 \times 22{,}550 = 36{,}000$ ft-kips. The final moment is little different for the two loadings, since the deflection correction is reduced with reduction in length to the point of contraflexure.

Although not discussed by the authors, maximum moment is produced at the crown by a central 0.3-span loading. Horizontal deflection of the haunches is small, and may be neglected in obtaining the deflection correction approximately. Deflection is in three segments or loops, with an accompanying increase in $H_w + H$ due to crown deflection. Since the distance between points of contraflexure is reduced to about 0.33 L, the arch is stiffer than under half-span load, and the deflection correction is correspondingly smaller. The value of $H_w + H$ is changed by deflection; therefore the deflection-theory increase in moment due to vertical deflection cannot be obtained as for half-span load, but it can be approximated by application of Eq. 92, using the reduced value of 0.33 L in place of $L/2$ for the length of strut in computing the buckling load, and using the value of H computed by the elastic theory. For the Rainbow arch two-hinged design: $H_e = 0.0565 \times 1.5 \times \frac{(950)^2}{150} = 510$ kips; $P_{f-v} = \left(\frac{0.50}{0.33}\right)^2 \times 20{,}850 - (6{,}790 + 510) = 40{,}700$ kips; $\frac{M_f}{M_e} = 1 + \frac{7{,}300}{40{,}700} = 117.9\%$; $M_e = 0.0725 \times 1.5 \times (950)^2 = 9{,}800$ ft-kips; and $M_f = 1.179 \times 9{,}800 = 11{,}550$ ft-kips. This correction would be increased slightly by use of Eq. 92, with the buckling load computed for the length of rib between points of contraflexure to account for the effect of horizontal deflection.

The problem of approximating the deflection-theory correction for the fixed arch near the quarter point is more complex than for the two-hinged structure, since both linear and angular deflection occur at the point of contraflexure near the skewback of the former, whereas only angular deflection can occur at the end hinge of the latter. The value of $H_w + H$ is only slightly affected by deflection for either type, however, vertical crown deflection being negligible. The percentage of deflection-theory correction for the fixed arch, as for the two-hinged arch, is best computed by Eqs. 92 and 93, using the distance between the points of contraflexure for the loading considered. The percentage so computed is practically constant between the respective points of contraflexure, a considerable decrease occurring only near the skewbacks in the fixed arch.

Final deflections for both types of arches may be approximated by increasing elastic-theory deflections by the percentage of deflection-theory correction for moment. The maximum vertical deflection by the elastic theory at the five-sixteenth point of a fixed arch for half-span load may be written:

$$\eta_e = \frac{\dfrac{9\,p\,L^2}{1{,}024}}{\dfrac{192}{35} \times 9.6\,\dfrac{E\,I}{L^2}} = \frac{M_e}{(P_{e-v})'} \qquad \text{(96)}$$

in which the numerator is the moment at the five-sixteenth point of the fixed arch, and the denominator is a buckling load. This buckling load is smaller than the buckling load for the 3/8 L distance between the points of contraflexure for half-span load, however, because the total vertical deflection, not the deflection from a straight line joining the points of contraflexure, is being measured. Similarly, the horizontal deflection at the five-sixteenth point, written in terms of the moment at the five-sixteenth point, is:

$$\rho_e = \frac{\dfrac{9\,p\,L^2}{1{,}024}}{\dfrac{384}{205} \times 9.6\,\dfrac{E\,I}{h\,L}} = \frac{M_e}{(P_{e-h})'} \qquad \text{(97)}$$

For the Rainbow Arch Bridge with a half-span load of 1.5 kips per foot of rib: $P_{f-v} = \frac{64}{9} \times \frac{9.6 \times 29{,}400 \times 11{,}688}{(950)^2} - (5{,}910 + 560) = 19{,}530$ kips;

$$P_f = \frac{26{,}000}{1 + 3\left(\dfrac{150}{950}\right)^2} - 6{,}700 = 17{,}500 \text{ kips}; \qquad \frac{M_f}{M_e} = 1 + \frac{6{,}470}{19{,}530} = 133.2\%,$$

considering vertical deflection; $\frac{M_f}{M_e} = 1 + \frac{6{,}700}{17{,}500} = 138.2\%$, considering radial deflection; and $M_f = 11{,}900 \times 1.382 = 16{,}400$ ft-kips. Comparison of the foregoing results for the deflection-theory correction indicates that in the fixed arch the effect of horizontal deflection is of minor importance and ordinarily may be neglected.

To compute deflections:

$$(P_{e-v})' = \frac{27}{35} \times 26{,}000 = 20{,}000 \text{ kips};$$

$$(P_{e-h})' = \frac{384}{205} \times \frac{9.6 \times 29{,}400 \times 11{,}688}{150 \times 950} = 43{,}400 \text{ kips};$$

$$(P_e)' = \frac{20{,}000}{1 + \frac{35}{9}\left(\frac{150}{950}\right)^2} = 18{,}250 \text{ kips}; \qquad \eta_e = \frac{11{,}900}{20{,}000} = 0.595 \text{ ft};$$

$$\eta = 1.382 \times 0.595 = 0.82 \text{ ft}; \qquad \rho_e = \frac{11{,}900}{43{,}400} = 0.275 \text{ ft};$$

$$\rho = 1.382 \times 0.275 = 0.38 \text{ ft}; \qquad u_e = \frac{11{,}900}{18{,}250} = 0.65 \text{ ft};$$

and

$$u = 1.382 \times 0.65 = 0.90 \text{ ft}.$$

The deflection correction would actually be less than the foregoing due to greater stiffness near the skewback than assumed in the formulas. A closer agreement with the percentage of correction of the authors is obtained for a 0.415-span load with a 0.32 L distance between points of contraflexure as shown in Fig. 12 and Table 3.

Half-span wind load moments as obtained by the usual elastic theory, like live-load moments, are subject to correction for the effect of deflection. Such correction is not considered by the authors of the first Symposium paper in writing Eqs. 16, 17, and 21 for permissible flange stress, including the effect of buckling.

Eqs. 17 and 21 are proposed for design use by the authors of the first Symposium paper. When corrected for the effect of deflection on wind moment, they should prove useful in conjunction with the usual computation of maximum stresses for the design loads. For box-girder rib construction the safety factor of approximately 1.8 currently used for (dead + live + impact)-load stresses appears proper for (dead + live + impact)-load + temperature + error stresses in arches, increased for deflection or buckling effect. For single-web rib construction the working stress should be decreased in proportion to L/b or L/r to allow for the greater tendency toward lateral buckling between bracing points. In conformance with current practice, the safety factor for box-girder ribs would be reduced to 1.5 with the addition of wind stresses, also increased for deflection effect.

It is regrettable that the authors of the second Symposium paper were unable to make a complete determination of the deflection effects on a circular fixed arch, as they have done so excellently for the two-hinged type, or that the findings obtained on the fixed model were not published, unless they were not considered reliable.

The approximate method of the writer for parabolic arches, with moment of inertia varying as the secant of the slope of the rib axis, gives final quarter-point moments for half-span load on two-hinged arches of varying rise ratio which are in reasonably good agreement with those of Eq. 24 for circular arches of constant moment of inertia where the length-rise ratio L/h is 6.3 or 5.0. Although the final positive moment at the quarter point by Eq. 24 for the Rainbow arch two-hinged design is less for $L/h = 5.0$ than for the flatter arch with $L/h = 6.3$, that for the arch of high rise with $L/h = 3.5$ is practically the same as that for the flattest arch ($L/h = 6.3$). This is contrary to the results for the parabolic arch, for which the final moment, including the effect of deflection, decreases with increase in rise for the range of rise ratios considered. Comparative results are shown in Fig. 42(*a*). Although the method of the writer will be less accurate for arches of high rise than for flat arches, it is probable that the difference in moments for the arch of high rise ($L/h = 3.5$) is due principally to the greater curvature of the axis of the circular arch. With increasing rise the greater average moment of inertia of the parabolic arch of variable section also will have a small, increasing effect in reducing the deflection correction over that of the circular arch of constant section. Thus

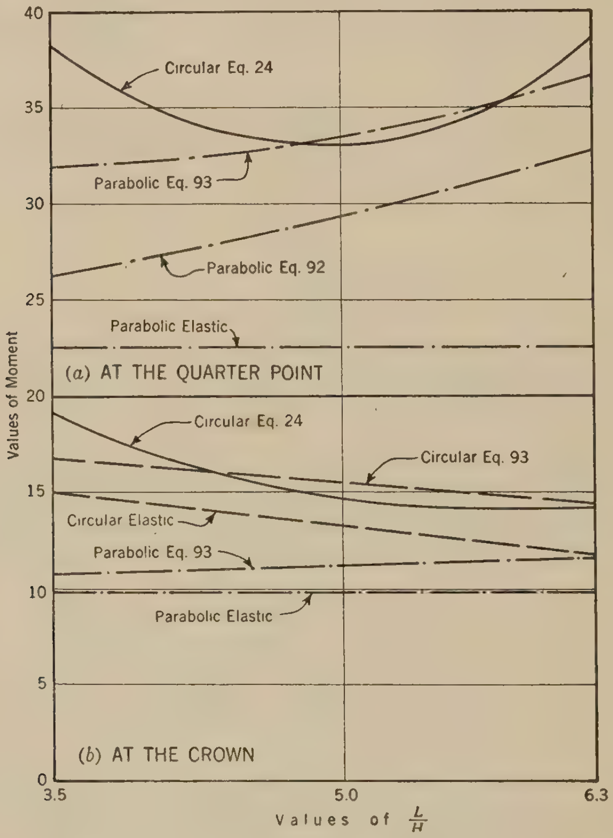

Fig. 42.—Comparison of Moments of Two-Hinged Arch for Varying Rise Ratios ($L = 950$ Ft; $I = 116.14$ Ft^4 at Crown)

the writer concludes, contrary to the authors, that for arches of high rise the deflection correction for parabolic or three-centered arches will be considerably smaller than that for circular arches.

Maximum moments at the crown of the two-hinged design for the Rainbow arch as determined by Eq. 24 and by the writer's approximate method for the circular arch of constant moment of inertia are compared with those for the parabolic arch of variable moment of inertia in Fig. 42(*b*). It is important to note that the crown moment, determined by the usual elastic theory, in the circular arch for one-third span central load, is appreciably greater than that in the parabolic arch for 0.3 span central load, even for the arch of flat rise, and that the difference increases with rise. Quarter-point moment by the elastic theory, for the rise range considered, is slightly less for the circular arch than for the parabolic arch. When the elastic-theory crown moments for the circular arch are increased by the writer's method for deflection-theory effect, and using π^2 in place of 9.6 in computing the buckling loads, good agreement is obtained for all rise ratios, with the possible exception of that for $L/h = 3.5$.

M. HIRSCHTHAL,[53] M. AM. SOC. C. E.—This Symposium on a long span arch bridge is naturally of great interest to engineers, particularly to those concerned with the design of railroad or highway bridges. The profession is grateful to Mr. Hardesty, et al., for the detailed presentation and analysis of the unusual erection and construction problems and their ingenious solution for the Rainbow Arch Bridge over the Niagara gorge from its very inception to its completion. The reason for some of the omissions and the inclusion of some of the material in the Symposium is not clear, however, in view of the thoroughness of the treatment of the entire project.

For instance, there is no information on the various considerations that led to the selection of the particular span length. On the other hand, the model tests seem to have been made on a two-hinged arch to corroborate its rejection rather than on a model of a hingeless arch to verify the stresses and deformations or strains found in the design of the structure selected—the one that was actually built.

Although model tests are very informative, it is dangerous to base all conclusions on them as being applicable quantitatively to prototypes, especially those of extraordinary size. The interest in the Rainbow Arch Bridge is (as has been true in the case of other bridges) due to its unusual span length—the "longest in the world." Had an arch of moderate span length been planned for this site, the writer doubts greatly whether model tests would have been made. Arch action is a normal structural phenomenon that occurs in many forms, although it still has some unexplained features, such as results of temperature effects which model tests (in addition to any mechanical movement of one support) could elucidate. However, even in arch action tests quantitative application of results to prototypes would have to be made with caution.

Since model tests had been made, it would have been exceedingly interesting to have had comparative results of tests on two models, one a fixed-end model and the other the two-hinged model described in the Symposium. Both, of course, should be of identical dimensions, so that resulting deformations for various conditions of loading could be compared. There is no doubt that the very magnitude of the structure produces problems in design that may readily be ignored in smaller structures. For these reasons, results from scale models, particularly when they are of different material from that of the prototype, must not be the sole basis of decision. A 5-ft model is slightly longer than $\frac{1}{200}$th of the span length of the prototype, and, since the deflection varies with the cube of the span for a scaled load, the slightest error will be enormously magnified in the study of deflections.

---

[53] Concrete Engr., D. L. & W. R. R., Hoboken, N. J.

Moreover, the writer questions the original selection of a two-hinged (flexible) arch and all the preliminary work attached to it. After complete analysis and detailed estimates were made, this type of design was discarded in favor of the hingeless arch (fixed) because of the economy of the latter. With outcrops of rock on either side of the gorge or waterway available for abutment foundations, a hingeless or fixed arch would suggest itself immediately as the logical and most economical type. This selection would be discarded only if it should prove too expensive.

In the consideration of economy, the writer is inclined to believe that the selection of three (or possibly even two pairs) of ribs would have resulted in some lessening of duplication of sections but would have reduced girder sections for the floor beams and floor system, thus causing a reduction in the dead load and obviating the necessity of using any alloy steel in the superstructure. This arrangement, moreover, would have required the selected arch-rib section for one rib only (if three ribs were used), whereas the side ribs could have had carbon steel sections, while a stiffer cross section of structure would have been provided. The study of the deformation of the hingeless arch should have led to the selection of a section of rib varying from crown to abutment to provide a deeper section at approximately the quarter point. This would have reduced greatly the deformations due to live load in the vicinity of the quarter point even though this varying section would have complicated the detailing somewhat.

Because the only partial live load considered in the arch analysis of the Symposium was that on half the span, it might be interesting to note that the specifications of the American Railway Engineering Association[54] for Masonry Arches for Railroad Loading require the following live-load conditions:

1. For maximum positive moment at the crown, assume the middle quarter of the span loaded.
2. For maximum negative moment at the crown, assume all of the span loaded except the middle quarter.
3. For the maximum positive moment at the springing line, assume five eighths of the span loaded from the opposite end.
4. For maximum negative moment at the springing line, assume the adjacent three eighths of the span loaded.

---

[54] *Manual for Railway Engineering*, A.R.E.A., 1943, Committee 8, Masonry, Specification 312, Section 10, pp. 8–61.

A structure as important as the Rainbow Arch Bridge should be designed for at least the maximum live-load specifications of HS20 trucks, as defined by the American Association of State Highway Officials.[55] The Veterans' Gorge Arch Bridge in Rochester, N. Y., was designed (in 1930) for 30-ton truck loads to anticipate future increase in truck loading. Moving artillery over the highways has raised the question of rating highway bridges to permit the passage of guns. The increase in live load would have added comparatively little to the total load and resulting stresses and therefore to the cost of the structure, but would have provided for future loading increases.

As for methods of design, it has hitherto been acceptable practice to design arches by the "elastic theory" (an unfortunate expression, as the "theory" is not elastic). In this Symposium, however, doubt is cast on the "assumptions" underlying this theory and a deflection "theory" or method is presented as being exact.

The cables of a suspension bridge form an inverted arch or catenary and are flexible to such an extent that a stiffening truss is introduced in order to minimize the deformations. The resultant action is a pull or tension exerted by the cables under load, in contrast to the thrust or compression resulting from the loads in the case of the arch. In both cases bending moments are caused by the eccentricity of the applied forces. However, an arch (steel or concrete) has relatively much greater stiffness without considering the stiffening effect of the spandrel system (generally ignored in arch design) to resist deformation or distortion.

All theories applied to structures are based on assumptions, and no assumptions are absolutely exact. The closeness of the results of the proposed to those in the actual structure will depend on the closeness of the assumption to actual conditions. No assumption is made in the "Theory of the Elastic Arch" (so-called elastic theory) which is unsound or questionable, particularly for a steel structure in which the modulus of elasticity changes but very slightly in the various sections of the arch. In fact, the only assumptions other than that of elasticity made in this type of analysis for the fixed arch (aside from that of uniformity of E) are that the supports shall be unyielding, so that the horizontal span length remains constant, and that there will be no vertical displacement of one abutment with respect to the other. For the Rainbow arch, with the two abutments fixed in sound rock, the assumptions are as closely approximated as possible. The resulting thrusts will result in an infinitesimal yielding of the abutments or of the rock foundation, but such yielding would be microscopic.

Hardy Cross, M. Am. Soc. C. E.,[56] showed that differences in the value of E in the various sections of such structures were not serious in affecting the analysis of the arch. He investigated effects of variations as great as one third and one half the values of E. Such large variations within the range of working stresses are unusual. In the light of recent research developments, control over concrete will be more strictly observed in the future, and greater uniformity in the product and therefore in the value of E may be expected.

[55] Standard Specifications for Highway Bridges, A.A.S.H.O., 2d Ed., 1935, Div. V, Section 2, Paragraph 7a.

[56] "Dependability of the Theory of Concrete Arches," by Hardy Cross, *Bulletin No. 203*, Univ. of Illinois, Urbana, 1930.

In the early stages of concrete construction for railroad structures in the United States, the arch type of design was quite popular. When the New Jersey cutoff of the Delaware, Lackawanna and Western Railroad Company was projected (1907–1911) between Hopatcong, N. J., and Slateford, Pa., of a total of seventy-six bridges and culverts included in the construction of the line, sixty (that is, 80%) were of the concrete arch type. In the construction of the Pennsylvania cutoff of the same railroad (1912–1915) between Clarks Summit, Pa., and Halstead, Pa., there were sixty-six arch structures, inclusive of two viaducts. One of the viaducts, the Tunkhannock Viaduct, is almost half a mile long, and includes the maximum span length (180 ft clear, or 208 ft center to center of piers), but this structure, of course, was designed for railroad engine loading.

Although considerably greater span lengths have been used for highway loading in the United States, the greatest extension of span length of concrete arches has been developed on the European continent, but no structure has approached the proportions of the Rainbow Arch Bridge.

Naturally, the thought would occur to a designer of concrete bridges: What could be done in concrete for a site like the Rainbow gorge? Fig. 43, for example, seems a rather startling extension of span length for a concrete arch and approaches closely the limits visualized by E. Freyssinet.[57] The writer, when designing the Veterans' Gorge Bridge over the Genesee gorge in Rochester, proposed and made preliminary studies of a 600-ft arch for the main opening to span between the outcrops of rock on either side of the gorge. The resulting structure, however, did not meet the esthetic requirements of the architects retained for the work, so that the 300-ft clear semicircular arch was adopted and built as part of the viaduct. Based on 5,000-lb concrete and intermediate grade reinforcing steel, with working stresses of 1,500 lb per sq in. and 20,000 lb per sq in., respectively, the center rib crown section would have been 16 ft deep by 8 ft wide, 23 ft deep at the springing, and the reinforcement would consist of 25, $1\frac{1}{2}$-in. square bars in the intrados and extrados. The floor system would have been a two-way reinforced concrete slab of 24-ft clear spans in both directions. The length of the span of the spandrel arches surmounting the main span would have been 24 ft.

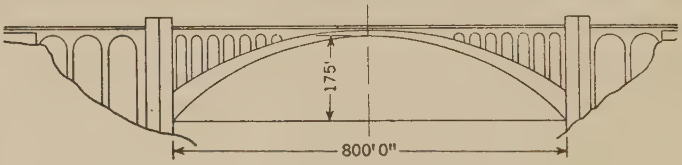

Fig. 43

The foregoing dimensions and sections are based on orthodox design. For economy of loads, the use of lightweight concrete, hollow arch ribs, and a larger percentage of alloy steel reinforcement would have to be investigated in an effort to reduce the dead load. In the concrete arch, dead loads result in stresses amounting to very nearly 50% of the total stress from all loads or forces and from the bending moments due to eccentricity of thrusts, including temperature effects and rib shortening. Incidentally, the field for the use of alloy steel for reinforcement of concrete has not yet been explored and may become of some importance in the future.

---

[57] "Memoires de la Société des Ingénieurs Civils de France," by E. Freyssinet, July–August, 1930.

Of course, the construction or erection of such an arch structure would present a complicated set of problems, the solution of which would include the construction of a cableway and the erection of an "umbrella" section over each abutment for the support of steel arch ribs, as falsework for the concrete arch ribs. It would involve the shifting of the arch-rib centers for the construction of the outside ribs and their dismantling—no inconsiderable task (much like the steel arch erection problem). The design of the long columns would be a special problem, as would the order in which the voussoir sections should be placed. All these are difficult but not insuperable problems. At the site of the Rainbow Arch such a proposed bridge would have been an interesting and instructive job.

Incidentally, the late William H. Burr, M. Am. Soc. C. E., proposed a 750-ft concrete arch to span the Harlem River at Spuyten Duyvil in New York, N. Y., some years ago, so that the span length proposed in this discussion is within range of a structure actually designed although not built.

George Stern,[58] Assoc. M. Am. Soc. C. E.—A valuable contribution to the literature on practical design of arches of long span is contained in this Symposium. The design of an arch bridge of 950-ft span represents a structural problem of the first magnitude. The use of high-strength structural steel with high allowable unit stresses leads to structural members of small cross section and to comparatively small rigidity of the structure.

In an arch rib of long span considerable deformation will occur and design by the usual so-called "elastic theory" will involve appreciable errors, as was correctly stated by the authors of the first Symposium paper. Many of these potential errors will be avoided by the use of the approximate method suggested in the Symposium. To obtain correct results, however, the deformation of the arch under the design loading must be considered in setting up the equations of equilibrium—that is, the "deflection theory" must be used.

Although the so-called exact method, outlined in the first Symposium paper obviously can be used to determine the final moments by a trial-and-error procedure, a direct analysis when not too laborious would be preferable. The equilibrium equations required for such a direct analysis may be set up as follows:[9]

The bending moment $M(x)$ at a point x of a two-hinged arch can be expressed as

$$M(x) = m(x) - H\left[y(x) - \eta(x)\right] \ldots\ldots\ldots\ldots\ldots (98)$$

in which H is the true horizontal thrust of the arch and $m(x)$ is the bending moment at the same point x of a simple beam of the same span and cross section as the rib. The vertical displacement $\eta(x)$ of point x is considered positive when downward. The second derivative of Eq. 98 is

---

[58] Stress Analyst, Aircraft Design Dept., Otis Elevator Co., New York, N. Y.

$$\frac{d^2M}{dx^2} = -W(x) - H\frac{d^2y}{dx^2} + H\frac{d^2\eta}{dx^2} \tag{99}$$

On the other hand, the following well-known relationships apply for a small element ds of a curved bar subjected to axial force, bending moment, and temperature change:

$$\frac{\Delta\, ds}{ds} = \frac{T}{E\,A} \mp \epsilon\, t \tag{100a}$$

and

$$\frac{\Delta\, d\theta}{dx} = -\frac{M}{E\,I\cos\theta} - \frac{T}{E\,A\,r\cos\theta} \pm \frac{\epsilon\, t}{r\cos\theta} \tag{100b}$$

in which $d\theta$ = the angle formed by the end tangents of the element ds, $\Delta\, ds$ = the change in length at the neutral axis, and $\Delta\, d\theta$ = the angular displacement of the element ds. The remaining notation is that used in the Symposium.

From the geometrical relations,

$$dy = ds \sin\theta \tag{101a}$$

and

$$dx = ds \cos\theta \tag{101b}$$

the following expressions for the vertical and horizontal displacements, $d\eta$ and $d\rho$, are derived:

$$d\eta = \frac{\Delta\, ds}{ds}\, dy + \Delta\,\theta\, dx \tag{102a}$$

and

$$d\rho = \frac{\Delta\, ds}{ds}\, dx - \Delta\,\theta\, dy \tag{102b}$$

By differentiating Eq. 102*a* twice,

$$\frac{d^2\eta}{dx^2} = \frac{\Delta\, ds}{ds}\,\frac{d^2y}{dx^2} + \frac{d(\Delta\,\theta)}{dx} \tag{103}$$

and, combining Eq. 103 with Eqs. 100, the following expression can be obtained:

$$\frac{d^2\eta}{dx^2} = \frac{T}{E\,A}\,\frac{d^2y}{dx^2} \mp \epsilon\, t\,\frac{d^2y}{dx^2} - \frac{M}{E\,I\cos\theta} - \frac{T}{E\,A\,r\cos\theta} \pm \frac{\epsilon\, t}{r\cos\theta} \tag{104}$$

By substituting for $T = H\sec\theta$, $\frac{d^2y}{dx^2} = -\frac{1}{r}$, introducing the notation $I\cos\theta = \bar{I}$ and $\frac{d^2\eta}{dx^2} = \eta''$, and, considering that M, as well as A and I, is a function of the abscissa x, Eq. 104 may be rewritten:

$$E\,\bar{I}(x)\,\eta''(x) = -M(x) - \frac{2\,H}{r}\,\frac{I(x)}{A(x)} \pm \frac{2\,E\,\bar{I}(x)}{r}\,\epsilon\, t \tag{105}$$

In general, the second term of the right side of Eq. 105, representing the effect of the normal stresses due to the axial thrust, has small influence on the results. The second derivative of this equation, substituted into Eq. 99, gives

$$[E\,\bar{I}(x)\,\eta''(x)]'' + H\,\eta''(x) = +W(x) + H\,y''(x) \tag{106}$$

Eq. 106 expresses the vertical displacement of a two-hinged arch rib as a function of the horizontal thrust H. In differentiating Eq. 105, the second term dependent on H was neglected. In the latter part of this discussion, however, the final solutions will also be given for the case in which that term is not disregarded.

Another relationship between horizontal thrust and vertical displacement can be derived from the fact that the relative displacement of the two hinged supports must be zero. Hence, from Eqs. 102, after some transformation,

$$\int_0^L d\rho = \int_0^L \eta' \, y' \, dx - \int_0^L \frac{\Delta \, ds}{ds} [1 + (y')^2] \, dx = 0 \ldots\ldots (107)$$

By substituting Eq. 100*a* and introducing an arbitrary cross-sectional area A_o, Eq. 107 can be transformed mathematically into

$$\int_0^L \eta(x) \, y''(x) \, dx + \frac{H}{E \, A_o} \int_0^L \left\{ \frac{A_o}{A(x) \cos \theta_x} [1 + (y')^2] \right\} dx$$
$$\mp \epsilon \, t \int_0^L [1 + (y')^2] \, dx = 0 \ldots\ldots\ldots\ldots\ldots\ldots (108)$$

Eqs. 106 and 108 represent two formulas with two unknowns, the horizontal thrust H and the vertical displacement η. As soon as the general solution of the differential Eq. 106 is obtained, H and η can be computed.

Eq. 106 is a nonhomogeneous differential equation of the fourth order; the derivation of its general solutions is far too laborious to be given in detail. The procedure followed was first to solve the corresponding homogeneous differential equation. In the case of an arch rib of constant cross section (that is, $\bar{I}(x) = I(x) \cos \theta =$ constant), the characteristic values λ_i and characteristic functions $\phi_i(x)$ of Eq. 106 can easily be computed since they represent simple sine curves. Thus the vertical displacement and the moment can be expressed in the form of Fourier series. On the other hand, if the moment of inertia of the rib varies, the characteristic functions are no longer true sine curves. To obtain these $\phi_i(x)$-values, some additional preparatory computation must be made. The formulas that can be derived to express these sinusoidal curves are not too elaborate, but their complexity increases the more closely the variation of the moment of inertia is considered.

Once the characteristic values λ_i and functions $\phi_i(x)$ of the corresponding homogeneous differential equation are computed, the general solution of the nonhomogeneous differential equation can be expressed by a uniform and convergent infinite series of these previously mentioned functions. This method of solving by series was first used by H. H. Bleich in his deflection theory of suspension bridges.[59] Just as the theory of arches shows a good analogy to that of suspension bridges, so also do the respective deflection theories correspond rather well if similar methods of attack are used. In the case of two hinged arch ribs, the aforementioned series converges so rapidly that, for all practical purposes, it is more than satisfactory to use only a few terms of the series. Thus, the general solution of Eq. 106 may be written

---

[59] "Die Berechnung verankerter Hängebrücken," by Hans H. Bleich, Springer, Vienna, 1935.

$$\eta(x) = \sum_{i=1}^{i=\infty} d_i \, \phi_i(x) \quad \text{(109)}$$

in which the factor d_i is given by

$$d_i = \frac{a_i + b_i H}{\lambda_i - H} \quad \text{(110)}$$

The parameters a_i and b_i are defined by the integrals,

$$a_i = \int_0^L w(x) \, \phi_i(x) \, dx \quad \text{(111}a\text{)}$$

and

$$b_i = \int_0^L y''(x) \, \phi_i(x) \, dx \quad \text{(111}b\text{)}$$

As stated previously, Eq. 109 can now be substituted in Eq. 108. Thus, by integrating term by term and by transformation, an expression can finally be derived which contains the horizontal thrust H as the only unknown value:

$$\sum_{i=1}^{i=\infty} \frac{(a_i + b_i H) \, b_i}{\lambda_i - H} + \frac{C}{E \, A_o} H \mp C_t \, \epsilon \, t = 0 \quad \text{(112)}$$

in which

$$C = \int_0^L \frac{A_o}{A(x) \cos \theta_x} [1 + (y')^2] \, dx \quad \text{(113}a\text{)}$$

and

$$C_t = \int_0^L [1 + (y')^2] \, dx \quad \text{(113}b\text{)}$$

In Eqs. 109 and 112, the effect of the normal stresses due to the thrust is disregarded. It was mentioned before that this effect on the vertical displacement is very small. Thus, in most cases, Eqs. 109 and 112 will give satisfactory results.

However, if the effect of the normal stresses is not neglected, the general solution of the differential equation of the two-hinged arch problem may be expressed by

$$\eta(x) = \sum_{i=1}^{i=\infty} \frac{a_i + b_i H}{\lambda_i - H} \phi_i(x) - \frac{2 \, I_A}{r \, A_A} \left[1 - \frac{\cos \alpha \left(x - \frac{L}{2} \right)}{\cos \frac{\alpha \, L}{2}} \right] \pm \frac{2 \, E \, I_A \cos \theta_A}{r \, H} \left[1 - \frac{\cos \alpha \left(x - \frac{L}{2} \right)}{\cos \frac{\alpha \, L}{2}} \right] \epsilon \, t \quad \text{(114)}$$

in which $\alpha = \sqrt{\dfrac{H}{E \, I_A \cos \theta_A}}$. In the terms representing the effect of the normal stresses, average values A_A, I_A, and θ_A are used for area, moment of inertia, and the angle θ. Using Eq. 114, the following final formula can be developed:

$$\sum_{i=1}^{i=\infty} \frac{(a_i + b_i\,H)\,b_i}{\lambda_i - H} + \frac{C}{E\,A_o} H + \frac{2\,I_A}{r^2\,A_A} \left(L - \frac{2 \tan \frac{\alpha\,L}{2}}{\alpha} \right)$$

$$\mp C_t\,\epsilon\,t \mp \frac{2\,E\,I_A \cos\theta_A}{r^2\,H} \left(L - \frac{2 \tan \frac{\alpha\,L}{2}}{\alpha} \right) \epsilon\,t = 0 \ldots\ldots (115)$$

The derivation of Eqs. 109, 112, 114, and 115 shows that they can be applied to any symmetrical two-hinged arch, irrespective of the shape of the arch axis, the variation in cross section of the rib, and the loading condition to be investigated.

The horizontal thrust H can now be calculated from Eq. 112 or 115 by the trial-and-error method. Once its value is known, the bending moment, shear, and unit stress may easily be computed by the conventional methods, and the vertical displacement can immediately be obtained from Eq. 109 or 114. (The writer is informed that Friedrich Bleich, M. Am. Soc. C. E., has developed, but not yet published, a deflection theory of two-hinged and hingeless arches. He uses a method similar to that outlined herein, but, by neglecting the effect of the normal stresses due to the thrust on the vertical displacement, equations are derived from which H can be calculated directly.)

A solution for the final moments in the preliminary two-hinged Niagara arch gave results which agree with those obtained by the authors of the first Symposium paper. Using the method outlined herein, the writer computed a 60% increase in the moment at the quarter point due to the deformation of the arch rib, as compared with the 63% increase obtained by the so-called exact procedure in the first Symposium paper.

Although few engineers will have the opportunity to design an arch bridge of the magnitude of the Rainbow Arch Bridge, the record of its design and construction will prove very valuable to future designers of similar projects.

SHORTRIDGE HARDESTY[60] AND J. M. GARRELTS,[61] MEMBERS, AM. SOC. C. E., AND I. G. HEDRICK, JR.,[62] ASSOC. M. AM. SOC. C. E.[62a]—The criticisms and extensions in the discussions have materially increased the usefulness of this Symposium and are appreciated by the writers.

Several discussers have objected to the use of the term, "elastic theory," to denote a method of structural analysis based on the assumption that the change in the geometry of the arch axis under load does not affect the stresses in the rib, and to the use of the term, "deflection theory," to denote a method which takes into account the effect of such change in geometry and thus gives a more nearly correct solution than does the elastic theory. To the writers the use of two terms seems merely to be carrying into arch analysis the nomenclature long used in the field of suspension bridges. The two usages[63,64] are exactly parallel.

---

[60] Cons. Engr. (Waddell & Hardesty), New York, N. Y.

[61] Associate Prof., Civ. Eng., Columbia Univ.; Designing Engr., Waddell & Hardesty, New York, N. Y.

[62] Stress Analyst, Grumman Aircraft Eng. Corp., Bethpage, L. I., N. Y.

[63] "A Practical Treatise on Suspension Bridges," by D. B. Steinman, 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1929, p. 246.

[64] "Elementary Treatise on Statically Indeterminate Stresses," by John I. Parcel and G. A. Maney, 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1936, p. 351.

The writers note that some discussers have apparently confused the loading used in the design of the arch rib with the half-span loading considered in Part II of the paper. In analyzing the stresses in the arch ribs, the moments and thrusts at each section were computed for a unit load at each panel point in turn. The live-load stresses at each section were then determined by loading those parts of the span that would result in the maximum stresses. The use of a single arbitrary length of loading for the design of the entire rib would give stresses much less than the maximum stress for most sections; hence such method would be seriously in error.

Mr. Di Genova's discussion, in general, is irrelevant to the subject of the paper. The answer to his claims of exactness for the "elastic theory" can be found by a careful reading of the paper, in connection with discussions on it, and also by reference to any good treatise on the "deflection theory" for suspension bridges. The deflections of the 950-ft two-hinged arch, which Mr. Di Genova says are relatively small, actually have the effect of increasing the bending moment at the quarter point by 72% and of decreasing the safety factor of the rib from 1.875 to 1.30.

Mr. Mackintosh's suggestion of combining M_{DL} with M_{LL} would give design moments which are too large unless the dead loading was unsymmetrical and produced moments of nearly the same spanwise variation as the unsymmetrical live loading of the critical condition. Ordinarily this is not the case, as dead-load moments and deflections are usually symmetrical, whereas the rib has the lowest resistance to buckling with a two-loop bending-moment diagram having positive moment over approximately one half the span and negative moment over the remaining part of the span.

Mr. Mackintosh, and later Mr. Beskin, have suggested an approximate beam-column correction of the form:

$$M_f = M_{ae} \left[\frac{1}{1 - \frac{T}{T_{cr}}} \right] \qquad (116)$$

The writers agree that this correction is sufficient when the rib is of uniform or nearly uniform section and when T is nearly constant throughout the length of the rib; but they were not willing to depend entirely on this form of approximation for the Niagara arch, where considerable variation existed in cross section and curvature of the rib axis. An evaluation of the approximations involved in this form of correction will entail essentially the computations referred to by the writers as their "exact" procedure.

Mr. Goodrich's request for an explanation of "Stern's Theory" has been supplied in a later discussion of the present paper by Mr. Stern.

Professor Spofford has suggested that a cost and quantity estimate would be a worth-while addition to the paper. The writers, therefore, have included the following tabulation of the final costs (1940–1941 exchange values):

Detailed Construction Costs:

Contract 1A. Substructure on the United States Side (McLain Construction Corporation)—

Unclassified excavation (4,735 cu yd at $5)	$ 23,675	
Concrete in footings (2,559 cu yd at $10)	25,590	
Concrete in arch abutments above footings (1,095 cu yd at $11)	12,045	
Concrete in shafts (3,061 cu yd at $8.50)	26,018	
Bar reinforcement for structures (369,039 lb at 4¢)	14,762	
Setting anchor bolts	1,000	
Core borings (60 lin ft at $4)	240	
Total for contract 1A, United States money		$ 103,330

Contract 2A. Substructure on Canadian Side (Aiken and MacLachlan)—

Unclassified excavation (6,117 cu yd at $2.35)	$ 14,374	
Concrete in footings (3,224 cu yd at $12)	38,688	
Concrete in arch abutments above footings (1,780 cu yd at $12.50)	22,250	
Concrete in shafts (3,236 cu yd at $12.75)	41,259	
Bar reinforcement for structures (418,453 lb at $4\frac{1}{2}$¢)	18,830	
Setting anchor bolts	640	
Core borings (105 lin ft at $5)	525	
Total for contract 2A Canadian money	$ 136,566	
Total for contract 2A United States money		$ 120,246

Contract 3A. Superstructure of Arch Span (Bethlehem Steel Company)—

Concrete in arch abutments (390 cu yd at $33.50)	$ 13,065	
Concrete in slabs and curbs (1,405 cu yd at $27)	37,935	
Bar reinforcement for structures (209,264 lb at 4.47¢)	9,354	
Reinforcing trusses for roadway slabs (305,136 lb at 5.75¢)	17,545	
Carbon steel in floor system 2,450 lb × 983 ft (2,407,527 lb at 8.232¢)	198,188	
Silicon steel in floor system 495 lb × 983 ft (485,594 lb at 8.9¢)	43,218	
Carbon steel in spandrel columns 1,195 lb × 950 ft (1,136,301 lb at 8.694¢)	98,790	
Carbon steel in rib laterals 950 lb × 950 ft (903,296 lb at 13.848¢)	125,088	
Silicon steel arch ribs and shoes 5,455 lb × 950 ft + 4 × 260,000 (6,223,496 lb at 14.525¢)	903,963	
Provision for utilities	2,823	
Extra work orders	1,812	
Total for contract 3A, United States money		$1,451,781

Contract 4. Superstructure of American Approach Spans (McLain Construction Corporation)—

Unclassified excavation (1,000 cu yd at $1.50)	$ 1,500	
Concrete in footings (310 cu yd at $11)	3,410	
Concrete in abutments above footing (216 cu yd at $16)	3,456	
Concrete in superstructure (3,368 cu yd at $27)	90,963	
Bar reinforcement for structures (593,303 lb at 4¢)	23,732	
Structural steel (20,741 lb at 15¢)	3,111	
Provision for utilities	500	
Earth excavation—special (5,000 cu yd at 45¢)	2,250	
Rock excavation—special (204 cu yd at $2)	408	
Protection of cliff	3,867	
Total for contract 4, United States money		$ 133,197

Contract 5. Superstructure of Canadian Approach Spans (Aiken and MacLachlan)—

Unclassified excavation (1,299 cu yd at $2.50)	$ 3,247	
Concrete in footings (864 cu yd at $13)	11,232	
Concrete in shafts (1,188 cu yd at $16)	19,008	
Concrete in superstructure of river road span (1,118 cu yd at $16)	17,888	
Concrete in superstructure of arch spans (3,334 cu yd at $27)	90,018	
Bar reinforcement for structures (1,020,300 lb at 6¢)	61,218	
Structural steel (63,018 lb at 30¢)	18,905	
Masonry facing (2,500 cu ft at $6.50)	16,250	
Arch stones (900 cu ft at $8)	7,200	
Special stones (2,600 cu ft at $10)	20,000	
Special stone details	1,550	
Provision for utilities	3,000	
Extra work orders	750	
Sales taxes	2,924	
Total for contract 5 {Canadian money	$ 273,190	
Total for contract 5 {United States money		$ 241,783

Contract AP1. Retaining Walls at American End (Charles H. Wing Company)—

Unclassified excavation for wall footings (3,141 cu yd at $1.25)	$ 3,927	
Unclassified excavation for parkway drive (9,063 cu yd at 54¢)	4,894	
Concrete in wall footings (499 cu yd at $11.15)	5,565	
Concrete in walls above footings (555 cu yd at $21.75)	12,072	
Concrete in railings (75 cu yd at $26.56)	1,992	
Bar reinforcement for structures (84,191 lb at 3.76¢)	3,166	
Extra work orders	2,300	
Total for contract AP1, United States money		$ 33,916

Summary of Construction Costs:

Bridge Between Abutments—		
Contract 1A, substructure on American side	$ 103,330	
Contract 2A, substructure on Canadian side	120,246	
Contract 3A, superstructure of arch span	1,451,781	
Contract 4, superstructure of American approach	133,197	
Contract 5, superstructure of Canadian approach	241,783	
Retaining walls and excavation—American side	33,916	
Lighting system on bridge	12,973	
Total bridge between abutments		$2,097,226
American Terminal—		
Paving and embankment of plaza	$ 63,743	
Paving and embankment of access road	50,519	
Buildings	166,000	
Lighting system	13,000	
Total American terminal		$ 293,262
Canadian terminal, cost to bridge commission		160,000
Name plates		2,000
Toll equipment		10,820
Office equipment and fixtures		16,000
Miscellaneous construction items		11,100
Borings		7,925
Engineering, architectural, and inspection services		193,989
Total construction cost (United States money)		$2,792,322

Mr. Mensch states that "J. A. C. Bresse warned his students not to use ribs so shallow as to cause excessive deflection due to a moving load. No real, valid reason has been given in this Symposium why this sound warning has been disregarded." Deflections were not disregarded in any sense. In fact, Part II of the paper is devoted entirely to the discussion of methods for evaluating the conditions which determine excessive deflections. The deflections of the final design are within permissible limits. Eqs. 18 and 19 are correct, and Eqs. 20 and 21 are clearly stated to be approximations. Mr. Mensch's Eqs. 39 to 51 are perhaps satisfactory for obtaining approximate sections. These equations apply the "elastic theory" to a particular case, the parabolic rib with $I = I_c \sec \alpha$, which yields simple integrals.

Mr. Mensch also appraises the paper erroneously when he states: "Contrary to the implied limitations expressed by the Symposium authors, Eqs. 39 to 51 are quite sufficient for the design of an arch of the Rainbow type, and the results agree well with those given in Table 1." Table 1 contains "elastic theory" results which the writers obtained by a more accurate integration, for this particular arch, than would be given by Mr. Mensch's equations. The comparison, therefore, has no bearing on the sufficiency of the "elastic theory." However, the approximations of Mr. Mensch's equations are hardly negligible even if deflection effects are neglected. His value of H, computed as 5,810 kips instead of the more accurate value of 5,911 kips, would represent a difference in moment at points near the crown of 101 kips × 150 ft, or of approximately 15,000 ft-kips. In comparing deflections, Mr. Mensch has added deflections at the crown point due to dead load, live load, rib shortening, and temperature to obtain a total of 14.48 in., which he has compared to the writers' value of 6.9 in. for (dead + live + impact)-load at the quarter point. This comparison has no meaning since the deflections are for different points of the arch rib and for different loads. The true comparison was given in the paper as 5.5 in. for the elastic theory as compared to 6.9 in. for the correct computations.

Under the heading, "Introduction," in the third paper of the Symposium it is stated that the arch was cambered for full dead load.

Mr. Ammann's contention, that the permissible limits for stresses should be assigned to the accurate stresses and not to those which are approximate, is strictly correct. As a matter of fact the designers applied this test in checking the most critical sections, but did not follow this procedure in preparing the stress sheet of the drawings because of the practical difficulties involved in the computation and preparation of a complete stress sheet showing the deflection stresses at every panel point.

The writers wish to thank Mr. Balog for calling attention to the Dischinger method of calculating deflection effects with its numerical application to the Rainbow arch rib.

Mr. Beskin has objected to the use of the word "theories" by the writers in referring to certain studies (see Appendix I) which have been made in connection with the deflection effects of arches. Since the writers were employing the papers in question as references, they accepted the titles of the original authors, who, correctly or incorrectly, used the term "theory" in describing their work.

Mr. Beskin has rightfully questioned the use of safety factors as they appear in Eq. 16. Although it is generally true that allowance should be made in design for increases in actual dead loads and live loads, in most structures the maximum temperature and wind loads are constant throughout the life of the structure. The factor of safety for these loadings, therefore, need serve only as a factor of ignorance to cover estimation of the present loads and approximations of the analysis. A factor of $N' = 1.33$ used with the 30-lb wind loading of present specifications and the maximum temperature range of the locality would seem to be sufficient.

The effect of axial thrust, although finally neglected, is not correctly expressed in Eq. 2. A more complete equation is:

$$\frac{d^2u}{ds^2} + \frac{u}{(r_o)^2} = -\frac{M}{E\,I} - \frac{T\,\mu}{r_o\,A\,E} + \left(\frac{M}{E\,I} + \frac{T}{r_o\,A\,E} + \frac{T\,\mu}{r_o\,A\,E}\right)\frac{T}{A\,E} + \frac{1}{2\,r_o}\left(\int\frac{T\,ds}{r_o\,A\,E} + \int\frac{M}{E\,I}\,ds + \int\frac{T\,\mu}{r_o\,A\,E}\,ds + C\right)^2 \quad\ldots\ldots(117)$$

in which μ = Poisson's ratio.

To illustrate the effect of axial deformation on radial deflections, consider the semicircular arch in Fig. 44 with radial loads of magnitude T. The bending moment in this case is zero throughout and the axial compression T is constant around the full length of the rib. It will be assumed that $\mu = 0$. If point A is assumed fixed and point B is free to deflect, then the tangential component of deflection, v, of point B is seen to be

$$v = \frac{\pi R T}{A E} \qquad \text{(118)}$$

and the radial component of deflection of point B is

$$u = \frac{v^2}{2 R} = \frac{R}{2} \left(\frac{\pi T}{A E} \right)^2 \qquad \text{(119)}$$

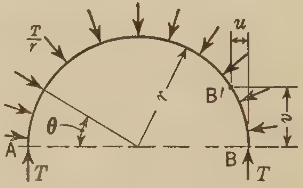

FIG. 44

The same result can be obtained by Eq. 117, which reduces to the following when $M = 0$,

$$\frac{d^2 u}{d s^2} + \frac{u}{R^2} = - \frac{1}{R} \left(\frac{T}{A E} \right)^2 + \frac{1}{2 R^3} \left(\int \frac{T}{A E} \, ds \right)^2 \qquad \text{(120)}$$

The solution of Eq. 120 for constant T is

$$u = \frac{1}{2 R} \left(\int \frac{T}{A E} \, ds \right)^2 \qquad \text{(121)}$$

and, since $ds = R \, d\theta$,

$$u = \frac{R}{2} \left[\left(\frac{T \theta}{A E} \right)^2 \right]_0^\pi = \frac{R}{2} \left(\frac{T \pi}{A E} \right)^2 \qquad \text{(122)}$$

This question of the effect of thrust on radial deflections, however, is academic, since both Mr. Beskin and the writers agree that its influence is negligible for steel or concrete ribs.

The writers inadvertently made the statement in the paragraph containing Eq. 6 that the term $\frac{u}{(r_o)^2}$ of Eq. 2 is neglected in the elastic theory and, therefore, in their "exact" procedure. The basic differential relation[65] of the "elastic" theory is

$$\frac{\Delta \, d\theta}{ds} = - \frac{M}{E I} \qquad \text{(123)}$$

in which $\Delta \, d\theta$ is the change in angle between the end tangents of the element ds. In the paper it was stated incorrectly that $\frac{d\theta}{ds} = - \frac{d^2 u}{d s^2}$—a relation that is exact for straight beams only. It can be proved that for curved beams the following relations[66] exist:

$$\frac{\Delta \, d\theta}{ds} = \left(\frac{1}{r_f} - \frac{1}{r_o} \right) = \frac{d^2 u}{d s^2} + \frac{u}{(r_o)^2} = - \frac{M}{E I} \qquad \text{(124)}$$

in which the element ds is assumed to remain of constant length.

---

[65] "The Theory and Practice of Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, 10th Ed., John Wiley & Sons, Inc., New York, N. Y., 1929, Pt. II.

[66] "Strength of Materials," by Stephen Timoshenko, 1st Ed., D. Van Nostrand Co., Inc., New York, N. Y., 1940, Pt. II, p. 457.

The actual working equation used in obtaining deflections by the elastic theory was:

$$\delta_a = \int_A^B \frac{M_{ae}\, m}{E\, I}\, ds \ldots\ldots\ldots\ldots\ldots\ldots\ldots(125)$$

in which m is the moment in the arch due to a unit load at point a in the direction of the deflection δ_a. Since both M_{ae} and m include the effect of $\frac{u}{(r_o)^2}$, the deflections and moments of both the "elastic" analysis and the "exact" procedure have been computed without neglect of the term $\frac{u}{(r_o)^2}$.

With regard to the use of an average value of T in Eq. 16 instead of the thrust at the point A which is being analyzed, the thrust near the quarter point is, in the first place, very nearly the average thrust. Secondly, since the change in H is negligible for deflection effects, the position of the thrust line remains very close to the position obtained in the elastic analysis, which accounts for the relation $\Delta m_{a1} = T_a\, u_{ae}$. Mr. Beskin is correct in stating that the thrust in the denominator should include the thrust due to wind and temperature.

Eq. 16 for the two-hinged rib, when revised in accordance with the foregoing discussion, becomes

$$s_y = N\left(\frac{T_a}{A_a}\right) + \frac{N\, M_{LL+I}}{S_a}\left[\frac{1}{1-(N\, T_a + N'\, T_t + N'\, T_w)\,\dfrac{u_{ae}}{M_{LL+I}}}\right] + \frac{N\, M_{DL}}{S_a} + \frac{N'\,(T_t + T_w)}{A_a} + \frac{N'\,(M_t + M_w)}{S_a} \ldots\text{(16 revised)}$$

and Eq. 17, also for the two-hinged arch, becomes

$$\frac{s_y}{N} = \frac{T_a}{A_a} + \left\{\frac{M_{LL+I} + T_a\,\dfrac{e'}{N}}{S_a}\right\}\left[\frac{1}{1-(N\, T_a + N'\, T_t + N'\, T_w)\,\dfrac{u_{ae}}{M_{LL+I}}}\right] + \frac{M_{DL}}{S_a} + \frac{N'}{N}\left(\frac{T_t + T_w}{A_a} + \frac{M_t + M_w}{S_a}\right) \ldots\ldots\text{(17 revised)}$$

Similarly, for the hingeless rib, Eq. 21 becomes

$$\frac{s_y}{N} = \frac{T_a}{A_a} + \frac{M_{LL+I} + 0.7\, T_a\,\dfrac{e'}{N}}{S_a}\left[\frac{1}{1-\left(\dfrac{N\, T_a + N'\, T_t + N'\, T_w}{T_a}\right)\left(\dfrac{\Delta m_{a1}}{M_{LL+I}}\right)}\right] + \frac{M_{DL}}{S_a} + \frac{N'}{N}\left[\frac{T_t + T_w}{A_a} + \frac{M_t + M_w}{S_a}\right] \ldots\ldots\text{(21 revised)}$$

In these revised equations the new term N' equals the load factor for temperature and wind loads (1.33 recommended). Present specifications account for the improbability of the simultaneous occurrence of maximum dead load, live load, wind load, and temperature load by increasing the allowable total stress. The writers believe that a more rational approach, especially when the stress-load relation is nonlinear, is the use of load factors as in the revised Eqs. 16, 17, and 21.

Mr. Beskin states that conclusions 1 and 2 are incorrect. The arguments he has submitted do not uphold this statement. In stating that the factor $\frac{T\,u}{M}$ should be considered in design, Mr. Beskin agrees with conclusion 1 which states "The useful strength of an arch rib is dependent in part * * *" upon $T\,u$. In regard to conclusion 2, the percentage error in total stress due to neglect of deflection effects is (approximately)

$$\text{Error } (\%) = E = 100 \left[\frac{s_a + \dfrac{s_b}{1 - s_a/s_c}}{s_a + s_b} - 1 \right] \quad \text{(126)}$$

In a given arch rib, if the dead load is increased, s_b and s_c will remain constant and the rate of change of E with respect to s_a will be:

$$dE = 100 \left\{ \frac{\dfrac{s_b}{s_c} \left[\dfrac{s_b + \dfrac{(s_a)^2}{s_c}}{(1 - s_a/s_c)^2} \right]}{(s_a + s_b)^2} \right\} ds_a \quad \text{(127)}$$

Inspection of Eq. 127 reveals that, for this case, an increase in s_a will always cause an increase in the percentage error in total stress. This was the condition the writers had in mind when stating conclusion 2.

However, if it is assumed that $s_a + s_b$ = constant and also that s_c = constant (which means that the rib section increases as the dead load increases), then:

$$dE = \frac{100}{s_a + s_b} \left[\frac{\dfrac{s_b}{s_a} + \dfrac{s_a}{s_c} - 1}{s_a\, s_c\, (1 - s_a/s_c)^2} \right] ds_a \quad \text{(128)}$$

In this case, as pointed out by Mr. Beskin, the percentage error in total stress will decrease for an increase in s_a, if $\frac{s_b}{s_a} + \frac{s_a}{s_c} < 1$.

Mr. Gronquist has suggested an interesting method of estimating deflection effects. The question of whether a correction factor should be applied to wind-load moments depends entirely on whether the critical wind loading produces a moment curve similar to that of the critical live load. The effect of wind loads on the rib will vary with the arrangement of the wind-bracing systems. In the Niagara design a symmetrical wind load was found to be critical for the quarter-point region and, therefore, the moments were not amplified by deflection.

Mr. Hirschthal has inquired about the considerations that determined the span length. The main abutments were located at a minimum safe height above the highest recorded ice level. The abutments so located determined the span length. With regard to his questions concerning the scope of the model tests made at Princeton University, it should be noted that these tests were not conducted as a part of the Niagara project, but as general research. The writers were aware of the work being done and, of course, were quite interested in the results, since the work paralleled closely the design calculations under way at the time. Those in charge of the Princeton University tests expected to continue with corresponding tests on hingeless ribs, but this work became "a war casualty."

The selection of the hingeless type of rib was not as obvious a choice as Mr. Hirschthal infers. Preliminary discussions with experienced fabricating and erecting contractors indicated a strong preference for the two-hinged type. In addition, the preliminary designs by the usual "elastic theory" methods indicated that the total material saving in the hingeless arch would be small. The two-hinged arch could not logically be eliminated from consideration until an investigation of the effects of flexibility proved that a satisfactory design would require an excessive amount of material.

The use of three ribs would have been undesirable for the following reasons: (1) The shallower ribs resulting from a three-rib design would increase the objectionable flexibility effects; and (2) the unit stresses due to wind loading would be 50% to 100% greater in the lighter ribs of a three-rib design.

Esthetically and economically, the rib of constant depth is preferable for steel construction.

Mr. Hirschthal's assumption that the arch was designed for live load over half the span length has already been shown, in the third paragraph of this closure, to be incorrect. The live-load assumptions were more exacting than those that would be required by the specifications of the American Railway Engineering Association for Masonry Arches.

With reference to the design loading, the H20 loading was the standard for heavy traffic structures when the Rainbow arch was designed. The H20–S16 loading did not appear in the bridge specifications of the American Association of State Highway Officials until 1941.

The writers appreciate Mr. Stern's discussion, which presents an interesting method of attacking the problem of flexible arches.

ELMER K. TIMBY,[67] ASSOC. M. AM. SOC. C. E., LAWRENCE M. MEAD, JR.,[68] JUN. AM. SOC. C. E., AND ROBERT MCELDOWNEY, JR.,[69] ESQ.—Many valuable ideas have been presented in the discussions on the model studies of flexible two-hinged arches for which the writers are grateful. They were disappointed because of their inability to include in the investigation the behavior of flexible fixed-end arches, which several of the discussers would have liked. Although the model project was suggested by the design of the Rainbow Arch Bridge and served to confirm the designers' calculations on the two-hinged arch, it was felt that a more general investigation, covering the range of variables of rise to span, load, and stiffness, would be of more value to the profession than the study of only one combination of these variables. In the time available it was impossible to study both two-hinged and fixed-end arches. The fixed-arch program (and perhaps studies of parabolic arches) was planned for investigation in 1942, but World War II intervened, and no one was available for this work. It is hoped that when the war is over the project will be continued.

[67] Lt., CEC—V(S), U. S. N. R.; formerly Associate Prof. of Civ. Eng., Princeton Univ., Princeton, N. J. (on leave).

[68] Stress Analyst and Structural Engr., Grumman Aircraft Eng. Corp., Bethpage, N. Y.

[69] 1st Lt., U. S. Marine Corps (formerly Apprentice Engr., Taylor-Wharton Iron & Steel Co., High Bridge, N. J.).

Mr. Ammann's suggestion that the "elastic theory" be called the "theory of the rigid system," and that the "deflection theory" be called the "theory of the flexible system" would clarify much confusion. Mr. Ammann misunderstood the writers' second conclusion, namely—that the test data would enable the designer to select a rib which in his (the designer's) opinion should be stiff enough to permit legitimate use of the "elastic theory."

Mr. Hirschthal questions the accuracy of the model studies and mentions the danger of applying them to so large a prototype. The writers maintain, however, that, if the accuracy of the measurements is increased in proportion to the decrease in the size of the model and the loads on the model, reasonable accuracy will not be sacrificed. For example, in the case of the model test which corresponded most closely to the proportions and loading of the Niagara arch, deflections could be measured to an accuracy of less than one part in fifty (or 2%) at the quarter point for maximum moment at the same point, even though the total deflection was only 0.07 in. on the model. An accuracy of 3% would probably be acceptable.

The writers cannot agree with Mr. Beskin that tests are of little value for analyzing or checking stress distributions of complicated or important structures. Mathematical treatment of many stress analysis problems is either inadequate or so complicated as to make test results far more practicable for actual design. As an aircraft stress analyst, Mr. Beskin must be familiar with the difficulty in treating, accurately, by mathematics, all phases of incomplete diagonal tension beams. For example, the method approved by the U. S. Army Air Corps for designing open section web stiffeners is based on an empirical formula developed to fit the results of a large number of static tests. Although several theoretical solutions of the problem appear reasonable and seem to cover the more important variables, none actually was verified sufficiently by test to be usable without unwarranted conservatisms.

In the case of a structure as important and costly as the Rainbow Arch Bridge, the model tests would seem justified for checking purposes even if they only proved (as they did) that the theoretical treatment included enough variables and was sufficiently accurate to insure a safe design.

In regard to the variation of dead load across the span, the writers felt that in such a general investigation, and with the limited time available, it was better to select a distribution that produced no dead-load moment—a condition sought in practical design—rather than to select some arbitrary percentage variation across the span. Undoubtedly the particular variation chosen will have some effect on the amplified final moments, especially in the case of the large ratios of dead load to stiffness and of rise to span. The actual dead-load distribution used varied as $\frac{r^2}{y^3}$ which reduces to $\frac{1}{r \cos^3}$, as Mr. Beskin deduced.

Mr. Beskin is to be congratulated for developing a theoretical formula which checks the test results so accurately. The writers consider their work well justified if it has stimulated the development of such theoretical solutions and has served as a check for them.

John I. Copp,[70] Assoc. M. Am. Soc. C. E., and Karl de Vries,[71] William H. Jameson,[72] and Jonathan Jones,[73] Members, Am. Soc. C. E.—The writers appreciate that the greater portion of the study given by many members of the Society to the papers of this Symposium was given to the first paper, on design, since that paper is naturally of more direct interest to designing engineers than is one covering fabrication and erection controls.

The method of weighing the crown thrust at closure has also been commented on, and a request has been made for a more complete description of the "weighing capsules." The writers would prefer to refer to the conclusion of the paper, and to emphasize that, in their opinion, weighing of the crown thrust of a properly constructed arch is unnecessary, and on an improperly or carelessly constructed arch it is useless.

FOREWORD

At a technical meeting of the Sanitary Engineering Division on January 22, 1942, with W. Rudolfs, M. Am. Soc. C. E., presiding, the subject of dewatering, drying, incineration, and use of sewage sludge was thoroughly explored. Five of these papers have been revised for publication in the present Symposium. The most important revision is in the isolation of a bibliography on the subject as an independent unit of the Symposium, subject to discussion on a par with any of the papers. Additions to this bibliography that occur in discussion will be appended to the bibliography in the final printing.

DEVELOPMENTS INDICATED BY EXPERIENCE AT BUFFALO, N. Y.

By C. R. Velzy,[1] M. Am. Soc. C. E.

Synopsis

Sludge from the primary treatment plant at Buffalo, N. Y., passes through tanks for a short period of digestion, and is then disposed of by vacuum filtration and incineration. There have been developments in sludge conditioning and in the operation and maintenance of filters. The major problem with incineration has been severe abrasion, particularly in the flash driers, induced draft fans, and cyclones. Resulting costs of maintenance have been reduced by changes in equipment and materials. Operating results and costs are stated briefly.

The sludge disposal facilities at Buffalo are part of a treatment plant designed for a population of 750,000. The plant provides primary treatment with chlorination. The raw sludge is the product, therefore, of primary sedimentation only. The design contemplated a suspended solids content in the raw sewage amounting to 0.30 lb per capita, and a removal of 50%, or 0.15 lb per capita. For the present population of approximately 600,000, this would result in a daily removal of raw solids of approximately 90,000 lb. For the year 1940–1941 the actual amount of dry solids removed from the sewage was 89,300 lb per day, and was somewhat less than that for the previous two years.

Sludge disposal at Buffalo includes short-period or partial digestion, vacuum filtration, and incineration. Sludge is conditioned for filtration with lime and ferric chloride. After filtration the sludge cake passes over a system of conveyer belts, where it is weighed on its way to drying equipment. The dried and powdered sludge is blown into the furnace and burns in suspension. Hot gases from combustion are used to dry the sludge, and all vapors from drying are returned to the furnaces to eliminate odors.

The raw sludge is pumped to four sludge tanks having a total volume of 750,000 cu ft, or a design capacity of 1.0 cu ft per capita. Each tank is 90 ft in diameter, with a side-wall depth of 27.5 ft, and is equipped with a floating cover.

In the sludge disposal building there are three vacuum filters of 500 sq ft of filtering area each and three sludge incinerators having a design capacity of 100 tons of sludge cake per day on the basis of a moisture content of 70%. The furnace units include cyclones for the separation of vapors from powdered sludge and for the removal of fly ash from the flue gases, a pneumatic ash-handling system, preheaters for the recovery of heat, and the fans and blowers for the handling of gases and powdered sludge. The furnaces are equipped with combination oil and gas burners for the use of auxiliary fuel to supply heat to make up deficiencies of heat units in the sludge. During three years of operation this equipment has performed well. Some changes in details have been made, others are under study, and it is expected that more developments will be indicated as the art progresses.

---

[1] Asst. Engr., Greeley & Hansen, Norfolk, Va.

The value of sludge tanks has been shown by the writer elsewhere (1).[2] They absorb the irregularities in quantity of raw sludge obtained, permit a six-day operating week in dewatering and incineration, provide gas as fuel for boilers and auxiliary heat for incinerators, and deliver a sludge of reasonably uniform characteristics for filtration and burning.

In the conditioning of sludge, the laboratory has made determinations of the theoretical quantity of chemicals required and has proposed a procedure by which the operator in the plant can make a quick determination of the amount of chemicals required. In connection with the application of chemicals, experiments have been made on details of the mixing tank with particular reference to baffling, mixing-paddle speeds, and detention. A short detention period with no baffles and proper mixing-paddle speeds is indicated, but more work is to be done before definite conclusions are drawn as to the best combination of these factors. In the equipment for the application of chemicals, there has been a tendency away from automatic devices and toward devices that will provide easy manual control and permit the operator to observe rates of application of chemicals and readily make necessary adjustments. For example, ferric chloride solution is now fed through a perforated rubber pipe, arranged so that the number of small streams of the solution is an indicator of the rate of feed. Thus the operator, or the superintendent, can quickly check the application of ferric chloride by counting the streams on this feeder and observing the dial on the weightometer.

In the operation of vacuum filters, studies have included experiments with different types of filter cloth and a number of modifications in the mechanical operation of the filters. Canton flannel has been found to be most satisfactory in operating results and in general economy in regard to cost and life of cloth. In the application of the cloth to the filter drum, it has been found that ordinary sash cord is a satisfactory substitute for the bronze strips which were originally used. The sash cord is inexpensive, is easy to apply, and results in greatly reduced time for applying new cloth.

On one of the filters a screw feeding device has been installed, with a surge bin above the screw. This device receives the sludge cake from the filter and discharges it uniformly to the first conveyer belt, producing a more satisfactory reading on the weightometer chart. With a variable speed drive, it also provides for a closer control of the loading on the incinerators. The device, as now used on one of the filters, is satisfactory, but a definite determination has not been made as to whether or not it is worth the cost.

After about two years of operation, it was found that the wire screen on the surface of the filter drum had become coated with lime scale so that the areas between the wires were materially reduced. This scale was removed successfully by the application of muriatic acid in the filter tub. Acid also has been used successfully in reducing the scale accumulations in filtrate lines and in the supernatant line which receives the discharge from the filtrate pumps.

---

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography at the end of the Symposium.

Fig. 1 shows a flow diagram of the drying and incineration processes. The fundamental principles of these processes have been described by D. C. Reybold (2). This flow diagram represents the present installation at Buffalo and differs in some mechanical details from the original installation. It also differs from other installations previously described. This discussion of problems and improvements is offered, not as a criticism of the original design, but as a description of developments normal to any process as new as sludge incineration.

The developments actually accomplished thus far are largely in the mechanical operation of the drying and burning equipment. The major problem has been due to abrasion of certain parts of the equipment. It appears that this could not be foreseen in the original design, as in other installations abrasion has been much less severe. In fact, it has been stated that in one of the Chicago, Ill., installations certain parts, which suffer from abrasion at Buffalo, give trouble because of the formation of scale. This is probably due to differences in the characteristics of sludge and perhaps in the character of auxiliary fuel.

In this connection, it is interesting to note that, during the first year of operation at Buffalo, when oil was used as an auxiliary fuel, scale formed on the preheater surfaces to such an extent that cleaning was required at frequent intervals. Since gas has been used exclusively as auxiliary fuel, the scale on the preheaters has disappeared, the soot blowers have become unnecessary and have been removed, and abrasion on the heater surfaces has made it necessary to replace some of the parts.

Abrasion has been particularly severe on the flash dryer, the induced draft fan, and at bends in pipe lines and ducts handling gases, powdered sludge, and fly ash. In the pipe lines and ducts this problem has been solved rather easily by the use of concrete wear backs at the bends. The concrete can be used in a thickness which will withstand wear for a considerable time and is easily replaced when it is worn through.

Wear on the flash dryer during the first months of operation was so severe on the bars and rings that the cages required replacement after about two months of continuous operation. At the suggestion of the manufacturer, a lower speed was tried in the cage mill. This has increased the life of the mill to about five months. It is possible that further improvement can be made. Adjustments in the type of assembly have resulted in easy replacement of worn parts and the reuse of portions of these parts.

The wear from abrasion on the induced draft fan has been so severe that originally the fan blades would last only approximately two months. The repair was difficult and costly because it required disassembling of the fan, replacement of blades, and reassembling of the fan. Hard surfacing of blades by arc welding was tried, but the slight additional wear did not warrant the cost. Ribbing of the blades with hard material was as effective as complete surfacing, and much less costly. The real answer was found in this case when

the fan was moved to the clean air side of the cyclone. One unit in this location has operated for more than a year to date (1943) without showing appreciable wear.

In the fly ash, cyclone abrasion has been less severe; nevertheless, it has constituted a problem calling for careful attention. Gunite has been tried with partial success. Better results probably would have been obtained if trap rock or other suitable aggregate had been available at Buffalo. Experiments have been made with brick linings and some other materials. It is believed that some form of concrete, or brick or ceramic material, will prove more satisfactory and less costly than steel. At the present time (1942), when steel is urgently needed for war, there is particular merit in finding some other satisfactory material. With the adjustments indicated to meet the abrasion problem, the maintenance costs on equipment will be materially reduced and better continuity of operation will be obtained.

Some of the operating results for dewatering and incineration for the three years of operation of the Buffalo treatment works are given in Table 1. Some of the developments in these operating results are worthy of note. The relatively high moisture content in raw sludge during the first year was largely due to inexperienced personnel and changing of operators. As the operators became more skilful in handling sludge and operating sludge pumps, they gained a normal control of the condition of the raw sludge. The increase in the volatile matter of raw sludge and digested sludge was apparently due to a decrease in the amount of grit carried by the sewage. During the first year of operation there was an extensive program of sewer cleaning that probably created a steady flow of grit to the treatment works. There has been some decrease in the solids burned per furnace hour. The heat content of the sludge cake has showed a marked increase, and there has been a corresponding decrease in the amount of gas used for auxiliary fuel. Computations show that the total quantity of heat dissipated by the furnaces has remained practically constant even with the decrease in solids burned.

TABLE 1.—COMPARISON OF OPERATING RESULTS FOR DEWATERING AND INCINERATION

Item	Description	July, 1938, to June, 1939	July, 1939, to June, 1940	July, 1940, to June, 1941

[a] Salaries and supplies.

The total flow for the year was 51,262 million gal, and the total quantity of solids removed as raw sludge (dry basis) and grit was 18,300 tons. From these data the following unit costs are obtained:

Total cost of treatment, in dollars per million gallons	8.25
Cost of treatment, not including pumping and chlorination, in dollars per million gallons	5.97
Cost of treatment, in dollars per ton of raw solids (dry basis) disposed of	23.50
Cost of treatment, not including pumping and chlorination, in dollars per ton of raw solids	16.70
Total cost of solids disposal, in dollars per ton of raw solids disposed of	9.38
Cost of solids disposal, including only direct costs and maintenance and repairs, in dollars per ton of raw solids disposed of	7.07

SUMMARY

Operating experience in the disposal of sludge from the Buffalo primary sewage treatment works has led to developments in the selection of materials and in the use and arrangement of equipment. Some of the developments indicated may be briefly summarized as follows:

1. Sludge tanks have proved valuable to take up the irregularities in daily sludge quantities, to provide flexibility in the operation of incinerators, and to supply gas for fuel.
2. In applying chemicals for sludge conditioning, the tendency has been toward the use of manual rather than automatic devices, and arrangements which permit the operator to readily observe rates of chemical application.
3. Canton flannel has proved most satisfactory as a filter cloth.
4. A sludge-feeding device between the filter and the incinerator has been useful, but there is still some question whether it is worth its cost.
5. Muriatic acid has proved satisfactory and economical for cleaning lime scale from filter screens and pipe lines.
6. Although at Buffalo the major problem in sludge drying and burning has been the abrasion of equipment, it appears that this problem may vary widely in severity in different plants. The variation is probably due to differences in sludge characteristics and may also be affected by the nature of auxiliary fuel used.
7. Maintenance costs due to abrasion may be minimized in general by placing fans on the "clean air" side of cyclones, by using minimum speeds on moving parts, and by using concrete or ceramic linings instead of steel on stationary parts subjected to abrasion.
8. Operating results over the first three years show reduction in moisture content of raw sludge and increases in the moisture content, volatile matter and heat content of digested sludge and sludge cake. Incinerators have maintained their rate of heat dissipation.
9. Operating costs have amounted to $8.24 per million gallons treated, including pumping and chlorination, and direct costs of sludge disposal have amounted to $7.07 per ton of raw solids.

VACUUM FILTERS USED IN PRIMARY SLUDGE DEWATERING

By Ralph E. Fuhrman,[3] Assoc. M. Am. Soc. C. E.

Synopsis

The primary dewatering of digested sewage sludge by vacuum filters is one of the many mechanical processes that gained popularity in the decade 1932–1942. In the early 1930's, this service of vacuum filters was still in the experimental or pilot plant stage, whereas a very few years later saw the installation of huge filter areas. Sludge treatment literature of this period abounds with observations on vacuum filtration of digested sewage sludge and it is the purpose of this paper to indicate various experiences in the District of Columbia.

Description of Facilities

Sludge at the sewage treatment plant of the District of Columbia is dewatered by the operation of four vacuum filters, each with a filter area of 500 sq ft. These units, and the related equipment serving them, are sufficient to dewater the primary digested and elutriated sludge produced by the plant within the work week consisting of five 8-hr days. Between operating periods, sludge is held in the digestion tanks to be withdrawn as desired. After elutriation, the sludge is elevated to the filter floor by three closed impeller centrifugal pumps large enough to pass a 3-in. sphere. The sludge delivered to the mixing tank is controlled by a volumetric meter actuated by the level of sludge within the filter pans or troughs. To the required amount of sludge is added ferric chloride as a conditioning agent. Under the usual method of operation the mixing time amounts to 3 or 4 min, after which the sludge passes through rubber-lined pipes to the filter units. Provision for the addition of lime was made in the plant, but so far the use of lime has not been necessary on digested and elutriated primary sludge. As auxiliary equipment, vacuum pumps with an operating displacement of 2 cu ft per min per square foot of filter area are provided, as are filtrate pumps and low-pressure blowers, for freeing the filter cake from the cloth.

Ferric chloride is stored in two 8,000-gal, rubber-lined tanks and is pumped to elevated tanks with float switches by centrifugal pumps. The elevated tanks supply sufficient operating head for the ferric chloride feeders at the mixing tanks. Ferric chloride, which is purchased and fed as a 40% solution, is siphoned into the storage tanks from railroad tank cars. All pipe lines handling ferric chloride are hard rubber, or steel pipe lined with hard rubber, and all lines conveying conditioned sludge or filtrate are rubber-lined steel pipes.

---

[3] Supt., Sewage Treatment Plant, District of Columbia, Blue Plains, Washington, D. C.

Elutriation facilities provided at the plant include two air-agitated tanks for the mixing of digested sludge with river water or supernatant from the elutriation settling tanks when countercurrent elutriation is used. The unit is provided with appropriate sludge pumps and wash-water pumps necessary for the elutriation process. Wash water may be drawn directly from the Potomac River or from the plant effluent conduit. Vacuum priming facilities are provided as all of the pumps are centrifugal.

OPERATING EXPERIENCES

In operation of the elutriation mixing tanks, experience indicated that large quantities of fine sand passed the grit chambers and settled out of the sewage in the sedimentation tanks. This material was pumped into the digesters with raw solids and, since it was unaffected by digestion, settled out in the elutriation mixing tanks in spite of air agitation through porous plate diffusers. The mixing tanks accumulated this very fine sand until practically no mixing of the passing liquids was attained. From this observation and others the mixing of sludge and wash water seems to be of minor importance, and as a trial the inlet and outlet of one mixing tank were connected by a 12-in. pipe. In this manner, the sand that formerly settled in the mixing tank is transported gradually with the sludge to the vacuum filters. The mixing of sludge and wash water seemed to be sufficient by the flow of these liquids within the pipe line. This total time of flow is usually about 20 sec in contrast to the mixing-tank period of 15 to 20 min. Plans are being made to try a similar scheme on the other mixing tank and if successful the problem of removing this fine sand will have been eliminated.

Initially the sludge pumps provided to elevate the digested, elutriated sludge from the elutriation tanks to the mixing tanks were sufficient to pass only a 2-in. sphere and in the early service of these pumps incessant clogging was experienced to the point where continuous dewatering was impossible. After considering a number of possible solutions to the problem, including the possibility of pumps equipped with cutters, plain centrifugal pumps similar in design to those originally installed were purchased, the only differences being in the size of the impeller passage, which was 3 in. in the new pumps, and the speed, which was 1,140 rpm as a maximum.

In the first two years after installation, some of the hard-rubber pipe lines showed much sagging between the supports of the pipes. Additional supports were first provided and although this reduced the possibility of a failure in the lines they were still unsightly. However, sufficient sagging was evidenced to put extra strains on the pipes. The remedy chosen was the replacement of these lines by steel pipe with a hard-rubber lining. This pipe has completely overcome the difficulties of the original material.

An operating procedure that has been found to be very important is that of prompt and thorough washing of filters at the end of an operating period. Filters at the plant are washed for 30 to 45 min after the operating period to remove, as far as possible, particulate matter that would "set" and tend to clog or blind the filter cloth. Analyses of discarded filter cloths have revealed 52% iron salts. At the suggestion of A. L. Genter, M. Am. Soc. C. E., reclamation of cloths was attempted with oxalic acid. For this use, a 1% solution of oxalic acid is made up in the filter pan and the filter is allowed to turn in the solution for a 24-hr exposure. For a particular cloth, for example, after 528 hr of service the oxalic acid wash was applied and service resumed until the cloth had served a total of 682 hr, an increase of about 30%. On the basis of a filter cloth cost of $120, the hourly cost of service was reduced from $0.23 to $0.18. Likewise, at a cost of oxalic acid of about $2.50 for the cloth, additional filtering service worth $35 was obtained. Some of these data have been reported previously (3).

During each summer of filter operation, fungus appeared on the filter cloths between the usual week-end shutdown from Friday afternoon to Monday morning. Within this period, the filter cloth disintegrated in spots all over the filter and rendered it practically useless. The responsible organism has not been identified, but it is probably one of the molds or bacteria known (4) to be destructive to wool.

The remedy for this attack is to apply a 100-ppm solution of copper sulfate to the filter cloths whenever the plant is shut down for more than 16 hr; that is, copper sulfate is applied every Saturday and Sunday, as well as any other nonoperating day, by rotating the filter with the solution in the filter pan long enough to saturate the wool cloth.

Before remedial measures could be developed, some cloths gave very short filtering service. The minimum life has been 32 hr of service and the maximum 899 hr. During the calendar years of 1940 and 1941, the minimum life was 227 hr, the maximum 682 hr, and the average life 408 hr. Cloths have cost from $87 to $134, with an average cost of approximately $115 each.

VALUE OF ELUTRIATION

P. D. McNamee has shown (5) that, without elutriation, the sludge produced at the District of Columbia plant would require about three times the ferric chloride now used. So far, it has not been practicable to operate the vacuum filters with unelutriated sludge to obtain plant data to check this value, but under the circumstances of the comparison, there is reason to believe it

TABLE 4.—VALUE OF ELUTRIATION

Item	Description	Dollars
1	Cost of construction, including mechanical equipment	40,500.00
2	Patent rights	12,000.00
3	Total investment (Items 1 and 2)	52,500.00
	Fixed Charges of Elutriation Facilities:	
4	Complete unit, amortized over 20 years at 3% (0.037 × Item 1)	1,498.50
5	Interest on the investment (0.03 × Item 3)	1,575.00
6	Total, per year (Items 4 and 5)	3,073.50
	Operating Cost for the Fiscal Year Ending June 30, 1941:	
7	Labor and supervision	2,496.00
8	Materials and supplies	163.00
9	Electrical energy	252.00
10	Total, for the year (Items 7, 8, and 9)	2,911.00
11	Total annual cost of operation and fixed charges, 1941 (Items 6 and 10)	5,984.50
12	Reduction in ferric chloride required	17,000.00
13	Value of elutriation, in dollars per year (Item 12 minus Item 11)	11,015.50

would be quite close to an actual operating figure. Acceptance of this figure makes possible an evaluation of the sludge washing facilities at this plant. Table 4 indicates the cost of construction and operation of this unit. The operating costs are those for the year ended June 30, 1941, which was a full operating year. During this period, $8,500 was spent on ferric chloride for conditioning the sludge prior to dewatering. Accordingly, without elutriation, ferric chloride, if it had been the sole conditioner, would have cost three times this amount, or $25,500. The value of elutriation may be given, then, as $17,000 less the operating cost of, say, $6,000 per year, or a saving of $11,000 per year. From these data, it is apparent that the elutriation unit will pay for itself every 4 or 5 years. These conclusions are based on the condition that ferric chloride alone would be the conditioner if elutriation were not practiced. Furthermore, it is assumed that costs of filtration, as affected by filter yield and life of cloth, would be the same, although all data indicate that greater yields may be expected from elutriated than from unelutriated sludge. For this reason, additional savings made possible by elutriation arise from reduced filter area and reduced filtering time. Consideration of these advantages would increase further the monetary savings affected by elutriation.

OPERATING RESULTS

During the 1941 fiscal year which ended June 30, 1941, the sludge dewatering facilities along with elutriation enjoyed a year of full operation. In the course of the year, volatile matter in digested sludge varied from 39.0% to 48.4%, manifesting the extra load on the digestion tanks resulting from the large population growth in the area served.

TABLE 5.—AVERAGE RESULTS OF ANALYSES OF ELUTRIATED SLUDGE

Month	Specific gravity	Solids (%)	Volatile matter in solids (%)	Wash water used, in 1,000 gal daily	Ratio of wash water to sludge volume	ALKALINITY, PPM		Effective wash water ratio[a]	Power for pumping wash water (kw-hr per day)

[a] In pounds per square foot per hour.

alkalinity reduction equivalent to 7.5 volumes of wash water. The gain represented by these figures may be attributed to counter current elutriation, which was used throughout the year.

TABLE 7.—COSTS OF SLUDGE ELUTRIATION, DEWATERING, AND DISPOSAL

Item	Description	Dollars
1	Ferric chloride (Fe_2Cl_3)................	8,500
2	Other operating costs of elutriation and dewatering.......................	23,313
3	Total (Items 1 and 2)................	31,813
4	Cost of sludge disposal (railroad shipment)...........................	20,929
5	Total operating cost (Items 3 and 4)	52,742

Table 6 shows the detailed operation of the sludge filters for the year. For the entire period, 23,770 tons of sludge cake were produced, with an average solids content of 28.9%. These 6,862 tons of dry solids were dewatered by the vacuum filters at the average rate of 5.9 lb per sq ft per hr. The ferric chloride used during the period was 218.54 tons, or an average dose of 3.18%. Costs of sludge dewatering are as given in Table 7.

TABLE 8.—UNIT COSTS OF SLUDGE TREATMENT AND DISPOSAL FOR 1941

Item	Description	General operating costs	Ferric chloride	Sludge disposal	Total
1	Per ton of sludge cake............................	$0.98	$0.36	$0.88	$2.22
2	Per ton of dry solids in the cake....................	3.40	1.23	3.06	7.69
3	Per million gallons of sewage treated..............	0.59	0.21	0.53	1.33

Table 8 indicates the unit costs of sludge treatment and disposal for the year. It should be emphasized that these costs are for sludge elutriation, vacuum filtration, and cake disposal only and do not include costs of sludge digestion.

SUMMARY

At the District of Columbia Sewage Treatment Plant, elutriation of primary digested sludge prior to vacuum filtration has been found beneficial to the dewatering process and economically justified. Some simplifications in the sludge mixing facilities have been made, and measures for prolonging the life of the woolen filter cloths have been practiced.

POSSIBLE ECONOMIES IN SLUDGE DISPOSAL PRACTICE

By George J. Schroepfer,[4] Assoc. M. Am. Soc. C. E.

Synopsis

Because of the fact that considerable information has been published (6)(7) concerning the processes used and the results of operation of the sludge disposal system at the Minneapolis–St. Paul (Minn.) plant, such data as are presented herein are limited in scope and are condensed and arranged to illustrate certain points which the writer wishes to make.

The sludge disposal processes at the Minneapolis–St. Paul plant were placed in operation in July, 1938. They consist essentially of concentration, dewatering on vacuum filters, and incineration. The vacuum filters, of which there are six, each have an area of 500 sq ft. The three incinerators are of the multiple-hearth type; each has eight hearths and is 22.25 ft in outside diameter.

Operation and Cost Data at the Minneapolis–St. Paul Plant

In Table 9 are shown comparative data on sludge filtration and incineration by years. It is interesting to note that it has been possible to maintain an average solids concentration in the sludge prior to filtration of more than 9% (91% moisture). The moisture content of the sludge cake has consistently averaged approximately 65%. In connection with statements that will be

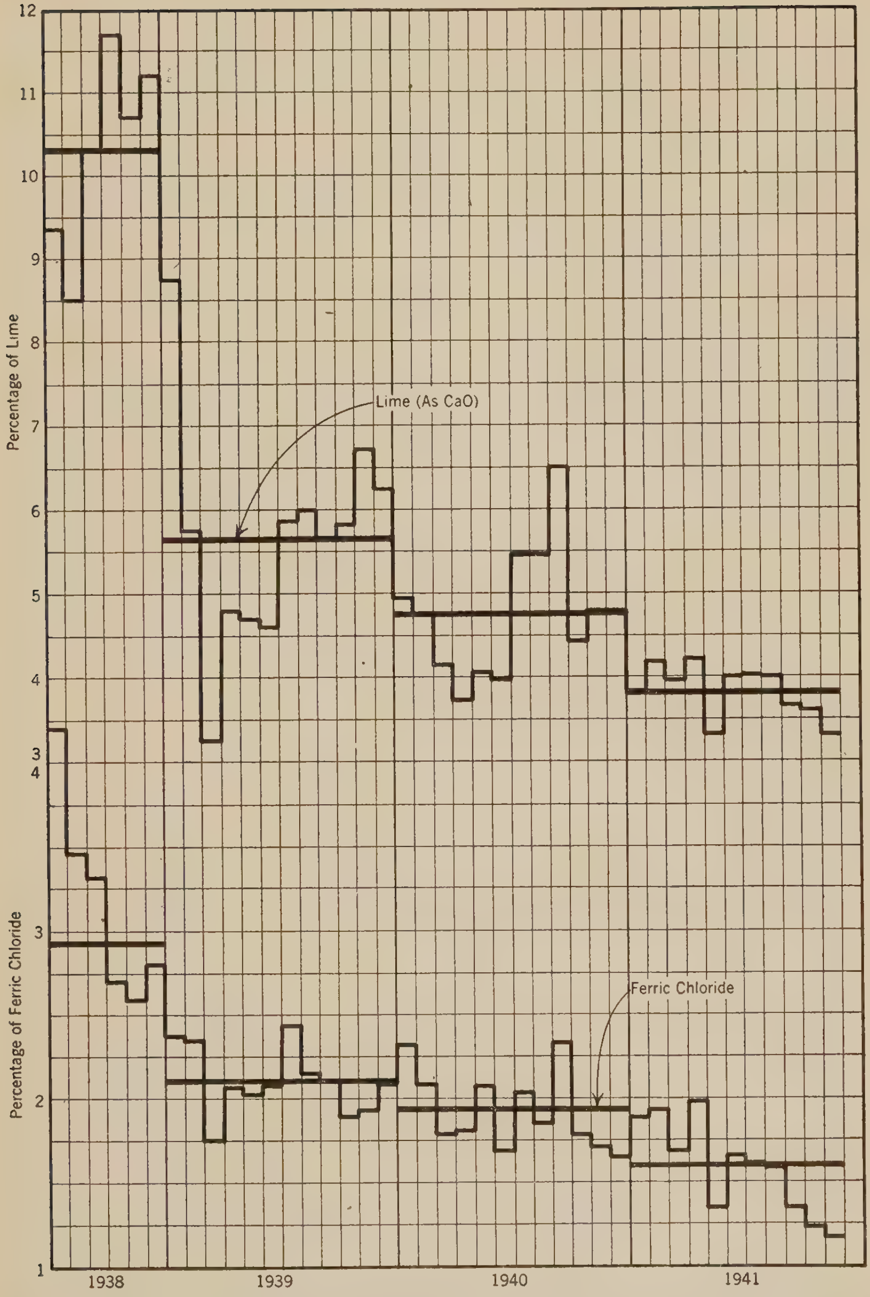

FIG. 2.—CHEMICALS FOR SLUDGE CONDITIONING, MINNEAPOLIS-SAINT PAUL (MINN.) SANITARY DISTRICT (EXPRESSED AS PERCENTAGES OF DRY SEWAGE SOLIDS)

made subsequently concerning this matter, the progressive and planned reduction in the filter rate from 5.50 lb per sq ft per hr in 1938 to 3.90 lb per sq ft per hr in 1941 should be noted. This ties in with the progressive reduction in chemicals shown in Table 9 and illustrated more graphically in Fig. 2. The reduction of chemicals to less than one half of their previous values is of some economic magnitude.

Costs of filtration and incineration for the various years of operation are shown in Table 10. The costs of operation and maintenance of the sludge disposal processes have been decreased from $6.97 per dry ton in 1938 to $3.41 in 1941. It is of interest to point out the relative magnitude of the cost of sludge disposal (which in this project has been between 40% and 45% of the total cost), as compared to the total cost of the collection, treatment, and sludge disposal processes. As shown in Table 10, the cost of chemicals for sludge conditioning has decreased progressively from $2.20 to $0.97 per dry ton. These are based on present chemical costs, which are somewhat lower than early costs. The magnitude of these reductions is shown in the daily costs to filter the present quantities of sludge. From a value of $242 per day in 1938, the costs have been reduced to $106.20 in 1941. This amounts to a total annual reduction of $50,000.

[a] July to December, inclusive, 1938. [b] January to October, inclusive, 1941. Supplementary data for 1941, 1942, and 1943 are given in Table 24. [c] Includes conditioning chemicals.

IMPROVEMENTS IN FILTRATION AND INCINERATION AS APPLIED TO THE MINNEAPOLIS–ST. PAUL PROJECT

In order that the remarks made herein can be evaluated properly in the light of definite conditions, certain improvements and operating goals as they apply to this project are mentioned briefly. This has the further advantage of restricting the observations to certain particular conditions, since the inconsistency of sludge behavior characteristics makes general observations inapplicable or even misleading. For this reason improvement changes effected at this plant should not be considered as "cure-alls," but rather as possibilities for exploration and development as they might apply to a different plant.

Concentration of Sludge.—It is a commonly recognized fact that, within limits, the more concentrated the sludge that can be produced the greater will be the efficiency of vacuum filtration, since, with a concentrated sludge, the gallonage of liquid sludge per ton of dry solids is reduced, resulting in decreased chemical costs and less work for the vacuum filters. The concentration of sludge in the Minneapolis–St. Paul plant is controlled by weighing a known quantity of sludge that is pumped from the sedimentation tanks at frequent intervals, as well as by soundings and determinations of moisture content of sludge in the tanks. The moisture content is further reduced by the control of the concentration tanks in which a further separation and concentration are effected by reason of the withdrawals of supernatant liquor. That such procedures are effective is shown by the fact that the moisture content of the sludge as removed from the settling tanks averaged 8.1% in 1940 and 1941, with an increase in solids, by concentration, to an average of 9.35% (see Table 9).

Conditioning of Sludge.—Considerable improvement in the conditioning of sludge, and resulting reduction in the cost of filtration, can be effected by improving the process of mixing in the conditioning tanks. In the case of air mixing, which is used at the Minneapolis–St. Paul plant, better results were obtained by increasing the number of points through which air is admitted to the sludge for mixing and by decreasing the pressure and violence of the mixing. In addition, the path of the sludge, which formerly passed through the tanks with over and under baffles, was modified to create a sinuous path, both vertically and horizontally, which procedure resulted in improved mixing. Furthermore, the detention period in the conditioning tanks has been reduced from 13 min in 1938 to 7 or 8 min at the close of 1941.

Instead of adding the chemicals to the tanks through one or two pipes, riffle boards for both lime and ferric chloride have been installed. This has resulted in considerably improved dispersion of chemicals.

Suitable chemical feed equipment must be provided with an adequate range and careful checking to keep the machines in accurate adjustment. In this connection, it is desirable to make tests with different chemicals to protect the plant against the inability to secure the chemicals regularly used. Instead of lime and ferric chloride, which are the usual conditioning chemicals, plant scale tests have been conducted using ferric sulfate and lime, and ferric chloride alone. As a safeguard, a quantity of ferric sulfate has been stored for more than a year. Although not as economical as the present combination (approximately 25%

more expensive), the usefulness of substitute chemicals in emergencies has been demonstrated.

Filter Mediums.—The type of cloth used as a filter medium should be considered. After some, but not extensive, experimentation, 8-oz Canton flannel has been adopted at this plant. However, the difficulty of obtaining this material during wartime, and its increased cost, have necessitated additional investigations leading to the possible use of a new cloth type. The life of filter cloths is also an important subject for investigation. For experimental purposes, cloths have been used for as long as 800 hr, but such procedures are distinctly not economical for the type of sludge disposed of at the Minneapolis–St. Paul plant. Newer cloths give somewhat higher yields for the same quantity of chemicals and, conversely, require less chemicals for the same yield. With high chemical dosages, the importance of this factor is not readily apparent, but with dosages approaching 1% of ferric chloride and 3% of lime, such factors show up quite markedly. In spite of the fact that the cloth is structurally in good condition, its use has been restricted to 350 hr. In recent months, because of increased cost of cloths, a longer period of usage has been adopted. When it is realized that cloth and wire constitute only approximately 3% to 10% of the cost of chemicals, the economy of maintaining satisfactory cloth will be readily apparent.

Tests have been made on a plant scale to demonstrate the effect of cloth age on filter yields. As a result of such tests, it has been shown that there is a loss in yield of 2.5% for each 100 hr of additional cloth life. Thus, at 500 hr, the yield of a filter is approximately 10% to 15% less than that of a new cloth, other conditions being constant. These results apply to an interval of 4 hr between washings (which is current practice at this plant). With longer intervals between washings, the yield with low chemical dosages falls off rather rapidly for older cloths. In fact, even after the first hour or two, the yield of older cloths drops off.

The aforementioned tests were conducted in an investigation to determine economical cloth life. The results of this study for present Minneapolis–St. Paul conditions are as summarized in Table 11. This comparison is based on present cloth costs, in 50-yd bolts, of $0.235 per sq yd, and indicates the economical life to be about 400 hr. At different cloth prices, such as the previous price of $0.135 per yd, or with varying chemical unit prices or required additions, the economical balance, of course, would vary.

TABLE 11.—COMPARISON OF DAILY COSTS OF FILTER CLOTH AND CHEMICALS (DOLLARS)

Description	Cloth Life, in Hours							
	100	200	300	400	500	600	700	800
Wire and cloth	36.00	18.00	12.00	9.00	7.20	6.00	5.15	4.50
Chemicals	73.00	75.50	78.00	80.00	82.00	84.00	86.50	89.00
Total	109.00	93.50	90.00	89.00	89.20	90.00	91.65	93.50

Regardless of the age of the cloth, an appreciable improvement can be effected by proper washing. It has been found that the washing can be improved considerably by rearranging the washer sprays to impinge along the filter drums almost at right angles to the drums, instead of tangentially, as in the usual installations. However, regardless of the efficiency of washing, certain material remains in the cloth even after extended periods of washing. Analysis of the blinding material in a number of cloths after approximately 300 hr to 400 hr of service indicates that approximately 60% is calcium carbonate and approximately 20% is grease. At the present price of cloth, it appears to be economical to give each cloth an acid bath, using one to two carboys of hydrochloric acid (in 600 gal of water), together with an inhibitor, after approximately 350 hr of service, thereby reducing the blinding and increasing the economic cloth life to approximately 500 hr to 600 hr. This expedient has the further advantage of providing an inexpensive means of removing calcium carbonate from the screens and splines of the filters, which formerly became so incrusted with material as to interfere with the free passage of water through the filter. This material was previously removed by sand blasting and other mechanical means, but because of savings in time and expense, and for other reasons, the chemical method of removal is more desirable.

It has been found economical, in the case of the Minneapolis–St. Paul plant, to wash filters frequently. During the first several months of operation, washing was confined to intervals of approximately 24 hr or longer. This was changed later to at least one washing of each filter every 8 hr, and in the last several months a washing has been required at least every 4 hr. This has marked effects on the quantity of chemicals required. In fact, the importance of maintaining a clean filter medium has resulted in the development, by the staff of the Sanitary District, of a method of washing filters while they are in service, either continuously, or at frequent intervals, as dictated by the relative economics. Although this method has not been incorporated in this plant to date (1942), because of its recent conception and the effect of priorities on procurement of the necessary material, its simplicity, and therefore its likelihood of operating satisfactorily, justify a description herein. Instead of its usual location, on the far side of the filter from the take-off plate, the wash-water pipe and nozzles would be installed immediately below the top edge of the take-off plate, so that the washing operation would be done in the section of the drum between the take-off and the submergence in the sludge, which section is not utilized in the usual installation. A trough suspended immediately above the sludge level would return the spent wash water to the overflow box on the filter. It is expected that, in addition to the advantages gained through maintaining a clean filter medium, the installation of this method of washing, in effect, will result in the addition of one filter, since it is necessary to have one filter in reserve a major part of the time to take the place of filters being washed.

Economic Speeds of Rotation of Filter Drums.—It is commonly recognized that, within limits, a change in speed of the filter drum increases or decreases the filter yield. It is possible to determine for each size of installation and type of sludge the economic range of speeds at which the filters ordinarily should be operated.

Adequate Filter Area.—The filter rate has a marked effect on the economics of filtration. Where incineration or drying is the practice, it is desirable to have a multiplicity of units so that uniform feed to subsequent units can be maintained at all times. An important loss of filter time results from washing of the filters and, to hold feeds constant, it is advisable to have a spare unit, in addition to the regular operating filters, to use during washing of regular units.

Return of Incinerator Ash.—Other papers by the author mention the advantage of returning incinerator ash to the raw sewage after filtration and incineration. This possibility, as well as a variation of it—adding ash to the sludge immediately prior to conditioning—bears investigation.

Incineration.—The desirability of maintaining a uniform feed of solids to the incinerator has been mentioned. By doing so, it is possible to improve operation and reduce maintenance cost. Sudden and large changes in sludge feed result in rapid changes in furnace temperatures, with consequent long-time damage to refractory materials.

As an experiment, the preheater has been removed on one of the three incinerators, which results in considerable savings in power (which constitutes 25% of incinerator costs) and maintenance costs. Although the original preheater was still serviceable, the result of investigations seemed to justify removal of the preheater from one furnace. This was done in May, 1941. Operation of this unit indicates a marked reduction from 17 kw-hr to 5.5 kw-hr in the quantity of power required. Operation of the unit over a period of six months has justified similar changes in the other two units at an estimated savings in power, replacement, and maintenance costs of $12,000 annually. This will result in a reduction in operation and maintenance costs of incineration of approximately 33¢ per ton.

Attention is called to the reduction in the quantity of fuel oil required by the incinerators (Table 9). Only 1.5 gal of fuel oil are now required per ton of dry solids incinerated, this quantity being required in heating up, cooling down, and holding temperatures in incinerators not in operation. A substantial savings in this item was effected by the installation of duct work so that the heat available in operating furnaces could be utilized to heat up, cool down, or maintain temperatures in any desired unit. In view of the fact that fuel costs are a minor item in sludge disposal expense at this plant (averaging 5¢ to 10¢ per dry ton), these savings are not of major importance, but are cited to indicate the possibilities available.

An interesting possibility relates to the utilization of the heat resulting from incineration. Various methods have been developed which indicate the possibility of generating sufficient steam for all heating purposes and electric power requirements.

In general, it can be stated that the possibility of effecting major economies and that the operating difficulties encountered are somewhat less in connection with sludge incineration as compared to vacuum filtration. The difficulty of making marked savings in incineration costs is evident from the fact that approximately 50% of the cost is labor, of which the major part is the time of one man on each shift to operate the incinerators.

EFFECT OF FILTER RATE ON COST OF FILTRATION

In the past, it was erroneously believed that the measure of the efficiency of sludge filtration was the thickness of the filter cake produced, a heavy mat being considered highly desirable. This mistaken impression has sometimes resulted in the use of higher filter rates in both design and operation than are economical. As an example, a number of plants are operating with filter rates of 5 to 10 lb per sq ft per hr. In some cases the installed area and filter size preclude the use of lower rates by the operator. Because of its importance to filter costs, the writer devotes considerable space to a discussion of this factor.

In the early period of operation of the Minneapolis–St. Paul plant, when chemical additions of about 3% of ferric chloride and 10% of lime were utilized, filter rates of 8 to 10 lb per sq ft per hr were common, the usual cake thicknesses being between 0.5 in. and 0.75 in. In addition to causing other difficulties (which are enumerated in earlier papers by the author), this type of operation was distinctly not economical. As shown in Table 12, filter rates were progressively reduced so that by October, 1941, the rates were only 3.55 lb per sq ft per hr. The attendant reduction in chemical requirements is also shown, but it should be emphasized that not all of this reduction can be attributed to the reduction in rate, as certain improvements and better operation were accomplished simultaneously. The test referred to in Table 12 was made during one day of operation with other influencing factors maintained constant, so that the effect of filter rates on chemical costs could be observed. The influence of filter rates on costs of operation and maintenance is shown in Table 13 and on total annual charges in Table 14. Referring to Fig. 3, it will be observed that chemical costs at high filter rates far outweigh other affected cost items, whereas at low rates the reverse is true. Conditions at the Minneapolis–St. Paul plant indicate that the economical filter rate is approximately 2 lb per sq ft per hr, based on total annual charges (including fixed charges). Considering operation and maintenance costs only, however, the economical rate is approximately 1 lb per sq ft per hr. It will be observed that the operation and maintenance costs at a 2-lb rate are less than half of what they would be at a 7-lb rate. Based on the tonnages produced at the Minneapolis–St. Paul plant, a

TABLE 12.—EFFECT OF FILTER RATE ON REQUIREMENTS OF CHEMICALS FOR SLUDGE CONDITIONING

No.	Description	(a) No. of Filters Used (Test on Plant Scale)[a]			(b) Average Results, by the Periods:

[c] Percentages by Dry Weight of Sewage Solids.

reduction in the filter rate from 7 lb to 2 lb per sq ft per hr would result in a saving in operation and maintenance costs of approximately $125 per day, or about $45,000 annually. Expressed in another way, the installation of one more filter in this plant would result in savings in operation and maintenance of $14 per day, or approximately $5,000 per yr, which would pay for the additional investment in two to three years. The magnitude of the costs involved compels attention to this important phase of filtration economics.

[a] From Table 13, Col. 5. [b] Other differential operation and maintenance costs from Table 13, Col. 10. [c] Dollars per dry ton.

What has been stated concerning this matter is subject to the following local and practical limitations: It is based on the conditions (type of sludge, chemical costs, etc.) existent at this plant. A comparable analysis can, and should, be made by other operating plants, based on the conditions obtaining there, to determine (*a*) the economics of operation of the present installation, (*b*) the possibilities of effecting economics by the enlargement of present facilities at some future date, and (*c*) economical rates for different types of sludges for the benefit of designers of future plants. Other practical limitations relate to the possible inability of present equipment to remove cake when it becomes exceedingly thin, although that limitation would not be effective at the economical value of 2 lb per sq ft per hr (⅛-in. thickness) determined herein. Furthermore, the cost of operation labor (maintenance labor and labor for changing cloth have been assumed to vary) has been assumed constant in this analysis, since it is quite definite for this plant that the same personnel which now operates six filters could operate eight filters (approximately the 2-lb rate), which number is dictated by the present size of this plant. Of course, the same number of men could not operate eighteen filters (1-lb rate) as would be required to operate three filters (6-lb rate). However, the usual decision in an operating installation will be on the question of whether one filter or, at most, two filters should be added. Therefore, usually no increase in personnel will be involved, since a large part of the operation labor is affected by the tonnage of material handled, which is assumed constant.

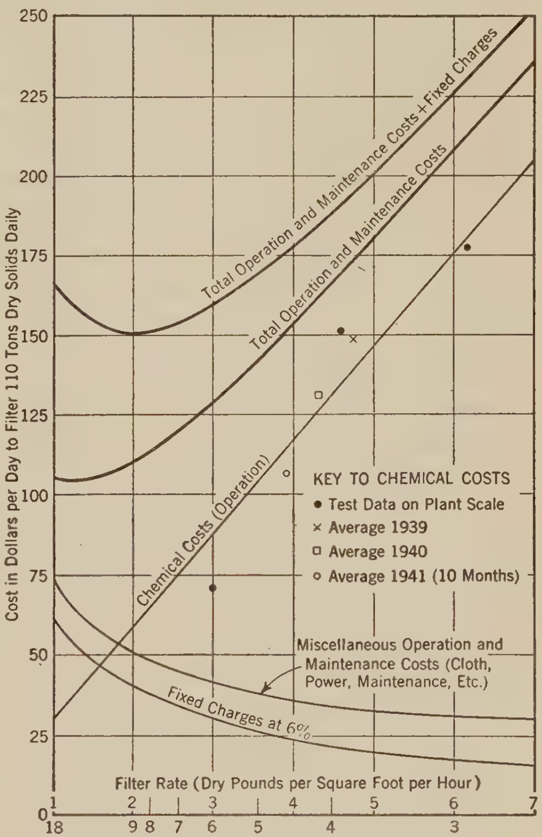

Fig. 3.—Daily Cost of Materials and Supplies, Power, Maintenance, Etc., to Produce 110 Tons of Dry Solids per Day

Costs of Dewatering and Incineration as Compared to Other Processes of Sludge Disposal

The relative complexity of efficient dewatering by vacuum filters presents again the question of the relative economy of this process of sludge disposal as compared to others available, particularly for the comparatively small plants. Sludge digestion and drying on sand beds are still satisfactory processes and should receive consideration in a decision on the most advantageous type of sludge disposal for a particular project. A number of factors, including practical and economic ones, usually will influence the decision in favor of dewatering, followed by drying or incineration, in large projects. In the case of very small plants, the decision is likewise comparatively simple in favor of the older type of processes. Dependent on the type of treatment by which the sludge is produced, and other factors, the decision in the case of plants serving populations in the range from 50,000 to 200,000 should be based on a thorough analysis of the many influencing and controlling factors involved. The quantities of material to be disposed of, as they influence the likelihood of securing efficient and economical operation of a more complicated mechanical and chemical process, must be considered. To expect that even the most conscientious operator of a plant in a community of, say, 25,000 people, in which 1 to 2 tons of dry solids must be disposed of daily, can even approach the efficient and controlled operation of a plant handling 50 or more tons daily is erroneous. Extending this idea further, a plant of the size of the Minneapolis–St. Paul plant handles quantities in a single week that the small plant referred to would encounter in a year or two of operation.

For illustrative purposes the costs of various sludge disposal processes are mentioned briefly. A. J. Fischer, Assoc. M. Am. Soc. C. E. (8), has estimated the costs of different sludge disposal processes as shown in Table 15. These are cited to show that, at the very least, an economic question is involved in medium-sized plants. Using actual costs as reported by the late H. F. Ferguson and W. H. Wisely, Assoc. Members, Am. Soc. C. E. (9), for communities using digestion and drying in a population range from 47,000 to 200,000 (to which range the writer makes special reference), the costs of operation and maintenance vary from $2.45 to $5.10 per dry ton (higher values for the smaller plants) and the total annual charges vary from $7.85 to $12.50 per dry ton. When it is realized that the operation and maintenance costs alone for several considerably larger plants using dewatering on vacuum filters, followed by incineration, range from $5 to $15 per dry ton, the point to which the writer alludes will be evident.

TABLE 15.—COSTS OF SLUDGE DISPOSAL, IN DOLLARS PER DRY TON

Population served	DIGESTION AND DRYING ON BEDS		DIGESTION, FILTRATION, AND INCINERATION	
	Operation and maintenance	Total annual charges[a]	Operation and maintenance	Total annual charges[a]
100,000	3.40	7.00	7.10	11.50
200,000	3.50	6.70	6.80	9.80

[a] Includes fixed charges on the investment at 7.5%.

Personnel Required.—The greater complexity of sludge filtration and incineration processes, both from mechanical and chemical standpoints, as compared with the older processes available, requires a higher quality of personnel for economical operation and maintenance. Of course, it is possible to filter sludge with large dosages of conditioning chemicals, and to incinerate sludge with high maintenance charges, but to perform this work economically requires a relatively high degree of skill. New problems are constantly arising and new possibilities must forever be explored. Whatever success the Minneapolis–St. Paul Sanitary District has had in economical operation of its sludge disposal processes is attributed largely to the advantage of having a relatively large number of professional engineers and chemists in supervisory positions.

It is not enough, however, to have men with technical training in charge. It is necessary that the interest and conscientiousness of the entire personnel, including especially the filter and incinerator operators, be maintained at a high level at all times. For example, as a means of awakening the interest of the filter operator, such possibilities as control of filtration by Buechner tests, frequent calculation of chemical dosages (as often as hourly), and shift competition on chemical requirements should be utilized. Operation should never be considered to have reached what appears to be the ultimate, so that standardization in practice, with consequent stagnation, will take place. New ideas (and there can be many) must be explored and developed continually, so that the entire staff, from the superintendent down, never loses sight of the possibilities of improvement. After all, a routine standardized task is certain to become uninteresting.

Dependability of Operation.—To accomplish the purposes for which a sewage treatment plant is constructed, it is necessary that the sludge disposal processes be able to handle the raw material produced as necessary. Digestion or a sufficient period of storage prior to filtration provides some leeway for the unexpected failures of equipment. Duplicity and multiplicity of units can be secured in the larger plants, but in the smaller plants this is sometimes not considered to be economically feasible. In addition to the economics of selection, dependability is another factor that must be taken into consideration in the decision between digestion and drying on sand beds and the mechanical processes. With from three to as many as several dozen vacuum filters in a larger plant, dependability as a factor is reduced in importance by thoughtful design; but in the smaller plants that are provided with only one vacuum filter and one drying or incineration unit the operator must be eternally vigilant to take advantage of all favorable opportunities to place his equipment in such condition that it will survive the period when its operation will be most in demand. Essentially, the point that the writer wishes to make is that, although operators of plants using digestion and drying may complain of the perversity of the bacteria in the digestion tanks, or the unpredictableness of the weather as it affects drying on beds, their problems dwindle into insignificance in comparison to those of the superintendent of a small plant with complicated and numerous mechanical devices which, even with proper care, display a persistent propensity to break down at the most inopportune times.

The statements concerning the efficiency and dependability of various processes of sludge disposal are made, keeping in mind certain limitations in their applicability. In large plants the decision is quite likely to be in favor of the mechanical processes, and properly so. In the small and medium-sized plants, thorough consideration must be given to all factors, including those peculiarly local factors which influence the decision. In the very small plants the writer feels that consideration should be given to the position of the operator, who is in the embarrassing position of complying with the requirements of public health officials as to dependable and satisfactory operation on the one hand, and meeting the demands of local public officials as to the economical operation on the other. The writer realizes, also, that all equipment improves in dependability and economy with development, and this has been the case with sludge disposal equipment. Furthermore, it is more than likely that, with careful observance of actual operation of equipment, along with more attention to details of design as they pertain to the smaller plants, on the part of designing engineers and equipment manufacturers, and that, with the present tendency to raise the standards of qualifications of small plant operators, mechanical processes, in the future, will be shown to be economical and dependable, even for the smaller plants.

Relative Costs of Filtration and Incineration

A review of the costs of filtration as compared with incineration at several plants will indicate the relatively large proportion of costs devoted to dewatering prior to incineration. The writer feels that with present practice too much of the cost of sludge disposal is devoted to the preliminary processes which serve simply to prepare the material for incineration. In spite of appreciable economies effected in filtration costs, the costs of dewatering at the Minneapolis–St. Paul plant are still approximately twice the costs of incineration. At several other plants this relation is still greater. As previously indicated, the possibility of savings in filtration is greater than in incineration. Developments in sludge disposal practice are likely to be along the line of reducing or eliminating the preliminary expenses. As a matter of fact, one or two small plants have been incinerating liquid sludges for some time. In connection with the studies of type of sludge disposal for the Minneapolis–St. Paul plant, the writer concluded in 1935 that, if the moisture content of the sludge could be reduced to 85% or 90%, dewatering on vacuum filters could be economically dispensed with, assuming that equipment was available for incinerating this type of sludge. The Sanitary District has begun experiments in which a portion of liquid sludge will be added to the filter cake in the incinerators as a means of determining the possibilities of this procedure.

Filter Rate Index

Because of the importance of the filter rate on the cost of filtration, it is desirable to use a more accurate index of filter rates than the commonly used unit of pounds per square foot of installed filter capacity per hour. This does not furnish an accurate measure of the number of square feet of filtering surface utilized in a given period, since it does not take into account varying filter speeds (changed quite frequently to hold uniform tonnage) which, of course, affect the filter area. Filter speeds used in two different plants may easily vary by as much as 50%. For this reason the writer suggests the use of the index, "pounds per square foot," based on actual filter surface used. To make the use of this unit possible, it is necessary only to install inexpensive revolution counters on the filter drums. Using the revolutions in a given period of time, the tonnage produced in that same period, and the area of the filter, it is possible to obtain an accurate filter rate for comparisons within a plant and with other plants. Incidentally, this furnishes a readily applied method of determining when it is desirable to change filter cloths, in terms of actual work done by the filter.

Summary and Conclusions

The writer has made certain observations and indicated certain possibilities of improving operations or effecting economies in sludge disposal processes. The presentation of this paper has afforded an opportunity to state certain general impressions that the writer has had for some time. He hopes that the discussions and considerations by others in this field will serve to clarify the relation between, and the applicability of, the various sludge disposal processes available, and thereby take advantage of the temporary lull in sewage disposal construction which will precede the period of expansion in the postwar era. The impressions of the writer are summarized as follows:

(1) Consideration should be given, in existing and projected plants, to the possibility of effecting economies by the utilization of lower filter rates than have heretofore been the general practice.

(2) A closer study and a better explanation for some of the occurrences in vacuum filtration can be made by the use of a filter-rate index, based on pounds per square foot of filter surface utilized. The index commonly used does not take into account the variation in filter speeds and other factors of importance in a close scrutiny of filtration characteristics.

(3) Since the decision between the mechanical processes and the older methods of sludge disposal is usually quite clear cut in the very large, as well as in the very small, plants, the writer suggests increased consideration in selection, in the case of medium-sized plants. Certain reasons are offered for the present inapplicability of the mechanical processes to the smaller plants.

(4) The writer feels the necessity of a higher degree of directive ability, for economical operation and maintenance of mechanical sludge disposal processes, than has heretofore been considered necessary. Even in the very small plants this should approach that of professional grade. In addition, the interest of all members of the staff must be promoted continually to improve the position of mechanical processes of sludge disposal.

USE OF SEWAGE SLUDGE AS FERTILIZER

By LeRoy W. Van Kleeck,[5] Assoc. M. Am. Soc. C. E.

Synopsis

The disposal of the settleable solids or sludge produced by sewage treatment plants is a major operating problem. Air-drying, incineration, use as fill, and other means of disposal for sludges have been discussed by others. The writer's plea is for more general use of sewage sludge, properly prepared as a soil conditioner, as well as for its fertilizer value. Failure to make use of it is a waste of a natural resource.

Introduction

One bomb dropped on London in 1939 was not released by a German war plane but by Sir Albert Howard, an eminent English agricultural scientist, who, in a paper (10) presented before the British Institute of Sanitary Engineers stated:

> "When the problems of waste disposal as a whole are considered, it is difficult to escape the conclusion that the West has completely lost direction. Why are the methods of the forest, in dealing with its wastes, more effective than those of the various Councils in our large cities? The answer is obvious if we study Nature's round—the wheel of life * * *. Trouble inevitably follows any attempt to short-circuit or to interrupt this wheel. This is always followed by disease in crops, in live stock and in mankind * * *.
>
> "The farmers of forty centuries, the cultivators of the East, the Chinese in particular, have closely followed the methods of the forest when dealing with their wastes. Nothing is ever thrown away. Vegetable and animal residues are mixed and converted into humus before being added to the land, so that the soil is not overworked by having to decay this material and grow a crop at the same time * * *. The consequence is that countries like China and Japan maintain over 2,000 people to the square mile as compared with about 60 in the United States. The Far East has been doing this for centuries without any loss of fertility. After less than one hundred years, the soils of the United States are almost worn out and a great national effort is now in progress to restore the lost fertility. You have all heard about the dustbowls and the floods of the Mississippi Valley—both the inevitable consequences of improper methods of agriculture which have taken no account of the correct utilization of wastes.
>
> "In Great Britain we are rapidly following in the steps of North America * * *."

In the voluminous discussion of this provocative paper, Lt.-Col. F. C. Temple stated (10*a*): "* * * engineers who have to deal with sewage or town refuse are not doing their job properly until they get the products from both back on to the land."

---

[5] Senior San. Engr., State Dept. of Health, Hartford, Conn.

In a written discussion of Howard's paper, Arthur J. Martin, past-president of the Institute, stated (10*b*):

> "The Author's protest against the neglect of our domestic wastes is very timely. The Sanitarian is notoriously a wasteful animal. He delights in destruction. He flouts the wise economy of nature and disregards the food cycle which she has established. We draw heavily year by year on the fertility of our soil and we squander plant food to the tune of scores of millions of pounds. We seek to redress the balance by means of artificial manures * * *.
>
> "The persistent neglect of sewage sludge is deplorable. It is doubtless attributable in part to the intense conservatism of the average farmer, but it is largely the result of the habit, to which the Author refers, of rating the value of a manure in terms of nitrogen, phosphorus and potassium and overlooking the humus of which our fields are so sadly in need * * *.
>
> "An engineer from Czechoslovakia told me last year that the whole of the sludge from Prague, a city of a million inhabitants, is utilized year by year on an area of eighty square miles. Some of the sludge is carried to a distance of fifty miles, and the supply cannot keep pace with the demand. Such instances go to show that sludge has only to be known to be appreciated * * *."

In view of the rather detailed information available on the use of sewage sludge as fertilizer (see bibliographical references (11) through (17), it would seem that for the purposes of this Symposium this paper can be confined to summarizing the latest information on the subject, together with the writer's personal experience with the use of sludges, particularly primary digested sludge, as fertilizer, or in a more appropriate term, as a soil conditioner.

USE OF LIQUID SLUDGE VERSUS DEWATERED SLUDGE

Liquid sludge normally contains from 85% to 98% water and is infrequently used as a fertilizer either in raw or digested form. The principal objections to its use are:

1. The large quantity of fluid bulk that must be transported unless pipe lines can be laid to near-by agricultural fields;
2. Difficulties of uniform application to the area to be fertilized;
3. The greater likelihood of objectionable odor; and
4. The possibility of pathogenic organisms being present. C. P. Mom and C. O. Schaeffer (18) isolated typhoid bacteria in liquid Imhoff tank sludge drawn to drying beds, but after drying no typhoid bacteria could be found. Although liquid sludge does contain additional fertilizer constituents which are lost in the drained liquor by dewatering processes, past experience encourages dewatering and storage of sludge as additional safeguards against the transmission of infection. No cases of sickness have been traceable to the use of properly conditioned digested or activated sludge.

Sludge is generally utilized, after it has been partly dewatered, by draining it on beds of sand (Fig. 4), by pressing, by centrifuging, or by vacuum filtration (Fig. 5). The partly dried sludge is then referred to as "sludge cake," and ordinarily contains 70% or less of moisture. Such cake is dry enough to be shoveled and spread like manure or moist soil.

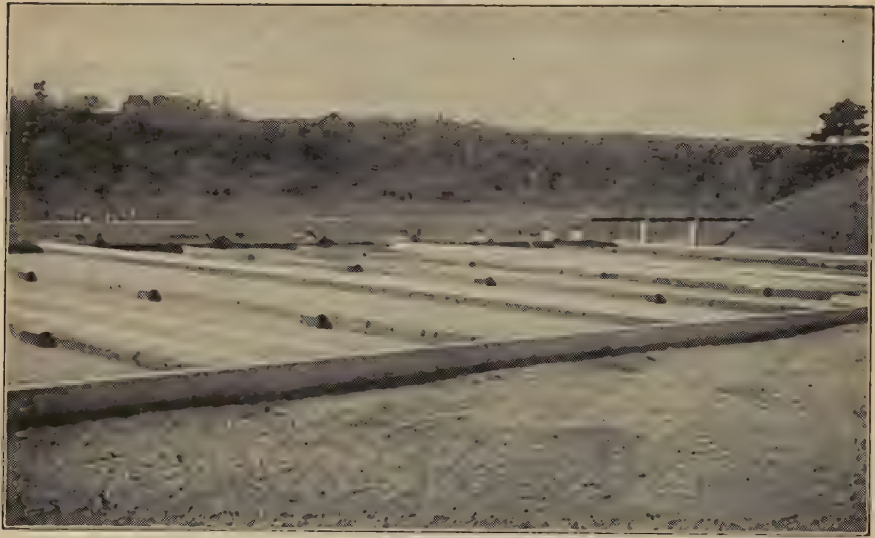

FIG. 4.—OPEN SLUDGE-DRYING BEDS

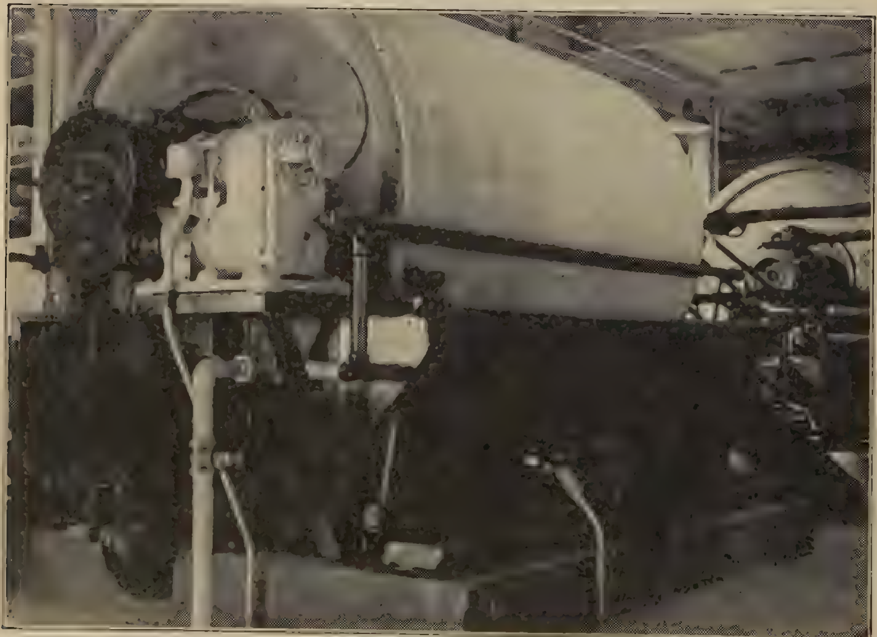

FIG. 5.—MODERN VACUUM FILTER FOR SLUDGE DEWATERING

USE OF RAW SLUDGE AS FERTILIZER

The use of raw primary sludge as fertilizer is not recommended, because:

1. It is odorous;
2. It has a higher grease content than digested sludge and is not readily assimilated by the soil;
3. It tends to bring about early and persistent soil acidity, especially if the sludge has been conditioned with iron salts;
4. Industrial wastes in the sludge may poison the soil;
5. It is a potential carrier of disease unless highly limed in sludge conditioning, when the high pH (usually ranging from 10.3 to 10.6) may destroy large numbers of bacteria. If heat dried, the bacterial content may be reduced; and
6. A sixth objection is that it is not humified for soil use. In this respect, Howard of England states (19):

> "The utilization of vegetable and animal wastes in crop production involves two definite steps, (1) the formation of humus and its incorporation into the soil, and (2) the slow oxidation of this product accompanied by the production of available nitrogen. Both of these stages are brought about by micro-organisms for which suitable environmental conditions are essential. The requirements of the first phase—the preparation of humus and its incorporation into the soil mass—are so intense that if the process takes place in the soil itself, it is certain to interfere with the development of the crop. The soil in fact gets indigestion! This explains to a large extent why crude sewage, crude refuse, and some of the sewage and refuse derivatives have been found wanting, or even harmful, by cultivators. In some places worse has happened; but it is clear that in many the first phase has not been sufficiently prolonged to allow the second to come into operation before the stuff was offered to the crop."

ACTIVATED SLUDGE

Raw or heat-dried activated sludge has a much higher fertilizing value than ordinary primary or secondary sludge for two reasons: One, the higher content of ammonia, and the other, its much higher availability. When digested, much of this fertilizing value is lost. Heat-dried and ground raw activated sludge is an organic fertilizer material especially suited to lawns because of its nitrogenous content. The analysis of Milwaukee sludge is as follows (dry basis):

Constituent	%
Nitrogen	6.2–6.5
Available phosphoric acid	2.5–2.75
Potash	0.5–0.75

The drying process is generally believed to free such sludge of harmful bacteria, although it does not completely sterilize it.

DEWATERED DIGESTED SLUDGES

Much of the digested sludge produced in the United States is so-called primary digested sludge—that is, from sewage solids that have been settled in tanks and subjected to anaerobic digestion. Secondary or humus sludge is frequently mixed with primary sludge and digested with it. Most of this paper is concerned with digested sludge. A comparison based on chemical analysis of digested primary sludge and related materials is afforded in Table 16. Items 2, 3, and 4, Table 16, are as reported by E. E. DeTurk (20) and Thomas P. Maloy (21).

TABLE 16.—COMPARISON OF TOTAL CHEMICAL CONTENTS (PERCENTAGE BY WEIGHT, DRY BASIS)

No.	Substance	Nitrogen	Phosphoric acid	Potash
1	Digested sludge[a]	1.7 (total)	1.5	0.15
2	Manure[b] (20)	1.97 (total)	1.29	1.96
3	Horse manure (21)	0.7 (available)	0.11	0.45
4	Sheep manure (21)	1.8 (available)	1.25	3.0
5	Commercial potato fertilizer	5.0 (total)	8.0	7.0

[a] Average of samples from a number of sewage plants in Connecticut. Some sludge cake produced in Connecticut also contains about 10% calcium oxide (lime). [b] Supposedly a mixture of animal wastes.

The nitrogen in sludge comes into action slowly, thus removing the danger of so-called burning of crops. Alleged burning of grass is usually caused by over-application of sludge cake, thus actually smothering the growing blades of grass, particularly if it is young.

Apparently sludge compares favorably (Table 16) with the ordinary run of manures. Its principal deficiency is in potash. According to DeTurk (20*a*): "The most important differences in the two materials are that the more easily decomposable nitrogen compounds of sludge have been more completely removed by its digestion process than is the case with manure, leaving a nitrogenous residue of lower availability (this is not shown by the table); and that the potash being mostly water-soluble has been largely washed out of the sludge while it is retained by the manure."

The chemical analysis of sludge does not, however, tell the entire story. Primary digested sludge is of considerable value as a soil conditioner, from its content of humus. Approximately 50% of the dry weight of sludge may be humus. Most of the organic matter in digested sludge is humus except for the ether-soluble fats. A sandy soil is particularly benefited by sludge, since its water holding capacity is increased. Unlike commercial fertilizers, sludge is not a balanced food for plants, nor is it an all-purpose plant food. Its application, however, works a mechanical change into soil, and improves its texture. The continued exclusive use of commercial fertilizers represents unsound and dangerous farming practice. Soils repeatedly planted to growing crops require the organic humus such as is found in manures, peat moss, green cover crops, and sludges. The value of sludge should not be judged only by comparison of chemical analyses with artificial fertilizers, but by the results it produces in plant growth.

Howard declares (10*a*), in connection with the use of unhumified materials:

> "We seem to be always thinking in terms of soil nutrients. This is a great mistake. In agriculture it is a question of the utilization of fungous tissue mobilized in the form of humus which really matters and which is one of the secrets of the agriculture of the East. This fungous question

> is far more important than nutrients and in this matter we have gone on completely wrong lines."

Rudolfs (22) believes that the soil improving and growth promoting values of sewage sludge are distinct and additional values to its fertilizer or plant food content by replenishing of organic matter and the minor elements needed by plants.

Digested sludge is comparatively free from weed seeds which are largely destroyed in the digestion process. Most manures on the other hand contain weed seeds which prove very objectionable, particularly when spread on lawns. Tomato plants and a few of the cucurbits may sprout in digested sludge, especially if the digesting temperatures are below 80° F, but they are not ordinarily troublesome.

Application of Digested Sludge and Hygienic Considerations

Sludge may be applied as a top dressing in the case of trees, shrubs, or lawns; in the hill in the case of melons, squash, or other vine crops; or it may be spread and then plowed or forked into the soil. When used as a top dressing for lawns, it should not be applied too thickly or it may choke the growing vegetation. Sludge may be applied when the ground is frozen or covered with snow. In such cases, it is raked and pulverized into the soil in the spring. Grinding sludge cake with machines (Fig. 6), or breaking it into smaller particles by hand, greatly enhances its application as a top dressing. Many sewage plants now wasting their sludge output would find a ready market if grinding were instituted. Except where applied to grass, trees, shrubs, or

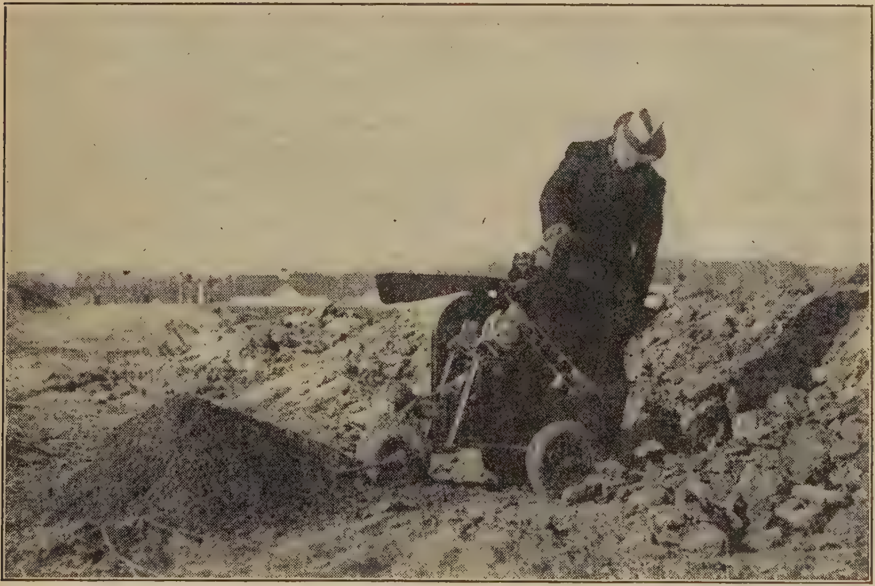

Fig. 6.—Grinding Makes Sludge Cake Suitable for Ready Use as a Fertilizer

perennial beds, sludge should be placed in the hill or plowed under in the fall or early spring before planting the crop.

Digested sludge is safe from the health standpoint if it is mixed with the soil and no more is applied to the growing crop. It is safer not to plant root crops eaten raw, such as carrot or radish, or vegetables grown in close contact with the soil, and eaten raw, such as lettuce, celery, or onions, in ground recently fertilized with digested sludge, unless the sludge cake itself has been subjected to storage for at least a month.

The digestion of sludge, combined with the more common methods of dewatering, such as vacuum filtration (in which case most sludges are conditioned with lime, giving a high enough pH-value to kill great numbers of bacteria) or air-drying, and its storage afford sufficient protection against intestinal diseases. However, reasonable care should be exercised in handling it.

Amount of Digested Sludge to Be Used

Although an excess of sludge will rarely do harm, except in cases of outright mechanical smothering of growing things, the following suggestions have been made for its application:

1. For orchards (15)	10 tons wet sludge cake per acre (or about 11 cu yd per acre)
2. For grass (16)	10 to 20 cu yd per acre (or 0.6 to $1\frac{1}{4}$ cu ft per 100 sq ft of soil)
3. For vegetables, shrubs, and flowers (15)	20 to 60 cu yd per acre (or $1\frac{1}{4}$ to $3\frac{3}{4}$ cu ft per 100 sq ft of soil)

Fortifying Digested Sludge

By mixing dried sludge with chemicals a balanced fertilizer can be obtained with the desired plant food. Fortified sludge should be applied in smaller amounts to the soil depending on the type of crop and the local conditions. The following formula is suggested for general use and is suitable for almost any crop or soil:

Chemical	Pounds
Sludge (dry basis)	360
Ammonium sulfate	25
Acid phosphate (20%)	50
Muriate of potash	15

In the case of dry sludge, 360 lb amounts to about 900 lb of sludge cake as removed from the average sand-drying bed, or 1,200 lb of cake as removed from the average vacuum filter. This is, roughly, two thirds of a cubic yard, or about 20 cu ft. Other formulas may be used for special cases, or for a particular soil.

Use of Sludge as Fertilizer

Sludge is particularly adapted to lawns, golf courses, pastures, and meadows, as well as to the flower and vegetable garden. Maloy (21) reports that trees fertilized with sludge had a healthier foliage, both in amount and color, and retained their leaves for a longer time in the fall than near-by unfertilized trees. A. M. Rawn, M. Am. Soc. C. E. (23), in 1941 stated that sludge has been used as fertilizer for citrus groves for about thirteen years with convincing results.

Sludge deepens the green color of grass and stimulates a luxuriant growth. Its benefits are noted into the second year. For flower beds it provides a much-needed humus for the hot summer months as well as a moderate but long-yielding amount of nitrogen. In vegetable gardens, it is beneficial for corn, potatoes, beans, spinach, asparagus, and vine crops.

For years the writer has grown plots of vegetables, shrubs, flowers, and grass with and without sludge. Its worthiness as a soil conditioner has been demonstrated by excellent plant growth and high yields.

When used continuously on land, sludge tends to acidify the soil. Hence, corrective measures must be taken every three or four years to avoid damage to plants requiring a neutral or near neutral soil, by checking acidity (caused largely by the breakdown of the greases and fats present in sludge) through judicious applications of powdered limestone, or hydrated lime.

Economic Value of Digested Sludge

While digested primary sludge does not have the market value of raw activated sludge, it may have an estimated value (based primarily on its chemical analysis only and without regard to its valuable humus content) of at least 50¢ per cu yd for unground sludge. Ground sludge brings a better price and is generally in demand. Mr. Rawn (23) states that dairy manure in Southern California in 1941 was selling for $1.50 per ton, delivered at the roadside. This is the commercial variety containing about 1.25% nitrogen. Digested sewage sludge (roadside delivery) was selling for $7.00 per ton in the same area. The difference in selling price, according to Mr. Rawn, is not indicative of high-pressure salesmanship; to the contrary, it portrays better than any other factor the difference in value, and is excellent proof of the fertility value of the product.

At most sewage plants, sludge is given away, or used as fill. The potential promoter or user of sludge can reasonably consider the cost of manure in his community as a rough index of the value of local sludge.

Why Digested Sludge Has Not Been More Widely Used as a Soil Conditioner

What are some of the reasons why digested sludge has not been used more extensively as a soil conditioner? Undoubtedly an esthetic dislike to its use, because of its source, and the fear of producing offensive odors are paramount in the minds of many laymen and agriculturists. Since properly digested, dried, and stored primary sludge and heat-dried and ground, raw activated sludge have been established as safe hygienically for application to the soil, there appears little room for argument from the health standpoint. With regard to odor, many of the more common animal manures, including cow, pig, and sheep wastes, have as much or more odor than sludge, especially if applied before thoroughly rotted or composted.

Another reason why sludge is not used is the lack of promotion for its use by many sewage plant superintendents and supervising officials. In some cases this is no fault of the operating personnel but is caused by a lack of time. The primary job of sewage treatment plant personnel is the protection of the public health and the prevention of nuisance from raw sewage, and not the manufacture or sale of fertilizer. Sludge disposal as fertilizer, when it involves salesmanship, storage facilities, grinding equipment, and in some cases bagging facilities, delivery and bookkeeping, is beyond the scope of many of the smaller treatment plants.

An objection to the use of sludge as a fertilizer is the lumpy or chunky physical form of much sludge cake, which makes it unsatisfactory for lawns, shrubs, and flower beds. Heat-drying and grinding, or grinding alone, produces a product much more suitable for home use.

There is a dearth of information among laymen on the proper application of sludge; its limitations; the need of occasional liming, and the types of vegetation for which it is adapted. Many homeowners and market gardeners could make excellent use of local sludge, but do not appreciate its humus value.

Because of the large quantity of sludge to be disposed of, or transportation costs, or other factors, the disposal of sludge cake by means other than as fertilizer has been found more practical or economical in most sewage treatment plants located in industrial areas or on the seaboard. Demands for sludge as fertilizer are seasonal. Storage is expensive. The cost of purchase and operation of equipment for drying and grinding wet sludge cake is appreciable. The cost of bags and bagging machinery is considerable. There is also the question of the market locally available. All these factors must be weighed in considering the problem.

In spite of these acknowledged limitations, however, the 1940 sewage plant operation reports for the cities of Minneapolis and St. Paul (Minn.) and New York, N. Y., carry favorable comments on the possibilities of using sludge at these plants for fertilizer rather than to continue present disposal methods of incineration and barging to sea.

According to Mr. Schroepfer (24), author of a companion paper in this Symposium:

> "When the Twin Cities sewage treatment plant was designed it was realized that an assured practical and economical method must be installed for regular day in and day out disposal of the large quantities of raw sludge filter cake to be produced. Incineration offered and still affords the most practical and economical method of disposal.
>
> "However, the Sanitary District has realized from the start that the sludge cake would have a certain value as a soil conditioner or low-grade fertilizer, somewhat comparable to manure, and that eventual development of its use for such a purpose would be desirable and might be of economic advantage to the District as well as to the farmers and people of the State. Manure is becoming scarce and a real need exists for a cheap, humus-containing fertilizer. The present method of disposal by incineration seems an economic waste of a natural resource, but the Sanitary District has no alternative unless another method can be developed at no added cost to the people of the Twin Cities. It is the District's hope that at least a portion of the sludge cake may be disposed of for use as a soil conditioner, to everyone's mutual benefit."

The report continues with remarks on experiments conducted to date. Results, it is reported, appear favorable, and it is noted that some of this raw sludge has been used in a fresh form. However, it is being recommended to experimental users that the sludge be stock-piled or composted for one month or longer before use. Not only will composting render it more friable and therefore easier to apply but, as has been discussed, it will permit changes to occur in the fresh organic matter so that a humus material for plant growth is available. Precautions from the health standpoint are mentioned, and it would seem that this phase should receive study before it is used extensively.

The New York City Department of Public Works states in its 1940 report (25):

> "The two primary objectives of sewage treatment are first, to reduce the sewage wastes to a liquid sufficiently pure to be unobjectionable, harmless, and relatively pure and secondly, to dispose of the impurities removed as sludge in an economical and unobjectionable manner. In this latter respect, this department has not lost sight of the possible value of the by-products of sewage treatment. In addition to the value of the combustible methane gas produced by the digestion of sewage sludge, the sludge residue after digestion has a distinct value as a soil conditioner."

The larger plants, of practical necessity, must grind and dry the sludge cake to create a sufficient market; otherwise the sludge is not in satisfactory physical form for immediate use and the high moisture content (60% to 70% in most cases) reduces materially the weight of actual dry sewage solids per pound of material. However, there are numerous small sewage treatment plants scattered over the United States from which natural digested sludge cake is obtainable for the cost of hauling. Certainly, such material is worth reasonable hauls of five to ten miles.

CONCLUSION

Admittedly, there are problems to be overcome at many treatment plants before all or (in some cases) even a part of the sludge cake can be disposed of as a soil conditioner. However, in view of the dearth of farm manure, the outlook for such disposal is encouraging with sound development.

EXPERIENCE OF CHICAGO, ILL., IN THE PREPARATION OF FERTILIZER

BY WILLIAM A. DUNDAS,[6] ESQ., AND C. P. MCLAUGHLIN,[7] ESQ.

SYNOPSIS

In the sludge disposal of The Sanitary District of Chicago (Ill.) a method has been worked out by a chain of experiments to dewater and heat dry activated sludge for use as fertilizer material or for incineration. The principles of design are indicated from the heat standpoint together with the control of odors. A typical heat balance is presented, with a discussion of the relative merits of various fuels. At the Southwest Works a combination of power generation with heat drying has been successfully used.

GENERAL

The Sanitary District of Chicago was established in 1890 to divert the sewage from Lake Michigan and later to treat sewage from a present area of approximately 442 sq miles. The present sewage load is from a population of approximately 4,000,000 and an industrial waste load that is equivalent to an additional population of nearly 3,000,000, making a total population equivalent to 7,000,000.

Practically all of the sewage is treated in four main plants (see Fig. 7)—the North Side, Southwest, West Side, and Calumet Sewage Treatment works. All plants, with the exception of the West Side Works, utilize the activated sludge process. Solids tributary to the West Side Works are disposed of by digestion in Imhoff tanks and drying on underdrained sand beds. Waste activated sludge is disposed of by dewatering, heat-drying, and processing for fertilizer uses or incineration at the Southwest and Calumet works. The waste activated sludge from the North Side Works is pumped to the Southwest Works for disposal with its waste sludge.

The sludge disposal facilities of the Calumet Works are designed to dispose of a daily average of 40 tons of dry solids by dewatering to 80% moisture on vacuum filters and heat-drying for fertilizer uses or incineration. The plant went into operation in July, 1936.

The sludge disposal facilities of the Southwest Works were designed to dispose of an initial average of 375 tons of dry sewage solids per day (100 tons of which comes daily from the North Side Works) by dewatering to 80% moisture on vacuum filters, followed by heat-drying for fertilizer uses or incineration. This plant went into operation in June, 1939.

When construction of the North Side Works was begun in 1923, sludge was to be disposed of by digestion in the Imhoff tanks of the West Side Works,

together with fresh sewage solids. The waste activated sludge was therefore pumped to the West Side Works. Although such mixtures of fresh sewage solids and activated sludge can be digested in this manner, the high moisture content of the digesting mixture indicated that a large tank capacity would be required. Moreover, the drying of such large volumes of digested sludge on underdrained beds would require large additional areas of land, and the use of the beds would be restricted to the warmer months of the year.

An intensive study of mechanical dewatering, heat-drying, and incineration was undertaken in 1931. An experimental plant handling 20 tons of dry solids daily by dewatering, drying, and incineration was constructed at the West Side Works and placed in operation in the summer of 1932. By February, 1934, this plant was remodeled to develop the flash system as applied to the drying of sewage sludge and to incineration by burning in suspension. Each of these plants was operated for a year on various sludges and on sludge mixtures. Throughout these tests a continuous type vacuum filter with an area of 570 sq ft was used for dewatering. Other tests were conducted on dewatering with a bag type of filter press and a paper-making machine.

The discovery by John R. Palmer, in 1925, of the efficacy of ferric chloride as a sludge conditioner was upheld by tests of other reagents. From this exhaustive group of experiments and from experience at the pilot plant at Calumet, certain fundamental facts and principles stood out as requisite for the efficient dewatering, drying, and combustion of sludge.

In the processing of activated sludge for fertilizer or burning, its moisture content must be reduced from approximately 97% to between 5% and 10%. To produce 1 ton of sludge containing 5% moisture, from sludge containing 97% moisture, requires the removal of 64,561 lb of water. Such a quantity of water is best removed by a combination of filtration and heat-drying. Economic and practical operating considerations have established the continuous type vacuum filter as the most satisfactory mechanical dewatering equipment for sewage sludges.

Before conditioning and filtration, sludge should be concentrated to reduce the quantity of water to be removed by the filter and to provide a filter feed of uniform consistency, which is a vital factor in successful filter operation. Sludge as drawn directly from final settling tanks or digesters may vary greatly in consistency. It is recommended, therefore, that some form of concentration be provided in all instances to assure uniformity in filter feeds.

Most sewage sludges do not filter freely and therefore require the addition of a conditioning chemical which coagulates the solids and releases the water. In dewatering sewage sludge by vacuum filtration, some form of conditioning has always been necessary. Ferric chloride alone is probably the most effective and economical reagent available for conditioning activated sludge. With other types of sludges, combinations of ferric chloride and lime are used and in some instances lime alone. Other available but probably less effective reagents are chlorinated copperas and ferric sulfate.

Another paper in this Symposium indicates that elutriation of digested sludge seems to offer a successful means for reducing the amount of chemical required for conditioning and improvement in filter operation. Elutriation or washing of the sludge seems to effect the removal of certain compounds in digested sludge that consume conditioning chemicals without producing conditioning effects.

Ferric chloride is the most expensive item of filtration cost in handling activated sludge. Close control of dosing is required. Underdosed or overdosed sludge will result in high cake moistures and low yields. The amount of ferric chloride required will be dependent upon the characteristics of the sludge involved. In Chicago the amount of ferric chloride varies daily, with a seasonal swing. Actual operating experience only will demonstrate the requirements for a particular case.

In the layout of the Chicago works, devices are installed to proportion the ferric chloride accurately and to mix it thoroughly with the sludge. Most devices that are available for the performance of this important function, although theoretically correct, fail in practical operation due to their complexity and inability to withstand the action of the chemical. Filtration should take place as quickly as possible after dosing and mixing. Continuous conditioning is used in Chicago. Routine filter operation requires checking at frequent intervals to determine the amount of chemical required for best operating results. Ferric chloride requirements of The Sanitary District of Chicago for conditioning activated sludge vary between 4% and 7% by weight of dry solids in the cake. Under these conditions, cake moistures may vary between 78% and 85%. Indications are that the amount of ferric chloride required may be related to the volatile content of the sludge.

On a continuous vacuum filter, as the cake mass forms on the filter cloth, each particle is under the pressure of the surrounding liquid due to the vacuum behind the cloth. As a particle lodges in the face of the cake, its motion decreases and the water flows by. A frictional drag is produced that causes the individual particles massed in the cake to press against each other. The finer particles will be carried on with the liquid into the cake to the point where they are stopped by frictional resistance either in the cake or within the filter medium. Examination of cake removed from a filter will show that it is more dense on the side next to the cloth than on the side away from the cloth. As the density increases, the size of the capillaries decreases and the resistance to flow of water increases, thereby increasing the time rate of filtration. In practical filter operation, when the density increases to such an extent that the passage of air and water ceases, the cake in some cases will crack and open at the weaker points in its structure. When this occurs, the pressure on the cake is relieved and further extraction of water is impossible.

The filtration rate for a compressible substance like activated sludge does not increase in proportion to the pressure because the increased pressure decreases the size of the voids between the particles, thereby restricting the flow of water. Although this phenomenon may not be the complete explanation for the difficulties encountered in the removal of water from activated and similar sludges, it is well substantiated in part by operating results in Chicago.

Filter operating costs at The Sanitary District of Chicago per ton of dry solids on a percentage basis are as follows:

Item	Calumet	Southwest
Ferric chloride	40	55
Labor	21	23
Power	8	8
Filter cloths and wire, etc.	2	3
Maintenance	29	11

At Chicago, ferric chloride is purchased in solution on a semi-annual contract basis. The last contract in 1941 was at the rate of 1.255¢ per lb of anhydrous ferric chloride, with freight on water allowed, making a cost per pound at the Chicago works of approximately 1.54¢.

The life of the filtering medium is largely a function of time rather than tonnage output. Cloths are subject to rotting, and their life is frequently determined by a crust of iron oxide formed on the back of the cloth. At Chicago, with ferric chloride conditioning of activated sludge, a long-nap woolen blanket has proved most satisfactory and economical. The life of a woolen blanket is approximately 3½ months. The cost per square foot, based on recent bids, is 18¢. The life of winding wire is approximately the same as the life of the filter medium. No attempt is made to reuse this wire. The use of woven wire for cloth backing has not been satisfactory.

Wood backing is being tried on a limited number of filters in Chicago, and indications are that it may prove more satisfactory and economical than wire cloth.

HEAT-DRYING

After sludge has been dewatered as far as economically possible by mechanical means, it must be dried thermally before it can be burned or processed for fertilizer. This drying process consists of transferring sufficient heat to the sludge to evaporate the entrained moisture. It is necessary to heat the sludge to the saturation temperature corresponding to the pressure in the system and to supply the latent heat of vaporization to the moisture. Since the evaporated water always leaves the dryer at a temperature above the saturation temperature, it is superheated and this requires additional heat.

In experimental work of The Sanitary District of Chicago, it was found desirable to separate the functions of drying and combustion so that each one would progress independently of the other in a separate unit especially designed for the efficient performance of its particular function.

The fundamental principles and factors found necessary for economical and efficient drying, free from nuisances, to prepare sludge for efficient combustion or for use as a fertilizer are as follows:

(1) Maximum surface exposure;
(2) Thorough agitation of the wet material;
(3) Temperature potential of gas;
(4) Velocity of drying gas;
(5) Responsive and flexible temperature control;
(6) Deodorization of gases vented from the drying operation;
(7) Instantaneous water removal; and
(8) Preservation of fertilizer qualities.

All drying operations utilize the first four of these principles in a more or less efficient manner. All eight of them are efficiently performed in the flash-drying equipment in use at Chicago.

Flash drying is a continuous operation in which the sludge in a finely divided state is dried instantaneously in a hot gas stream. At Chicago a mixture of superheated water vapor and other gases is used as the drying medium. The temperature of the drying medium as it enters the system is approximately 1,100° F, and the velocity is approximately 5,000 ft per min. At this temperature the evaporation of the moisture is almost instantaneous, and the passage through the drying cycle is a matter of seconds. Research by F. W. Mohlman has shown that dried sludge from a flash-drying system shows practically no trace of pathogenic organisms. The sludge never reaches a temperature sufficiently high to affect any of the properties valuable as fertilizer. The average temperature of the dried material as removed from the drying system is approximately 180° F. The temperature of the vapor and gases vented from the drying systems to the furnaces for deodorization is approximately 350° F. The drying systems are operated slightly under atmospheric pressure to prevent the escape of dust and gases. All operations are automatically controlled. Briefly, the sequence is as follows:

Activated sludge cake containing 78% to 85% moisture as discharged from the filters is conveyed to individual mixers where it is mixed with sufficient sludge, previously dried in the system, to reduce the moisture content and prepare a nonsticking friable mass. In this form the sludge is introduced into the drying system, where it is picked up in the high-velocity, high-temperature gas stream. A cage type of disintegrating mill interposed in the drying circuit breaks the sludge into small particles, causing maximum exposure of wet surface and complete dispersion of the particles in the drying medium. The sludge particles carried in the superheated vapor and gaseous drying medium are discharged into a cyclone separator where dried sludge is separated from the vapors and gases in which it was conveyed. Part of the sludge removed from the separator is returned to the sludge mixer, and the surplus is withdrawn as fertilizer material or pneumatically conveyed to a separate furnace where it is burned in suspension. When fertilizer is being produced, the heat required for the drying system is furnished by the combustion of auxiliary fuel. A portion of the vapors and gases vented from the sludge separators is recirculated through a heat exchanger where it is reheated by an exchange of heat from the hot products of combustion vented from the furnace and returned to the drying system. The surplus or waste vapor is vented to the furnace for deodorization.

Heat for sludge drying may be carried directly by furnace gases or it may be transferred from furnace gases to air or water vapor by means of heat exchangers. Air-drying has two distinct disadvantages. It results in lower efficiency since it is an additional medium introduced to the system, which must be raised from room temperature to the stack temperature, and it supplies oxygen which might cause fires.

The rate of evaporation is dependent on the temperature of the drying medium, the size of the sludge particles, and the rate of removal of the water vapor. The greater the temperature differential between the drying medium and the sludge, the greater the evaporation will be. The sludge particles should be kept as small as possible during the drying process, since the smaller they are, the greater will be the area of wetted surface exposed to the heat. In other words, more moisture is in direct contact with the hot gases. Water vapor formed in the center of a particle of sludge must force its way to the surface to be liberated, and thus the smaller the sludge particles, the shorter will be the distance traveled by the vapor. When the particles are too large, the surface may become dried and case-hardened before the moisture in the center has been evaporated. This hard surface offers resistance to the release of the interior moisture and results in the dryer discharging a product that is dried on the surface but has a wet center. The rate of drying is also affected by the relative velocity between the material and the drying medium. When vapor is released from the sludge, it tends to form an insulating medium around the sludge particle, retarding further evaporation unless it is instantly removed. Failure to remove the water vapor results in an increased pressure in the system that requires more heat to evaporate the water in the sludge.

Responsive and flexible control is a vital necessity in any drying and combustion operation. Where sludge is dried for incineration, it is desirable that the character of the material and its moisture content as fired be maintained as uniform as possible. Where sludge is dried for fertilizer uses, it is necessary that the size of particles be kept uniform and that the temperature of the drying system be automatically controlled to avoid driving off valuable fertilizer ingredients, and to insure a moisture content in the dried material between 5% and 10%. Where drying and combustion occur independently of each other, automatic temperature control is a relatively simple matter, inasmuch as the demand for heat in the drying system can be met by liberating more or less heat in the furnace. With the cage type of drying mill used by the Sanitary District, the size of particle is dependent upon the speed of the mill, its interior arrangement, and character of the sludge feed.

tension of Calumet Sewage Treatment Works

Sludge, like other similar organic materials, has an inherent tendency to heat and burn spontaneously when stored in large quantities over a period of time. This tendency may be caused by bacterial or chemical action or a combination of both. It is also a function of the moisture content, fineness, and initial temperature of the material stored. Experience at Chicago indicates that the moisture content should be held below 10%, the heat-dried sludge should be as free as possible from dust, and the temperature at the time of loading in cars should be below 100° F. This is accomplished by screening, dedusting, and cooling in water-jacketed conveyers.

All heat-dried activated sludge as produced for fertilizer uses at Chicago is loaded in cars in bulk, after screening and cooling, for immediate shipment to consumers. No material at present is bagged or stored in bulk. Facilities for a limited tonnage of bulk storage are now under construction at the Southwest Works.

Fig. 8 is a schematic diagram of the process at the Calumet plant. Three drying systems of the flash type, with individual furnaces, are installed at this plant. Each is designed to evaporate 6,500 lb of water per hour and to handle 20 tons of dry solids per day.

Fig. 9 is a schematic diagram of the Southwest plant. Eight drying units are installed at this plant. Each unit has an evaporation capacity of 20,000 lb of water per hour and handles approximately 62.5 tons of dry solids per day.

Combustion

In the combustion of sewage sludge as well as commercial fuels many factors are involved, due to the great variation in their characteristics. Specific requirements for the proper combustion of a particular sludge must be considered as a distinct problem requiring individual consideration. However, it is possible to draw certain general conclusions as to the combustion requirements of sludges. These conclusions form the basis of design of all combustion apparatus and thus are worthy of careful study.

The term "combustion," as applied to furnaces, is used in referring to the vigorous reactions of oxygen with different substances, whereby heat and light are liberated. Combustion therefore differs from other slower reactions with oxygen only in the vigor of the reactions and in the forms and quantities in which energy is liberated.

The chemistry of combustion of sewage sludge is elementary and differs but slightly from that of other solid fuels. The elementary substances encountered in the combustion of sewage sludge and commercial fuels are oxygen, nitrogen, hydrogen, carbon, sulfur, and combinations of these elements (see Table 17). Oxygen is the sole supporter of combustion. A combustible substance is one capable of combining with oxygen to produce heat. Combustion is complete when the combustible elements and compounds have united with all the oxygen they can use.

In the combustion of sludge, carbon and hydrogen are the most important of the combustible elements from the standpoint of heat liberation. These elements occur either in a free or combined state as in all solid, liquid, and gaseous fuels. For the most part, the hydrogen, carbon, and sulfur compounds in sludge are unstable in nature. In sludge cake, these compounds are associated with a relatively high percentage of water and ash, as compared with commercial fuels.

Every combustible substance has a definite ignition temperature to which it must be raised before it will combine chemically with oxygen. Below this temperature no combination takes place. Furthermore, this ignition temperature must exist in the presence of sufficient oxygen or there will be no combustion. The ignition temperatures of combustible elements and compounds commonly found in sludges are given in Table 17(*a*), Col. 5.

In the drying and burning of sludge, odors are produced largely by the liberation of hydrocarbon compounds. By observation, this liberation is found to begin at relatively low temperatures and to increase in intensity with

increased temperature. Odors are also released from the solids and gases in solution with the water, which is evaporated into steam. Emulsified organic fats likewise give off offensive odors with a slight application of heat. The ignition temperatures of the CH compounds lie between 1,100° and 1,200° F, approximately. The end products of complete combustion of all CH compounds are water vapor and CO_2, both of which are odorless. Therefore, all gases and water vapor produced in the heat-drying of sludge should be raised to a temperature of not less than 1,300° F in the presence of sufficient oxygen to effect complete combustion of the offensive CH compounds.

13	Water vapor	H_2O	..	18	....	....
14	Sulfur dioxide	SO_2	..	64	....	....

[a] Approximate. [b] The potential heat content of sewage sludge is 7,000 Btu (British thermal units) per lb.

Likewise, sludge and similar organic materials must be burned at high temperatures with sufficient oxygen present to complete combustion if odors are to be avoided in the products of combustion discharged to the atmosphere. Sulfur dioxide, one of the end products of complete combustion of sulfur and its compounds, is objectionable if discharged into the atmosphere in large quantities. The percentage of sulfur and its combustible compounds as found in most sludges is relatively low compared with the content of many bituminous coals. Therefore, it is of little consequence. The amino compounds are dissociated at these temperatures and likewise are of little consequence.

The ignition temperature of combustible substances (Table 17(*a*), Col. 5) is well above the boiling point of water (212° F at 14.7 lb per sq in. absolute pressure). Thus, the material is thoroughly dry when ignition and combustion take place. A large ball of sludge with a hard dry surface may become ignited and smolder while the moisture is being driven off from the interior. Such combustion is inefficient and may produce odors unless sufficient auxiliary fuel is burned within the furnace to maintain a temperature sufficiently high to ignite the combustible gases emitted by the smoldering material and dissociate any noncombustible compound of an offensive nature. The experience of The Sanitary District of Chicago has shown that complete deodorization of gases can be assured only after the gases have been raised to a temperature of more than 1,300° F in the presence of sufficient oxygen to complete combustion of the volatile compounds. Efficient combustion of sludge, free from objectionable odors, therefore, is possible only with thoroughly dried material unless the obnoxious gases are deodorized after combustion.

The chemical reaction of combustion results from a rearrangement of the atoms of the constituent elements into new compounds. It is in accordance with fixed laws and may be computed from the molecular weights given in Table 17.

Air is the source of oxygen supply for commercial combustion operations, and is considered as a mechanical mixture of oxygen, nitrogen, carbon dioxide, water vapor, argon, and other inert gases. For combustion purposes, the carbon monoxide and the inert gases are usually included as nitrogen. The generally accepted percentages for atmospheric air are:

For oxygen (Q_2)—
by volume, 20.91
by weight, 23.15
and for nitrogen (N_2)—
by volume, 79.09
by weight, 76.85

The following reactions occur only when the exact amount of oxygen required for combustion is present and the oxygen is wholly utilized:

Combustible	Reaction
Carbon (to CO)	$2\,C + O_2 = 2\,CO$
Carbon (to CO_2)	$2\,C + 2\,O_2 = 2\,CO_2$
Carbon monoxide	$2\,CO + O_2 = 2\,CO_2$
Hydrogen	$2\,H_2 + O_2 = 2\,H_2O$
Sulfur (to SO_2)	$S + O_2 = SO_2$
Sulfur (to SO_3)	$2\,S + 3\,O_2 = 2\,SO_3$
Methane	$CH_4 + 2\,O_2 = CO_2 + 2\,H_2O$
Hydrogen sulfide	$2\,H_2S + 3\,O_2 = 2\,H_2O + 2\,SO_2$

Carbon enters into combustion in two forms, CO and CO_2. The former is incomplete, the latter complete. The combustion of hydrogen is always complete to H_2O. If insufficient air is supplied, a portion of the hydrogen combines with the supply of oxygen present to form water, and the remainder passes to the stack.

From the proportionate parts by weight of oxygen and nitrogen in atmospheric air, 4.32 lb of air are required for each pound of oxygen. This air also supplies 3.32 lb of nitrogen that does not enter into combustion. The ratio 3.32 : 1 is known as the "nitrogen ratio." Nitrogen serves no useful purpose and is a direct loss in combustion work, since it must be raised to the furnace exit temperature. Based upon approximate molecular weights, carbon, hydrogen, and sulfur require the following weights of oxygen for complete combustion:

One pound of:	has the following oxygen requirement (lb):
Carbon	$\frac{O_2}{C} = \frac{32}{12} = 2.667$
Hydrogen	$\frac{O}{H_2} = \frac{16}{2} = 8$
Sulfur	$\frac{O_2}{S} = \frac{32}{32} = 1$

The heat value of any sludge may be determined by actual experiment in a calorimeter. Where such apparatus is not available, approximate heat values may be calculated for certain combustible compounds from the ultimate chemical analysis, using Dulong's formula:

$$q = 14{,}600\ C + 62{,}000 \left(H - \frac{O}{8} \right) + 4{,}050\ S \qquad (1)$$

in which q is the heat of combustion in British thermal units (Btu) per pound, and C, H, O, and S, respectively, denote the proportional parts by weight of carbon, hydrogen, oxygen, and sulfur.

In the complete combustion of 1 lb each of carbon, hydrogen, and sulfur, the resulting products of combustion will be as follows:

Computation	Pounds
$1 \text{ lb } C + 2.667 \text{ lb } O_2 =$	$3.667\ CO_2$
$2.667 \times 3.32 \text{ lb } N_2 =$	$8.85\ N_2$
$1 \text{ lb } H_2 + 8 \text{ lb } O_2 =$	$9\ H_2O$
$8 \times 3.32 \text{ lb } N_2 =$	$26.56\ N_2$
$1 \text{ lb } S + 1 \text{ lb } O_2 =$	$2\ SO_2$
$1 \times 3.32 \text{ lb } N_2 =$	$3.32\ N_2$

Methane, one of the members of the CH series, is computed in a similar manner: $CH_4 = C + 4H$; or, from atomic weights, $16 = 12 + 4$. Thus, 1 lb of methane is composed of 0.75 lb C + 0.25 lb H. To burn 0.75 lb of carbon will require $0.75 \times 2.667 = 2.00$ lb O_2. To burn 0.25 lb of hydrogen will require $0.25 \times 8 = 2.00$ lb O_2. The total oxygen requirement is $2 + 2 = 4$ lb. The total air required is $4 \times 4.32 = 17.28$ lb. The products of combustion will be as follows:

Computation	Pounds
$0.75 \text{ lb } C + 2.00 \text{ lb } O_2 =$	$2.75\ CO_2$
$0.25 \text{ lb } H + 2.00 \text{ lb } O_2 =$	$2.25\ H_2O$
$17.28 \text{ lb air} \times 0.7685 =$	$13.28\ N_2$

These computations, although simple, are important in combustion work, particularly where digester gas and liquid fuels are used as major or auxiliary sources of heat for drying and incineration. The theoretical dry air required for a combustible compound, therefore, is:

$$A = 11.52\,\mathrm{C} + 34.56\left(\mathrm{H} - \frac{\mathrm{O}}{8}\right) + 4.32\,\mathrm{S} \qquad (2)$$

in which A = theoretical weight of dry air required per pound, C, H, O, and S being the proportional parts by weights of the carbon, hydrogen, oxygen, and volatile sulfur in the compound. The term $\left(\mathrm{H} - \frac{\mathrm{O}}{8}\right)$ represents the available hydrogen and corrects for hydrogen combined with oxygen in the fuel. Part is probably in the form of moisture, or is combined with organic nitrates, and part may be present in carbonates of mineral matter found in the sludge or fuel. This assumption probably is sufficiently accurate for ordinary calculations.

A series of calculations for different fuels will show a wide variation in theoretical air requirements per pound of fuel. When expressed in terms of theoretical air requirements per 10,000 Btu, a close agreement will be found among all fuels, including sludge, peat, coal, and oil. The average value of such a comparison will indicate a theoretical air requirement of 7.5 lb per 10,000 Btu, with a maximum departure not exceeding 2%.

Excess Air.—From the chemical standpoint, to supply the proper amount of oxygen for complete combustion appears relatively simple; but this is not the case. The primary problem in combustion is to maintain the supply with its accompanying nitrogen as near to the theoretical amount required as possible. The efficiency of combustion, therefore, may be measured by the relation between the air actually supplied and that theoretically required for combustion. It is vitally important that the air supply be admitted at the proper time and in such a manner that the oxygen comes into intimate contact with the combustible substances in the sludge, which include the combustible solid particles and gases as they are distilled from the sludge.

The air supplied to a furnace for combustion is classified broadly as primary and secondary. Primary air is that required for propagation of flame, whereas secondary air is that introduced to complete combustion after the flame has been propagated.

As stated, nitrogen introduced into the furnace with the oxygen required for combustion performs no useful function in combustion. It passes through the furnace unchanged except in temperature and volume. It absorbs heat and reduces the temperature of the products of combustion. All these factors necessitate designing the furnace space, connecting flues, and ducts sufficiently large to accommodate the excess gases. Any excess oxygen supplied to the furnace results in the same loss as for nitrogen. Such oxygen is accompanied by additional nitrogen, which further accentuates the loss. On the other hand, where insufficient oxygen is supplied for complete combustion, the loss due to the presence of the nitrogen is inappreciable as compared with that due to incomplete combustion. For example, if 1 lb of carbon is burned to carbon monoxide, the heat produced is 4,380 Btu, whereas if the combustion is carried to CO_2 the heat produced is 14,540 Btu. This factor will be discussed further in connection with furnace losses.

Smoke and Odors.—Smoke and odors are a widely discussed topic in connection with the combustion and drying of organic refuse and commercial fuels. Most of the definitions of smoke are unsatisfactory and vague.

The common conception of objection to smoke is based on its visibility. Most smoke ordinances are based on the visibility, density, and color of escaping stack gases, with little or no attention to the invisible or more objectionable compounds which are by far the worst offenders in atmospheric pollution. The amount of solids discharged from a stack is not a complete indication of its nuisance value. A stack may appear smokeless and still discharge a large volume of objectionable gases into the atmosphere. The color of smoke is usually imparted by carbon particles. The presence of a small amount of carbon is sufficient to give color to large volumes of invisible gases, which may or may not represent a nuisance or a combustion loss. A certain amount of color may also be given to gases by particles of fine ash and other mineral matter carried in suspension in the gases, neither one of which represents a combustion loss. When burning pulverized fuel, the amount of this material in escaping gases is considerable unless efficient means are provided for its interception, as the passing of all waste gases through some form of dust collector such as a settling chamber, centrifugal separator, or electrical precipitator.

The effectiveness of such means varies over a wide range and is dependent upon various factors, principally the dust density of the gases. The plain settling or expansion chamber, unless of tremendous volume with resultant low gas velocities, will remove little if any of the fine flocculent dust. A centrifugal separator, showing removal efficiencies as high as 94%, is more effective. This provides maximum removal per dollar invested. The most effective of all separating devices is a commercially patented electrical precipitator. Tests on this equipment installed in the Calumet and Southwest works in Chicago indicate a removal of 97% of suspended solids from the stack gases. The selection of dust-separating equipment should be based on the degree of separation desired. This is determined to a great extent by the remoteness of the plant from habitated areas. Investigations in connection with large power plants, where coal is burned in suspension or on stokers, indicate that a large quantity of the flocculent solids discharged from stacks is deposited at a distance varying from 5 to 15 miles from the source, unless efficient means for interception are provided.

The presence of a large volume of visible water vapor in stack gases is not objectionable from the standpoint of atmospheric pollution, if discharged at a height to permit complete dispersion.

In the early experimental work of the Sanitary District, all gases vented from the sludge dryer and furnace were passed through a vapor condenser and scrubber in an attempt to remove odors. This method of odor elimination proved ineffective and expensive in operation and maintenance. All the metallic parts (condenser, piping, and spray nozzles) were attacked by sulfurous acid and other compounds that formed when the vapors reached the dew point. The interior surfaces of the equipment became coated with a very corrosive, tarry compound with an offensive odor. When heated, this substance gave off an offensive brown gas which ignited at a temperature of approximately 1,200° F and burned freely in the atmosphere. The vapor condenser and scrubber were found to act solely as a wet-type dust collector.

Heat of Combustion.—As previously stated, the term "combustion" is limited to the rapid chemical combination of the combustible constituents of a fuel with oxygen, resulting in the production of heat. The heat of combustion is therefore the heat resulting from the complete oxidation of such combustible elements and compounds. The amount of heat so generated is a constant for any given combination of combustible elements and compounds, irrespective of the manner in which combustion takes place so long as it is complete. The unit measure of quantity of heat is the British thermal unit, or the Btu, which is $\frac{1}{180}$th of the amount of heat required to raise the temperature of 1 lb of water from 32° to 212° F.

The heat of combustion of any fuel can be computed approximately from the ultimate analysis by use of the Dulong formula (Eq. 1). In computing heat values of sludges, great care should be exercised in applying Eq. 1, inasmuch as sufficient check data are not available to determine the precision of results computed by this formula. Accurate calorific values are obtainable only by calorimetric methods, which give the following values for common combustible materials:

Combustible	Heat value (q), in Btu per lb
Carbon to CO	4,380
Carbon to CO_2	14,540
Hydrogen	62,000
Methane	23,850
Sulfur to SO_2	4,050

Temperatures of Combustion.—The actual temperature resulting from the combustion of sludge or any other fuel is obtained most satisfactorily by means of a pyrometer. The theoretical temperature may be calculated from the formula,

$$T = \frac{q}{W\,C} + t \qquad (3)$$

in which T = final temperature of products of combustion, in degrees Fahrenheit; q = British thermal unit per pound of fuel; W = weight of products of combustion, in pounds per pound of fuel; C = mean specific heat of the products of combustion; and t = initial temperature of fuel and air supply, in degrees Fahrenheit.

Assuming the complete combustion of 1 lb of carbon with the theoretical amount of air supplied at an initial temperature of 60° F, then $T = \frac{14{,}540}{12.52 \times 0.27} + 60 = 4{,}360°$ F, approximately.

Such calculated temperature is entirely theoretical and is the temperature that would exist in the furnace if combustion were complete, if no dissociation occurred, and if no heat were lost by radiation. Actually, some heat is radiated to the furnace walls before combustion is complete. At temperatures greater than 3,000° F, dissociation begins to occur, whereby water vapor breaks down into hydrogen and oxygen and carbon dioxide breaks down into carbon monoxide and oxygen. Just as the combining of these elements into water vapor and carbon dioxide liberates heat, so heat is absorbed when the reactions are reversed, resulting in a lower temperature. In computing heat balances, dissociation may be ignored since, after the gases are cooled during the process of heat recovery, the reactions are again reversed and the heat is again liberated. Since it is generally impossible to burn each particle of fuel in the presence of the proper amount of oxygen, incomplete combustion takes place, resulting in a lower temperature. Under actual combustion conditions there is always an excess supply of air present that also reduces the temperature.

In practice, factors may occur with different types of sludges and equipment which, for practical reasons, require that furnace temperatures be kept below the maximum attainable. Under such conditions high percentages of excess air are introduced into the furnace, resulting in reduced combustion efficiency. An important factor is the fusion temperature of the ash. For practical reasons, furnaces containing metallic parts must operate with a high percentage of excess air to maintain a safe operating temperature well below the maximum available.

Specific Heat.—Calculations involving combustion and heat transfer require the use of specific heat values. The specific heat of a substance is the number of British thermal units required to raise the temperature of 1 lb of the substance 1° F. Actually, the specific heat is not a constant for all conditions of pressure and temperature and, if accurate results are desired, a correction must be made for the actual pressure and temperature conditions that exist.

When heat is added to a gas while its volume is kept constant, the external work is zero, but if heat is added while the pressure is held constant, the volume increases and external work is performed. Therefore, the amount of heat necessary to raise 1 lb of a gas 1° F at constant pressure is greater than that required at constant volume because it requires heat to perform external work.

In heat computations dealing with furnace gases and sludge drying gases, the variations in pressure are small. The change in specific heat due to pressure changes thus can be ignored. The specific heat of a gas, however, varies greatly with the temperature. Any calculation in which extreme accuracy is desired should use the mean specific heat of the gas between the temperatures involved. For example, the specific heat of air is usually taken as 0.24, yet it varies from 0.238 at 50° F to 0.275 at 2,000° F.

Heat Balance.—In designing a drying and incineration system, it is necessary to make sufficient heat calculations to determine the quantity of fuel required, the air needed for combustion, the size of furnace required, and also gas quantities for determining fan and duct sizes. A summary of these data, showing the heat input to the system and the distribution of this heat among losses encountered and the useful work done, is known as a heat balance. The ratio of the heat utilized in the performance of useful work to the total heat supplied is the efficiency of the system.

A heat balance may be an actual balance obtained from the results of a test on the unit involved or it may be a theoretical balance. In the first case the fuel is weighed and its heat per pound obtained from calorimeter tests. The work done is accurately measured, as are all losses. In making a theoretical balance, certain assumptions must be made, such as radiation losses, stack temperatures, and the heat value of the fuel.

A heat balance for a flash-drying system as used in The Sanitary District of Chicago, in which the water vapor evaporated from the sludge is returned to the furnace for odor removal, would have for its heat input the heat released from the burning of the sludge and auxiliary fuel or from the burning of auxiliary fuel only if the dried sludge is prepared for fertilizer.

The heat output includes the heat used to evaporate the moisture in the sludge and the following losses:

(*a*) Radiation loss in the drying system. This consists of heat radiated from the surfaces of the dryer, ducts, separators, etc., and amounts to approximately 125,000 Btu per ton of dry solids.

(*b*) Loss due to moisture and hydrogen in the fuel. The hydrogen in the dried sludge forms water with the oxygen in the air. This water, together with the water in the sludge, must be raised to the boiling point, converted into steam, and then superheated to the temperature of the stack gases. The heat required to perform this work is taken from the heat generated from the combustion of the sludge and is therefore a loss.

(*c*) Loss due to incomplete combustion. Even when excess air is present, it is not possible to obtain complete combustion of the sludge. Some particles, for instance, drop unburned into the furnace ash hopper and others pass out as soot with the stack gases. These losses generally amount to approximately 4%. When producing fertilizer, using oil or gas as fuel, this loss is negligible.

(*d*) Stack losses. These losses correspond to the heat that is added to the fuel, combustion air, and waste vapor to raise them from the temperature at which they enter the furnace to the temperature at which they leave the system and enter the stack. These losses are unavoidable but, since they represent the greatest loss of heat in the system, they should be kept at a minimum by maintaining the exit temperature as low as possible, without risking danger of condensation, and by keeping the excess air at a minimum.

(*e*) Radiation and unaccounted losses. These losses allow for radiation from the furnace setting, air leakage into the drying system, and any losses not included in the other items.

The following is a heat balance for one drying unit as installed at the Calumet plant of The Sanitary District of Chicago, based on producing fertilizer and burning oil for fuel:

Assumptions.—

(1) Sludge feed, 20 tons per day at 80% moisture and 55° F.
(2) Average temperature, 50° F.
(3) Air, 30% and vapor, 70%, by volume in hot tower at 1,000° F.

(4) Temperature at outlet of separator, 300° F.
(5) Dried sludge removed from system as fertilizer.
(6) Fuel oil at 19,500 Btu per lb.
(7) Dried sludge, 180° F and 5% moisture.
(8) Drying system radiation losses, 125,000 Btu per ton of dry solids.
(9) Furnace radiation, incomplete combustion, hydrogen, and unaccounted losses, 10%.

Computations.—

Item	Computation	Quantity
(*a*)	Dry solids, in lb per hr $\frac{20 \times 2,000}{24}$	1,667
(*b*)	Moisture, in lb per hr $\frac{1,667 \times 80}{20}$	6,667
(*c*)	Moisture evaporated in drying system, in lb per hr $6,667 - \left(\frac{5}{95} \times 1,667\right) = 6,667 - 88$	6,579
(*d*)	Vapor—Air Mixture (% by Weight):	
	Air (30%) 1 molecular lb = 29 = 8.7 lb	41
	Vapor (70%) 1 molecular lb = 18 = 12.6 lb	59
	Total 1 molecular-lb mixture = 21.3 lb	100
(*e*)	Specific heat of drying mixture $0.41 \times 0.24 + 0.59 \times 0.47$	0.375
(*f*)	Air leakage, in lb per hr $\frac{0.41}{0.59} \times 6,579$	4,570
(*g*)	Radiation losses from drying system, in Btu per hr (at 125,000 Btu per ton of dry solids) $\frac{1,667}{2,000} \times 125,000$	104,000
(*h*)	Waste vapor, in lb per hr $6,579 + 4,570$	11,149
(*i*)	Heat required by drying system, in Btu per hr $6,579\,[212 - 55 + 970 + (300 - 212) \times 0.47]$ $= 1,670\left(0.30 + \frac{0.05}{0.95}\right)(180 - 55)$ $+ 4,570\,(300 - 50) \times 0.24 + 104,000$	8,131,500
(*j*)	Drying mixture required, in lb per hr $\frac{8,131,500}{(1,000 - 300)\,0.375}$	30,900
(*k*)	Mixture to circulating fan, in lb per hr $30,900 + 6,579 + 4,570$	42,049
(*l*)	Heat required from furnace, in Btu $8,131,500 + 11,149 \times 0.375 \times (475 - 300)$	8,863,500

At 20% air and 17.8 lb products of combustion per lb of oil (26):

Item	Computation	Quantity
(*m*) Useful heat, in Btu per lb of oil	$0.9 \times 19{,}500\ [(475 - 50) \times 0.25 \times 17.8]$	15,660
(*n*) Oil required, in lb	$\dfrac{8{,}863{,}500}{15{,}660}$	567
(*o*) Products of combustion	567×17.8	10,080
(*p*) Furnace temperature, in degrees Fahrenheit	$\dfrac{567 \times 0.9 \times 19{,}500 + [11{,}149 \times (300 - 50) \times 0.375]}{(10{,}080 \times 0.25) + (11{,}149 \times 0.375)} + 50$	1,690
(*q*) Recirculated gases to give 1,475° F entering the heater, in lb	$\dfrac{(10{,}080 + 11{,}149)\ (1{,}690 - 1{,}475)}{1{,}475 - 475}$	4,570
(*r*) Total heat supplied	$567 \times 19{,}500$	11,050,000
(*s*) Heat balance, in Btu:		
Furnace radiation, incomplete combustion, hydrogen, and unaccounted losses, 10%		1,105,000
Drier radiation losses		104,000
Dried sludge losses	$1{,}670 \left(0.30 + \dfrac{0.05}{0.95}\right)(180 - 55)$	73,500
Useful drying	$6{,}579 \times 1{,}127$	7,400,000
Stack losses	$6{,}579\ (475 - 212)\ 0.47 + 4{,}570\ (475 - 50)0.24 + 567 \times 17.8\ (475 - 50)\ 0.25$	2,350,000
Total heat balance		11,032,500
(*t*) Evaporated heat, in Btu per lb of H_2O evaporated	$\dfrac{11{,}050{,}000}{6{,}579}$	1,680
(*u*) Efficiency (%)	$\dfrac{1{,}127}{1{,}680}$	67

Fuel.—The heat for drying sludge preparatory to incineration or use for fertilizer may be derived from burning the sludge itself or from some commercial form of fuel. In many incineration operations, the heat content of the sludge may prove sufficient to supply the needs for drying and maintaining a furnace temperature sufficiently high to assure complete deodorization. Under these conditions, auxiliary fuel is needed only during starting periods. Digester gas, if available, is an excellent fuel for this purpose. Where the supply of digester gas is intermittent and variable, it is advisable to supplement it with natural gas or fuel oil. City gas, if available, is also satisfactory, but its cost is usually prohibitive.

The quantity of fuel required for starting depends largely upon the size and type of furnace and the mass of refractory to be heated to the working temperature. Some furnaces can be safely brought to working temperature in less than an hour, whereas some types require 24 hr to 72 hr, depending upon their size. Furnaces of the latter type also require the burning of fuel during the cooling down period, which varies between 24 hr and 48 hr.

For drying and incinerating sludge in an installation of moderate size, where supplementary fuel is needed frequently in regular operation, such fuels in order of their desirability, without reference to cost, are digester gas, natural gas, and fuel oil, or combinations thereof. In the larger installations, powdered coal is very satisfactory and economical. Where combinations of gaseous and liquid fuels are utilized, automatic means for change-over usually should be provided for protection against failure of either source of fuel supply.

Where sludge is processed for fertilizer and no sludge is burned, the entire heat requirement must be derived from some form of commercial fuel, or digester gas, if available. For the small or moderate-sized drying plant, as a practical consideration, it is imperative that gaseous or liquid fuels, or their combinations, be used. The first cost of such an installation is relatively low compared to an installation for burning coal. Usually the higher cost of gaseous and liquid fuels for this purpose over that of coal is offset by higher combustion efficiency, simplicity in operation, and flexible temperature control.

Where sludge is dried for fertilizer, the effect of the type of fuel on the final product is negligible. Therefore, with installations where large amounts of fuel are required, the relative economy of the fuel per unit of heat should determine the type. Coal burned in suspension or on a grate usually will be found more economical than other types of fuels in the larger installations, and when burned on a grate it may be the most economical for small units. Some of the advantages and disadvantages of various fuels are listed in Table 18.

Power Generation at Southwest Works

Whether the generation of power should be combined with drying and incineration of sludge is largely a question of economics. Such a combination ordinarily is not economical except for large installations like the Southwest Works at Chicago where conditions for the combination were very favorable. In the large flash type of drying system, with incineration furnaces, most of the elements of a steam generating plant, both as to equipment and personnel, are present.

At the Southwest Works, the annual costs of steam generation consist principally of fixed charges on the steam generating equipment plus fuel costs. A further advantage is inherent in the treatment plant design due to an abundant supply of plant effluent available for condensing purposes, at ample head to provide gravity flow through the condensers, before release to the outfall. Thus, the necessity for condenser circulating water pumps is eliminated at a considerable saving in the cost of power. The combined effect of these items results in a very low cost for power.

Steam for plant power purposes is generated in four units each of the water-tube, vertical, bent-tube type, combined with a waterwalled furnace in which dried sludge can be burned in suspension together with pulverized coal.

Each unit has a maximum steam generating capacity of 110,000 lb of steam per hour at a pressure of 425 lb per sq in. and a maximum temperature of 725° to 750° F. In addition to supplying heat for generating steam, each furnace is capable of liberating sufficient heat for sludge drying to evaporate as much as 49,000 lb of water per hour at atmospheric pressure and of passing this quantity of water and other gases through the furnace for deodorizing. The total evaporation for each unit under maximum steam and average drying conditions is approximately 150,000 lb of water per hour, of which 110,000 lb is high-pressure steam and 40,000 lb is steam at atmospheric pressure.

TABLE 18.—ADVANTAGES AND DISADVANTAGES OF VARIOUS FUELS

No.	Description	COAL BURNED:		Fuel oil	Natural gas	Digester gas
		In suspension	On grates

[a] Relatively. [b] Compared with coal. [c] Particularly the lighter oils. [d] Exceptionally low. [e] Natural gas is not available in all sections of the United States, and where it is available, the supply is usually unreliable. [f] Coal must be pulverized with costly equipment, and preheated air is necessary. [g] Fuel oil must be strained and heavy fuel oils must be heated. [h] For coal and ash handling. [i] Compared with gas. [j] Burning equipment must receive careful attention and, with coal, fly ash wears the fans and ducts. [k] Requires competent firemen.

Each furnace is equipped with six burners for pulverized coal and four for dried sludge, arranged for vertical firing through the top arch of the furnace.

A water-tube slag screen is provided in each furnace immediately above the hopper bottoms. The furnace volume of each unit, exclusive of back passes of the boiler and hopper bottoms, is approximately 8,000 cu ft. The total heat absorption surface of each boiler is approximately 13,875 sq ft, 3,185 sq ft of which is waterwall surface. The superheater, in addition, contains approximately 4,000 sq ft of surface.

The furnace gases which supply heat for the drying systems are taken off at the top of the furnaces and drawn through the vapor heaters by variable-speed induced draft fans. The gas then passes through dust precipitators for ash removal and thence to the stacks. Gases passing through the boiler and superheater are drawn through an air preheater by a variable-speed induced draft fan. They are exhausted from the preheater to an electrical precipitator where the ash carried in the gas stream is removed before release to the atmosphere by way of the stacks.

Sufficient heat is extracted from the gases in passing through the air preheater to provide primary and secondary combustion air at a temperature of approximately 400° F. Air for combustion is drawn directly from the boiler room by a forced draft fan discharging through the air preheater into a system of ducts where the proportion required for primary and secondary uses is automatically controlled.

The effectiveness of combining sludge drying with steam generation at this plant has been proved by nearly three years of operation. Aside from the production of cheap power, the arrangement reduces furnace maintenance costs due to the protection of the refractories by the waterwalls. Greater flexibility is afforded since furnace operation is not dependent on the drying load alone. More than half the fuel burned is for steam generation. Therefore, sudden changes in drying load do not upset furnace conditions as they would if the furnace were designed for drying only. With some combinations of filter-cake moistures and heat values of sludge, there will be more heat available in the sludge than is necessary for drying. Where drying only is done, this excess heat must be wasted to the stack; but if steam is generated, this heat can be utilized.

Conclusion

The intent of this paper has been to present, in an easily understandable manner, the major fundamentals relative to the drying and incineration of sewage sludge as has been developed to date in The Sanitary District of Chicago. Considerably more can be accomplished along these lines and it may be concluded that the art in its present stage will undergo many changes in developments over a period of time.

DISCUSSION

A. L. Genter,[8] M. Am. Soc. C. E.—Mr. Schroepfer's contribution to this subject is excellent in that it shows how far the economics of raw sludge dewatering can be pushed with engineering acumen and operating skill. However, as he states, it relates strictly to raw sludge handling in a specific plant; that is (see heading, "Effect of Filter Rate on Cost of Filtration"),

> "It is based on the conditions (type of sludge, chemical costs, etc.) existent at this plant [Minneapolis-St. Paul]. A comparable analysis can, and should, be made by other operating plants, based on the conditions obtaining there, to determine (*a*) the economics of operation of present installation, (*b*) possibilities of effecting economies by the enlargement of present facilities at some future date, and (*c*) economical rates for different types of sludges for the benefit of designers of future plants."

The question of comparison with other plants is not so much how other vacuum filter practice fits into the picture of Minneapolis-St. Paul, but how the practice at this plant fits into the economics of another type of plant where the sludge solids are further mineralized—that is, the bulk of the sludge is reduced by sludge digestion, and the fouled natural sludge moisture is removed by elutriation prior to filtration. This procedure is essentially the reverse of practice at Minneapolis-St. Paul where solids reduction follows filtration. The First Progress Report of the Committee of the Sanitary Engineering Division on Sewerage and Sewage Treatment (27) shows that sludge elutriation is practiced for some 3,000,000 population in various parts of the United States and Canada, namely for a greater total population than at Minneapolis-St. Paul. Instead of referring to Mr. Fischer's six-year-old and rather incomplete paper for illustrative purposes of comparison, as Mr. Schroepfer has done (8), the writer deems it more appropriate to compare the 1941 averages at Minneapolis-St. Paul to some of these widely spread typical plants for the same year. The tables and remarks herewith submitted are intended therefore for this purpose.

In the light of what is now known about the chemical conditioning and vacuum filtration of various types of sewage sludges, it should be emphasized at the outset that the raw sludge at Minneapolis-St. Paul is relatively easy to condition with low chemical doses prior to filtration. This can be attributed to (1) its relatively low volatile and high ash content, (2) consequent high concentration of solids, and (3) low alkalinity of the water associated with the sludge solids. If the volatile percentage at Minneapolis-St. Paul were the same as that of the primary raw sludge at the Richmond-Sunset treatment plant in San Francisco, Calif. (82% instead of 62.1%), the annual chemical conditioning costs would be at least 250% greater than those listed by Mr. Schroepfer. Furthermore, such a sludge would be materially thinner, would require more filter area, filter hours, and incineration hours, with a consequent increase in power expended.

The items of volatile-to-ash ratio in the sludge solids, alkalinity of sludge water, and the amount of sludge solids per capita per year control local vacuum filter operating economies in all plants. They are relatively favorable at

---

[8] Cons. Engr., Baltimore, Md.

Minneapolis-St. Paul notwithstanding the facts that the solids per capita are unduly high and the natural tendency in dewatering raw sludge is to increase the vacuum filter equipment. Mr. Schroepfer's record of pushing the economics of sludge dewatering to limits below those of other plants dewatering relatively large amounts of raw sludge is primarily an excellent engineering account of all the economic consequences of the vagaries of raw sludge—(1) "inconsistency of sludge behavior characteristics" (see heading, "Improvements in Filtration as Applied to Minneapolis-St. Paul Project"), (2) frequent washing of filter cloths (every four hours), (3) lime incrustation with the consequent necessity of frequent acid washing of cloths, screens, drums, and filter piping while using analine inhibitor, (4) problem of returning incinerator ash to help mineralize the sludge, thereby increasing the solids to be dewatered, and (5) the use of "a relatively large number of professional engineers and chemists in supervisory positions" (see heading, "Costs of Dewatering and Incineration as Compared to Other Processes of Sludge Disposal: Personnel Required"), together with (6) skilled operators to control all these functions.

With sludge digestion and elutriation, this list of functions and problems cannot help but be in the opposite direction; in other words, there is much less sludge to be handled, greater mineralization of the sludge solids, far less dependence on the vagaries of sludge, far less chemical and power requirements, and greater filter yields. The writer agrees thoroughly with the argument that operating intelligence is a prerequisite to sludge filtration economy in all plants. However, Mr. Schroepfer's following statement (heading, "Costs of Dewatering and Incineration as Compared to Other Processes of Sludge Disposal") needs qualification: "To expect that even the most conscientious operator of a plant in a community of, say, 25,000 people, in which 1 to 2 tons of dry solids must be disposed of daily, can even approach the efficient and controlled operation of a plant handling 50 or more tons daily is erroneous." With equal operating acumen in both cases, this depends principally on the sludge processing methods employed. Undoubtedly, in a larger plant with more equipment and greater operating staff, a greater amount of sludge solids will be disposed of per man-hour of work. However, when it comes to dewatering various types of sludges in vacuum filters, "efficiency" is a relative term. Doing a job efficiently means doing it very well at the least possible cost. Mr. Schroepfer has demonstrated ably that it is difficult and requires "eternal vigilance" to dewater large quantities of raw sludge each day, economically, and that he and his associates are doing this job exceedingly well. However, the application of efficiency to dewatering elutriated digested sludges is far easier from the operator's standpoint and cheaper from the taxpayer's viewpoint. For this reason, the small plant serving about 25,000 population at Annapolis, Md., is included in Table 19.

This plant is under a superintendent devoting his time to a distant sewage pumping station, sewage chlorination, and the entire treatment plant operation without the benefit of chemical control other than that which his time allows and the Maryland State Department of Health requires. At the treatment plant, a helper aids him in operating a small elutriation tank and vacuum filter with ancillary equipment. This work requires only three days weekly and then only 4 or 5 hr daily, without the eternal vigilance and fight against lime incrustation evils common to Minneapolis-St. Paul. The latter plant serves a population about 32 times greater than does the plant at Annapolis, and yet the chemical cost during 1941 at Minneapolis-St. Paul was 187 times greater than at Annapolis (see Table 19(*c*)). Undoubtedly the same operator at this small plant could operate, in the same time schedule and at the same wage, a vacuum filter six times larger (390 sq ft), and handle six times as much elutriated sludge with practically the same ease as at present, thus reducing labor costs per ton of sludge solids to one sixth the present cost. This fact, plus the high power cost (3.5¢ per kw-hr), naturally increases costs per ton of sludge solids dewatered. However, such factors have little to do with efficiency and ease of filter control and operation. The correction of these latter factors primarily starts in the sludge itself; in other words, they depend on the constancy of sludge characteristics or uniformity conditions which produce the chief aid to constancy of operating averages.

Such operating comparisons, as herein offered, ultimately come back to the taxpayer through the annual operating budget, meaning that the essential items controlling sludge dewatering costs should be measured in terms of per capita per year. This is the yardstick adopted in Table 19.

Table 19(*a*) presents the basic data from which most of the information in the remainder of the table is drawn. Sludge dewatering practice in the listed plants is limited to handling primary raw sludge (Minneapolis-St. Paul), digested primary (Buffalo, N. Y.), and elutriated digested primary in the remainder of the plants serving populations of about 800,000 at the District of Columbia (about the same as Minneapolis-St. Paul) down to 25,000 at Annapolis. The flocculation and primary treatment scheme used at the Richmond-Sunset treatment plant is somewhat similar to that used at Minneapolis-St. Paul, although the primary sludge at the former plant is of much higher volatile content and therefore more difficult to settle, digest, and dewater. The greatest sewage flow is at Buffalo. The flows at Minneapolis-St. Paul and the District of Columbia are practically identical. Both Baltimore, Md., and the District of Columbia treatment plants serve about the same population and are the largest elutriation installations. However, Baltimore treats some of its sewage by sludge activation and the digested sludge contains some digested waste activated as well as digested primary, and the digested sludge is given only single-stage elutriation treatment. Consequently the results for the District of Columbia plant are listed herein. Springfield, Mass., is included with Hartford, Conn., as sludge incineration is used at the former plant and not at the latter.

For 1941 the per capita expenditures at the listed plants for sewage treatment (operation and maintenance, exclusive of pumping and chlorination) were: Minneapolis-St. Paul, 38¢; Buffalo, 47.35¢; District of Columbia, 17.26¢; Hartford, Conn., 30¢; Springfield, Mass., 43¢; Winnipeg, Manitoba, Canada, 15.91¢; Richmond-Sunset, 31¢; and Annapolis, 33.6¢. As the various charges included in such accounting are dependent on numerous factors of local significance, such a tabulation is of little value except to compare, roughly, the total treatment costs in those plants employing digestion and elutriation with the Minneapolis-St. Paul plant. To arrive at better comparisons of items essential

TABLE 19.—COMPARISON OF ESSENTIAL ITEMS THAT CONTROL DEWATERING COSTS (1941 DATA)

(a) BASIC DATA

Item No.	Description	Minneapolis-St. Paul, Minn.	Buffalo, N. Y.	District of Columbia	Hartford, Conn.	Springfield, Mass.	Winnipeg, Manitoba, Canada	San Francisco, Calif.	Annapolis, Md.

[a] Primary digested and elutriated. [b] In all elutriation installations, the cost of sludge elutriation is included in the filtration costs. [c] Annapolis uses Ferri-floc at $36.10 per ton; but during 1940 used a ferric chloride dose of 1.7% on solids, at a cost of $99.60 per ton. [d] In all elutriation installations, the data include power for all elutriation purposes. [e] For total filter days and hours see Items Nos. 14 and 15, Table 19(*a*). [f] Item No. 49 multiplied by Item No. 1, Table 19(*a*).

to obtaining economic filter operation further breaking down of such data is necessary.

The same statement is valid for Table 19(*b*), which is the first step in the process of breaking down sludge disposal costs. It is evident from Table 19(*a*) that the unit cost of chemicals and power varies materially at the different plants. Aside from these facts the sludge lifts differ in the various plants. At Minneapolis-St. Paul all filtration costs include the minor cost of sludge concentration and all costs from and after the point where sludge is pumped from the settling tanks to the point where sludge cake is discharged in the furnaces. The same principle is followed in the remainder of the installations listed in Table 19(*b*). This procedure necessarily includes the entire operating costs for elutriation in the installations using this process.

At Springfield the power is estimated roughly and is taken amply high. The total treatment cost already listed includes an item for depreciation and fixed charges beyond actual operating and maintenance costs. Although Table 19(*b*) has been adjusted to this fact, the higher power estimate has not been changed. This installation has higher sludge lifts than the other plants listed and includes the cost of all changes made during 1941, which was the first full year's operation of this relatively new plant. According to a private communication from J. D. McDonald, engineer in charge of this plant, the 1941 filtration costs included cost of extra ferric chloride and filter cloths purchased beyond 1941 needs and making various minor changes about the filters, conditioning mixer, and incinerator. Aside from these facts, running any vacuum filter to suit an incinerator's sensitive nature necessarily prolongs hours of filter operation and increases power. This was particularly true during the first year's operation at this plant.

At the other elutriation plants the cost of disposing of sludge cake by freight-car shipment or trucking is included. At Annapolis the sale of sludge cake paid for all trucking charges.

At Hartford, the filtration costs were 1¢ per capita higher in 1941 than in 1940 due to the material reduction in population served during 1941—150,000 against 201,400 in 1940. This decrease was brought about by the necessity of diverting a portion of the sewage flow from plant treatment while work on the Park River conduit was in progress.

It is to be regretted that the total cost of sludge filtration and incineration at Buffalo could not be broken down into the items listed in Tables 19(*b*) and 19(*d*), although other tabulated essential information is available.

As chemical and power costs for sludge filtration make up the major portion of total annual filter operating costs and the unit prices for chemicals and power vary materially in the plants listed, Table 19(*b*) should be tabulated with these costs uniform in all cases. However, it is simpler to present these essential items as in Tables 19(*c*) and 19(*d*).

In Table 19(*c*), Item No. 29 shows the per capita cost for chemicals placed on the price paid for ferric chloride at Minneapolis-St. Paul. As the Buffalo plant pays less for ferric chloride than does any other plant listed, the other per capita chemical costs are adjusted to the Buffalo price in Item No. 30. The differences in favor of the elutriation installations are striking. During 1942 the ferric consumption and costs at both Hartford and Springfield improved.

At Hartford the improvement was principally due to securing and using more wash water in elutriation during the latter half of 1941. In fact, the filter yield was materially increased at the same time.

Table 19(*d*) is more or less self-explanatory. The total kilowatt-hours used for sludge filtration during 1941 are shown for all plants except Buffalo. In the elutriation installations the figures include all power used for elutriation. As the expression "population served per filter hour per day or year" has little meaning, due to the fact that different plants use different sizes of filter units, and measure filter hours in terms of each unit, it is rather obvious that filter hours per capita should be reduced to some identical filter area. For this reason, the annual filter hours per thousand population per 100 sq ft of area in the various plants is shown in Table 19(*d*). For example, Minneapolis-St. Paul, Baltimore, Buffalo, and the District of Columbia all use some multiple of 500-sq-ft filter units (see Table 19(*f*)), and the other plants listed use other sizes. Minneapolis-St. Paul recorded 39,919.1 filter hours in 1941 based on one filter unit of 500 sq ft in area serving 805,000 population. Hence, the population served by 100 sq ft of area during this time was $\frac{805{,}000}{5}$, or 161,000; and, for each 1,000 population per 100 sq ft, the filter hours were $\frac{39{,}919.1}{161} = 248$. The other plant data are calculated and listed in the same manner.

Dewatering less sludge solids at higher filter yields in the elutriation installations causes the power and filter hours to be notably lower in such cases. The lowest figure is for the smallest installation at Annapolis. At this plant the flow of digested sludge to elutriation is by gravity, the sludge lift to the vacuum filter is very low, and one or two other mechanized devices for moving and concentrating sludge are absent. Therefore, the power consumption should be relatively low.

Table 19(*e*) is self-explanatory. Again all of the essential factors relating to life of filter dressings, absence of acid washing, etc., are markedly in favor of the elutriation installations. Baltimore is not listed although it shows the lowest filter-cloth consumption of all—1,200 hr of cloth life, or only 2.5 sq ft of cloth dressing per 1,000 population per year. To keep filter yields up and ferric chloride consumption down at Winnipeg, wool cloth dressings are changed more frequently. The wool blankets used at this plant are manufactured locally and cost only $21.00 each. Annapolis uses canton flannel for its small 65-sq-ft filter. Each filter dressing costs just $1.19, or only $6.95 for the entire year of 1941. As a wool blanket lasted practically a full year and cost about $27.00, it is evident why canton flannel is used. Changing cloths on such a small filter unit is an easy and inexpensive task.

Table 19(*f*) relates to population actually served per filter hour per square foot of filter area, per filter operating day, in each plant listed for 1941. Although this essential figure is again materially in favor of the elutriated sludge plants, such a tabulated comparison is not fair to these plants for the simple reason that the vacuum filters in these plants operate only a fraction of the time listed for raw sludge dewatering at Minneapolis-St. Paul. If all the plants were operating on the Minneapolis-St. Paul time basis, without changing the coagulant dose used in 1941, and at the same filter yield, Table 19(*g*) would result. In other words, the average population per square foot per filter hour for all the elutriation installations would be almost ten times greater than at Minneapolis-St. Paul. Of course, it might be argued legitimately that such practice in the installations using only one or two vacuum filters would not allow time for filter repairs and redressing. However, if a spare filter were provided as a standby in such cases, the results would still be at least seven times greater; and if all plants began with approximately the same amount of raw sludge solids per capita, the digestion-elutriation installations would appear about four times better in this particular respect, which the writer considers one of the basic defects in the economy of dewatering large quantities of raw sludge in vacuum filters. As a matter of fact, Mr. Schroepfer's own analytical conclusions show that for Minneapolis-St. Paul the economics of filtration require still more filter area. It should be evident, from the study of Tables 19(*f*) and 19(*g*), that the tendency in the plants employing sludge digestion and elutriation is in the opposite direction—doing the dewatering job with the least amount of vacuum filter equipment and at the least annual operating expense. After all, these items are of material importance to the taxpayer.

Mr. Schroepfer leans to the opinion that filter equipment at Minneapolis-St. Paul may be eliminated by reducing the sludge moisture to 85% or 90% and incinerating the raw sludge directly by increasing the amount of incineration equipment. Sludge digestion is essentially a wet combustion process itself in which the solids are mineralized before further dewatering. In view of the fact that the bacteria in this process do this work for nothing and with much less wear and tear on the relatively long-lived equipment involved, produce much less solids to be dewatered, and plenty of gaseous fuel for plant heating, the writer seriously questions the economics of raw sludge incineration compared to sludge digestion, elutriation, and vacuum filtration, especially on the sludges listed in Table 19(*a*). In fact, by using the latter procedure at Minneapolis-St. Paul, it is doubtful if final sludge incineration would be needed because the digested sludge cake would have a soil value that is out of the question with raw sludge.

According to the writer's estimates, destroying only 60% of the volatile matter in the unthickened raw sludge by digestion at Minneapolis-St. Paul, followed by elutriation of this sludge with river water and filtration, would save over $25,000 more a year in chemicals and power than the 1941 records show. With Mr. Schroepfer's natural genius for pushing filtration economies to the limit in practice, this estimate would undoubtedly be improved. In this estimate no account is taken of the savings due to elimination of lime incrustation, acid washing of filters, extra labor involved in these unnecessary items, frequent cloth changing, and the ultimate use of digestion gas for plant heating.

In the discussion of the relative economies of the vacuum filtration of raw and digested sludges, the argument that initial costs and fixed charges for digestion and elutriation space and equipment may offset the gains due to sludge mineralization has lost is validity in the numerous installations practicing this procedure. Mr. Fuhrman's paper on sludge dewatering at the District of Columbia clearly demonstrates this fact. Extensive filtration and incineration equipment for raw sludge is very short lived compared to digestion and elutriation tanks. Consequently, amortization charges against the former are much higher than against the latter. Notwithstanding these facts the argument has been further invalidated through the recent development of the relatively inexpensive "coilless" digester by A. M. Rawn, M. Am. Soc. C. E., whose contribution (28) to the advance of sludge digestion is outstanding. Expensive construction of tanks with floating covers, hot water coils, and elaborate heat exchanging equipment may be eliminated. As for tank space required for countercurrent or multi-stage elutriation, this is relatively small (0.02 to 0.1 of that installed for digestion). According to the percentage of solids present in the digested sludge, water ratio used for solids washing, and operating hours per operating day, it varies from 0.02 to 0.2 cu ft per capita, the latter value being for thin digested waste activated sludge and eight operating hours per filter operating day.

Acknowledgment.—For aid generously contributed in furnishing data for Table 19, acknowledgment is made to: Messrs. Schroepfer, Velzy, and Fuhrman, Symposium authors; Ellwood Johnson, Robert J. Ross, and Benjamin Benas, Members, Am. Soc. C. E.; George E. Symons, Assoc. M. Am. Soc. C. E.; and Paul D. McNamee, chief chemist, District of Columbia Sewage Treatment Plant; John D. McDonald, engineer in charge of sewage treatment, Springfield; W. M. Scott, Chairman of Commissioners, Greater Winnipeg Sanitary District, Winnipeg; and C. G. Weber, superintendent of the Annapolis Sewage Treatment Works.

WILLEM RUDOLFS,[9] M. AM. SOC. C. E.—Adequate preparation and proper disposal of sewage sludge continue to be among the principal problems of sewage treatment. In general, the processing of sludge for fertilizer or burning requires that the moisture content of primary, digested, or activated sludge must be reduced as much as possible by chemical and mechanical means. Dewatering and air-drying of sludge on sand beds continue to be practiced to a considerable extent, especially where beds can be used throughout most of the year, where natural sand beds are available, for small plants where considerable land but no technical skill is available, and because the method is economical.

As a rule, dewatering of sewage with the aid of chemicals by means of vacuum filtration is not advisable for small plants, except where local conditions such as area available, proximity to dwellings, and final disposal of the sludge require special methods. Nevertheless, there are a number of small plants utilizing vacuum dewatering without any apparent need. The cost is frequently out of proportion and the operation not as good as efficiency and economy demand.

Sludge pressing with the aid of chemicals is used in a few cases; one plant dries its digested sludge successfully by spraying; but preparation for dewatering by cooking; or by direct dewatering by centrifuge, has not been adopted in the United States.

Dewatering.—Most of the dewatering by vacuum filtration is restricted to larger plants. The several Symposium authors are in agreement that for most efficient practice certain requirements are essential:

1. The sludge should be concentrated as much as possible before filtration;

---

[9] Chf., Dept. of Water and Sewage Research, New Jersey Agri. Experiment Station, New Brunswick. N. J.

2. Operation of the filters should be as nearly continuous as possible;
3. A conditioning agent must be used;
4. The conditioning agent must be added in accurate proportions and thoroughly mixed with the sludge in the shortest possible time;
5. Filtering must proceed as soon as possible after mixing, to take advantage of the floc formed; and
6. Flexible machinery and close control are essential.

The present method of vacuum filtration is an adaptation of industrial dewatering of slurries. The mechanical structures have not changed greatly, although some minor modifications have been made. The crux of the vacuum filtration method has been, and still is, the proper type and use of chemicals for conditioning. The type of chemical used at present is limited to iron and aluminum salts, with or without lime. Selection of the chemical has been determined by local conditions, availability, character of sludge, etc., but not always on scientific grounds. Under all conditions good coagulation is necessary to avoid troubles. Although great advances have been made in the knowledge of the behavior of sludges and the action of chemicals, much remains obscure. Operating experience at Buffalo, Minneapolis-St. Paul, Chicago, and Washington, D. C., indicate developments. As filter medium, Canton flannel or woolen blankets are used. Difficulties with clogging by iron or lime can now be overcome, but clogging of the filters by thin jelly-like sludge occurs frequently at smaller plants with less efficient operation. Lime scale is removed successfully from filter screens, troughs, and piping with the aid of muriatic acid, at Buffalo; but such removal has failed at other places.

Thorough distribution and rapid mixing of the conditioning chemicals in the shortest possible time are stressed by all authors. Under certain conditions mechanical stirring appears to be favored over air-mixing: Mr. Schroepfer has improved air-mixing facilities by increasing the number of points by which air is admitted, thus reducing the violence of mixing; Mr. Dundas states that most devices available for mixing, although theoretically correct, fail in practical operation on account of their complexity and inability to withstand the action of the chemical; and Mr. Velzy reports that at Buffalo the tendency is to stay away from mechanical appliances for the application of chemicals. Although all agree that rapid mixing and application of chemicals are necessary, there seems to be no definite agreement on the procedure. Practices in a number of small plants vary much more widely than indicated by the Symposium authors. It is questionable whether standardization of practice is desirable or needed.

Some problems requiring further study are indicated. Information is required as to the reaction between coagulants and sludge ingredients; the effect of greases and soaps on the rate of filtration; the effect of thickness of cake on yield; filter washing to prevent binding and reducing the life of cloth; removal of scale and incrustations; type of filter cloth for different sludges; sludge feeding methods to the filters to obtain even loading at all times; improvement of dispersion of chemicals (riffle boards, perforated pipes, ejectors, pumps, sprays, etc.).

The operating cost for conditioning and vacuum filtration as given by the different authors varies greatly. The low figure of $2.19 per ton of dry solids at Minneapolis-St. Paul for primary and chemical sludge is outstanding. Washington, with primary elutriated sludge at $4.64 per ton dry solids, is near the average and somewhat higher than the Chicago range for primary and activated sludge of $3 to $4 per ton of dry solids. Cost data published from a number of small plants, where flows are treated below 10 mgd, vary from $8 to $20 per ton, some being even higher. To these costs must be added the expense of handling and disposal of the cake by dumping, fertilizer production, or incineration.

Drying and Incineration.—Difficulties with drying and burning of the sludge appear to be less than those encountered in dewatering. Uniform feed and continuous operation are stressed to produce maximum surface exposure of the sludge particles in drying and to prevent rapid changes in furnace temperatures. The usual practice of returning previously dried material, which is agitated and mixed with dewatered sludge, appears to have reduced damage, prevented scorching, and alleviated odors. There are still some difficulties. Abrasion of flash drier fans and pipes had been severe at Buffalo, which was reduced by the use of gunite; nevertheless, "it has constituted a problem calling for careful attention." Removal of the preheater in one of the incinerators resulted in considerable savings in power and maintenance cost at Minneapolis-St. Paul. The odor problem of Chicago was solved with electrical precipitators. Constant control, close supervision, a considerable degree of technical and directive ability, skilled labor, and a high degree of interest of the staff are required for economic operation and maintenance.

It is of considerable interest that the cost of dewatering the sludges appears to be from one and one-half to two times the cost of incineration. The total operating cost reported for disposal of the sludge varied from $3.53 to $7.69 per ton of dry solids. Comparison of these costs with those available for barging primary and activated sludges, which varied for the same years from $2.88 to $4.00 per ton dry solids, indicates the present advantage of cities located near the sea. There appears still to be room for improvement in drying and incineration; but since most of the difficulties and the higher cost occur in the conditioning and dewatering of the sludges, studies on simplified dewatering, sludge concentration with, or without aid of chemicals, to a sufficient extent to allow direct incineration, may lead to fewer difficulties and lower cost.

Fertilizer.—For years far-sighted soil scientists have deplored "the wealth that flows to sea." It has been estimated that sewers in the United States carry away enough nitrogen to fertilize 1,000,000 acres of farm land. Although some of the larger cities realize the possibilities, and are considering more extended use of sludge as a soil conditioner, numerous small plants have had material available, which constitutes, in Mr. Van Kleeck's words, "an economic waste of a valuable natural resource."

The use of raw primary sludge as a fertilizer is not recommended for a number of reasons given by Mr. Van Kleeck. The principal objections are odor, grease, acidity, pathogenic organisms, and insufficient humification. Unquestionably, these objections are valid when the material is applied in the raw state to truck-garden crops or used around dwellings. However, the utilization of raw sludge as a soil builder or fertilizer may be reconsidered if the material is to be used by farmers who may store and compost it. Raw sewage sludge mixed with soil, plant residues, or manure and allowed to decompose aerobically for a number of months makes an excellent material of an equally good or better grade than digested sludge. All objections raised disappear because such composted material has an earthy odor and contains a minimum of grease; acidity has been destroyed; pathogenic organisms are killed; and humification has taken place. The rate of decomposition in compost piles is high and naturally varies with the seasons. The heat produced is material even during the colder season.

Although any type of sludge has some fertilizer and fertility value and is capable of improving soils, especially the moisture holding capacity, its value should not be overemphasized. With the present great demand for soil-building material in "Victory Gardens" it has become a question of restraining rather than stimulating the use of sludge. Thousands of people who had no gardens before turn to the "wealth that flows to the sea" and believe that a bag of sewage sludge automatically insures abundant and luscious crops. Disappointment may lead to a wholesale condemnation of the use of sewage sludge. On the other hand, with restrained recommendations, the use of sludge for agricultural purposes may be greatly increased after the emergency is over.

The chemical composition of digested sludge varies materially from place to place. Analysis of many hundreds of samples collected all over the United States shows the following percentage ranges and averages on the basis of bone dry material:

	Range	Average
Volatile matter	42 –64	51
Total ash	58 –36	49
Grease and fats	3 –17	8
Total nitrogen (N)	1 – 4.5	2.2
Phosphorus (P_2O_5)	0.6– 5.7	1.5
Potassium (K_2O)	0.3– 1.6	0.7

It is clear that digested sludges are not complete fertilizers and not balanced plant foods. They contain major and minor elements, growth promoting substances, and aid in replenishing organic matter, and as such are valuable as subgrade fertilizers and for soil improvement. Their value is not constant, but varies materially even at a given place.

Lloyd M. Johnson,[10] Esq.—A wealth of information, covering the development and design of a system for dewatering and drying activated sewage sludge, is presented in this Symposium. Fundamental principles are presented in a logical and understandable manner by Messrs. Dundas and McLaughlin. This paper leads the sanitary engineer through the hitherto foreign fields of combustion, in easy stages. Therefore, it is a timely contribution to the development of a new art in sewage disposal—namely, drying for fertilizer purposes, or combined drying and incineration.

---

[10] Commissioner of Streets and Electricity, Chicago, Ill.; formerly Engr. of Maintenance and Operation, San. Dist. of Chicago.

Three developments discussed by Messrs. Dundas and McLaughlin should be emphasized: Odor control, fertilizer production, and power generation.

Odor Control.—The control of odors is by high temperature deodorization, which consists of raising the temperature of all the gases and vapors in contact with the sludge during the drying period to at least 1,300° F. There is no argument concerning the necessity for high temperature deodorization in locations where odors would create a public nuisance. This has been recognized for decades in garbage incineration. In consequence, garbage incinerators must operate at deodorizing temperatures of 1,300° F and greater. Where odor control is required, high temperature deodorization is the most economical method. No costly chemicals and no special apparatus are required. High temperature deodorization is an integral part of the sludge-drying system.

Fertilizer Production.—The flash-drying system used by The Sanitary District of Chicago is well suited for fertilizer production. Furthermore, the system has great flexibility because the dried sludge can be incinerated whenever the fertilizer market is unfavorable. Before the sludge-drying and incineration system was developed, the end product of a sewage treatment plant was sludge-bed cake. This cake varied in moisture content from 20% to 60%. Thus, after passing through a highly developed and refined treatment process, the city was still confronted with the problem of disposing of huge quantities of sludge-bed cake. With the application of flash drying and incineration, the end product became either a highly desirable and salable fertilizer or a sterile ash well suited for fill. Every sludge, no matter how low in nitrogen content, has some value as a fertilizer and soil conditioner. Experience has shown that a ready market exists, and the sales value will materially help to compensate for the cost of treatment. On the other hand, it is necessary for the city to pay for the trucking and disposal of ash. Thus, as a general rule, provision should be made for fertilizer production in preference to incineration. For very large operations such as those at Chicago, the quantity of ash also becomes a problem. It must be remembered that dried sludge is 50% ash, and it is sometimes difficult to find sufficient low ground for disposal of this ash over a long period of time. Furthermore, ash is highly abrasive and requires considerable maintenance on any ash handling system.

The desirability of fertilizer production is by no means confined to the large cities. As a matter of interest, fertilizer is successfully produced and marketed in communities of 5,000 population.

Power Generation.—The operations at Chicago are unique in that power generation by steam is practiced. It is quite customary for power to be generated by gas engines fired with digester gas. The size of the operations at Chicago make power generation by steam a most economical solution. This process may be applied to much smaller communities if public utility rates are particularly unfavorable or if the location of the plant makes public utility power impractical.

Isador W. Mendelsohn,[11] M. Am. Soc. C. E.—This Symposium of five selected papers affords an opportunity for deserved consideration of one of the major problems of sewage disposal. Presentation in such grouping makes for clearer comparison and more extensive analysis of data evolved in plant operation at Buffalo (B), Washington (W), Minneapolis-St. Paul (M), and Chicago (C) regarding sewage sludge dewatering, incineration, and final use. The Symposium also presents certain limitations which merit attention in rounding out discussion of sewage sludge disposal.

---

[11] Capt., Corps of Engrs., U. S. Army, Asst. Post Engr., Camp Hood, Tex.

To the writer, one of the most significant features of the Symposium is the exceedingly large number of tests performed at the plants to develop satisfactory and economical operation in disposal of sludge. By no means do these include all experimental work on sludge disposal at these plants. For ready comparison these researches and results are grouped as follows.

Concentration of Sludge.—

(B) Sludge concentration tanks have proved their value by delivering sludge of reasonably uniform characteristics for filtration and burning, absorption of irregularities in quantity of raw sludge obtained, provision of a 6-day operating week in dewatering and incineration, and provision of gas as fuel for boilers and auxiliary heat for incinerators.

(M) Concentration of sludge by weighing a known quantity pumped from the sedimentation tanks at frequent intervals, by soundings and determinations of moisture content of sludge in tanks, and by withdrawals of supernatant liquor has increased the total solids of the sludge from 8.11% in raw sludge to 9.35% in concentrated sludge.

(C) Concentration of sludge has reduced the quantity of water to be removed by the filter and provided a filter feed of uniform consistency—a vital factor in successful filter operation.

Conditioning of Sludge.—

(B) A mixing tank with no baffles and with proper mixing-paddle speeds and a short detention period gave best results. In the application of chemicals, equipment has been developed to provide easy manual control in preference to automatic devices, such as feeding ferric chloride solution through a perforated rubber-pipe arrangement so that the number of small streams of solution is an indicator of the rate of feed.

(W) In the operation of elutriation mixing tanks, fine sand settling out in the tanks has been removed gradually to the vacuum filters with the sludge by connecting the tank inlet and outlet with a 12-in. pipe. To reduce sludge pump clogging and interference with continuous dewatering, the sludge pumps elevating the digested, elutriated sludge from the elutriation tanks to the mixing tanks were provided with 3-in. instead of 2-in. impeller passages and a maximum speed of 1,140 rpm. To overcome sagging of pipe lines between supports, steel pipe with hard-rubber lining was substituted for hard rubber ferric chloride pipe lines.

(M) Better results were obtained by increasing the number of points through which air is admitted to the sludge for mixing and by decreasing pressure and violence of mixing. Improved mixing resulted from changing the path of the sludge through the tanks with over and under baffles to a sinuous path both vertically and horizontally, and reducing the detention period in conditioning tanks from 13 min in 1938 to 7 or 8 min at the close of 1941. Installation of riffle boards for both lime and ferric chloride instead of adding chemicals to the tanks through one or two pipes provided better dispersion of chemicals. Ferric sulfate and lime and ferric chloride alone can be used satisfactorily as substitutes in emergencies, but they are not as economical by about 25% as ferric chloride and lime.

(C) In conditioning sludge for many years, ferric chloride alone has been found the most effective and most economical reagent available for conditioning activated sludge. With other sludges, combinations of ferric chloride and lime and in some cases lime alone are efficacious; chlorinated copperas and ferric sulfate are probably less effective. Special proportion devices for continuous conditioning and frequent checking of sludge to determine the amount of chemical have established better dosage control of ferric chloride, which has been found to be the most expensive item of filtration cost in handling activated sludge. The amount of ferric chloride required may be related to the volatile content of the activated sludge; ferric chloride requirements for conditioning activated sludge of The Sanitary District of Chicago vary between 4% and 7% by weight of dry cake solids, and resultant cake moistures vary between 78% and 85%.

Operation of Vacuum Filters.—

(B) Canton flannel filter cloth has proved most satisfactory in operation, cost, and life of cloth; and ordinary sash cord has proved a satisfactory substitute for bronze strips in the application of the cloth to the filter drum. Experiments are in progress with a screw feeding device and a surge bin above the screw, to receive the sludge cake from the filter and discharge it uniformly to the first conveyer belt. Formation of lime scale on the wire screen on the surface of the filter drum was removed successfully with the application of muriatic acid in the filter tub; this acid also has been used successfully in reducing scale accumulations in filtrate lines and in the supernatant line receiving the discharge from the filtrate pumps.

(W) Washing filter cloths in a 1% solution of oxalic acid for a 24-hr exposure after certain period of use extended their life 30%; application of a 100-ppm solution of copper sulfate every Saturday and Sunday by rotating the filter cloth in the solution in the filter pan to permit saturation overcame filter-cloth disintegration by fungus growths in the regular filter shutdown from Friday afternoon to Monday morning.

(M) Eight-ounce Canton flannel filter cloth was found to be most satisfactory at this plant. The difficulty of obtaining this cloth during wartime necessitated additional studies leading to the possible use of a new cloth type. The economic life of filter cloths has been restricted to 350 hr; tests made on a plant scale to demonstrate the effect of cloth age on filter yields show that at 500 hr the yield of a filter is approximately 10% to 15% less than that of a new cloth, other conditions being constant, with 4-hr intervals between washings. An appreciable improvement is effected by proper washing, as noted by rearranging the washer sprays to impinge along the filter drums almost at right angles to the drums, instead of tangentially. It appears to be economical to give each cloth an acid bath after 350 hr of service (using 1 to 2 carboys of hydrochloric acid in 600 gal of water), thereby reducing the binding and increasing the economic cloth life to approximately 500 or 600 hr. (This expedient provides an inexpensive means of removing calcium carbonate from the screens and splines of the filters, which formerly became so incrusted with matter as to interfere with the free passage of water through the filter.) Especially is it economical in chemicals to wash filters frequently, the periods between washings having been reduced from 24 hr to 4 hr. Frequent filter washings led to the development of a method of washing filters while in service by installing the wash-water pipe and nozzles (instead of its usual location on the far side of the filter from the take-off plate) immediately below the top edge of the take-off plate, so that the washing operation is done in the section of the drum between the take-off and the submergence in the sludge, which section is not utilized in the usual installation. A trough suspended immediately above the sludge level returns the spent wash water to the overflow box on the filter. Besides maintaining a clean filter medium, this washing procedure in effect adds one filter. For each size of installation and type of sludge, it is possible to determine the economic range of speeds at which filters ordinarily should be operated. The filter rate has a marked effect on the economics of filtration; instead of expressing the filter rate as pounds per square foot of installed filter capacity per hour, the index of pounds per square foot is favored to include varying filter speeds. Uniform feed is desirable where incineration or drying is the practice, and for this a spare filter unit is desirable in addition to regular operating filters for use during washing of regular filters.

(C) A long-nap woolen blanket is most satisfactory and economical for filtering activated sludge conditioned with ferric chloride. The life of a blanket is approximately 3½ months; the life of binding wire is about the same as the filter cloth. Use of woven wire for cloth backing has not proved satisfactory; wood backing may prove more satisfactory and economical than wire cloth.

Operation of Incinerators.—

(B) Mechanical developments at Buffalo include replacement of oil by gas exclusively as an auxiliary fuel, resulting in the disappearance of scale on preheaters caused by oil fuel, removal of soot blowers as unnecessary, and abrasion on heater surfaces making necessary replacement of some parts. Abrasion in pipe lines and ducts has been solved by use of concrete wear backs at bends; lower speeds in the flash-drier cage will have increased its life to about 5 months; adjustments in the type of assembly have resulted in easy replacement of worn parts and reuse of portions of these parts; moving the induced draft fan to the clean air side of the drying system cyclone has reduced the severe abrasion of the fan. Concrete, brick, or ceramic material linings in place of steel linings for stationary parts subject to abrasion are under experimentation.

(M) Sudden and large changes in sludge feed cause rapid changes in furnace temperatures with consequent long-time damage to refractory materials. Removal of the preheater is expected to reduce the operation and maintenance costs of incineration by about $0.33 per ton; fuel oil required for incineration has been reduced, only 1.5 gal now being necessary per ton of dry solids incinerated for heating up, cooling down, and holding temperatures in incinerators not in operation. Substantial fuel-oil savings were effected by installation of duct work so that available heat in operating furnaces could be utilized for heating up, cooling down, or maintaining temperatures in any desired unit. There is a possibility of the utilization of incineration heat for generating sufficient steam for all heating purposes and electric power requirements. Tests are under progress on incineration of filter cake to which has been added a portion of liquid sludge in the belief that, if the moisture content of sludge is reduced to 85% or 90%, dewatering on vacuum filters prior to incineration could be dispensed with economically, provided suitable incinerators are available.

(C) Extensive tests on sludge drying and incineration have led to the use of flash-drying equipment which satisfies the eight fundamental principles and factors for economical and efficient drying free from nuisances to prepare sludge for efficient combustion or for use as a fertilizer—maximum surface exposure, thorough agitation of the wet material, temperature potential of gas, velocity of drying gas, responsive and flexible temperature control, deodorization of gases vented from the drying operation, instantaneous water removal, preservation of fertilizer qualities. Heat-dried sludge should have a moisture content below 10% and be as free as possible from dust. The temperature of sludge at time of loading in cars should be below 100° F to prevent spontaneous combustion when stored in large quantities over a period of time. This is accomplished by screening, dedusting, and cooling in water-jacketed conveyers. It is necessary to raise the temperature of all gases and water vapor produced in the heat-drying of sludge to not less than 1,300° F in the presence of sufficient oxygen to effect complete combustion of offensive hydrocarbon compounds. Furnace spaces connecting flues and ducts of the sludge burner should be designed sufficiently large to accommodate excess gases such as nitrogen and oxygen. Tests with a commercially patented electrical precipitator indicate a removal of 97% of suspended solids from furnace stack gases. The presence of a large volume of visible water vapor in stack gases has not been objectionable in atmospheric pollution, if it is discharged at a height to permit complete dispersion. Where supplementary fuel is needed frequently in regular operation for drying and incinerating sludge in moderate size installations, such fuels in order of desirability, without reference to cost, are digester gas, natural gas, and fuel oil, or combinations thereof, and in large installations, powdered coal is very satisfactory and economical. At the Southwest Works, almost three years of operating plant tests on combining sludge drying with steam generation have proved its feasibility in providing cheap power, reducing furnace maintenance costs due to protection of refractories by water walls, and furnishing greater flexibility since furnace operation is not dependent on the drying load alone. More than half of the fuel is burned for steam generation so that sudden changes in drying load do not upset furnace conditions as they would if the furnace were designed for drying only. With all these improvements in drying and incinerating sewage sludge on record, still more developments are foreseen.

Operating Results.—

(B) For the first three years of plant operation, moisture in raw sludge was reduced from 96.54% to 92.77%; in digested sludge it increased from 87.8% to 90.89%; and in sludge cake it increased from 61.8% to 63.1%. Volatile matter in raw sludge, digested sludge, and sludge cake increased from 57.6% to 62.9%, from 41.5% to 47.5%, and from 38.8% to 42.9%, respectively. Heat content of sludge cake increased from 3,790 to 4,320 Btu per lb; filter rate in pounds of dry solids per square foot per hour decreased from 7.58 to 6.77.

(W) Elutriated sludge contained 44.4% volatile matter in solids; 3.8 volumes of Potomac River water to one volume of digested sludge gave a total alkalinity reduction equivalent to 7.5 volumes of wash water, which was due to countercurrent elutriation. Sludge cake contained 28.9% solids; filter rate averaged 5.9 lb of dry solids per square foot per hour.

(M) Moisture in raw sludge decreased from 92.85% to 91.89%, in the thickened sludge from 90.98% to 90.65%, and averaged 65% in filter cake. Volatile matter in filter cake increased from 52.1% to 58.8%. Filter rate was reduced from 5.50 to 3.90 lb of dry solids per square foot per hour. Filter rates of 5 to 10 lb per sq ft per hr were not found economical, since reductions in filter rates were attended by reductions in chemical requirements. Conditions at Minneapolis-St. Paul indicated 2 lb per sq ft per hr as economical, based on total annual charges, including fixed charges, the basic influencing factors being type of sludge, cost of chemicals, etc.

Operating Costs.—

(B) The total cost of treatment excluding pumping (sedimentation, sludge disposal, and chlorination) was $6.92 per million gallons, or $19.38 per dry ton.

(W) Sludge elutriation, vacuum filtration, and sludge cake disposal costs only, excluding sedimentation and sludge digestion, were $1.33 per million gallons, or $7.69 per ton of dry solids in the cake.

(M) The cost of filtration alone decreased from $4.92 to $2.12 per dry ton and the cost of incineration decreased from $2.05 to $1.29 per dry ton. The total cost of collection, treatment, and sludge disposal decreased from $15.40 to $8.25 per dry ton; and the cost of sludge disposal varied between 40% and 45% of the total cost.

Use of Sewage Sludge as Fertilizer.—

(M) Tests are in progress on the use of sludge cake as a soil conditioner, the sludge being composted for a month or more to render it more friable and a better humus material for plant growth.

General.—Despite the numerous improvements in sewage sludge dewatering, incineration, and final use cited in the Symposium, it is of outstanding importance to note that each paper definitely indicates that still further developments are foreseen.

The Symposium shows that the many improvements were the result of combined efforts of sanitary engineers, mechanical engineers, chemists, and plant unit operators. It consists of papers on operation of sewage plants each serving populations of more than 500,000. According to the 16th Census of the United States in 1940 (29), there were only fourteen cities of 500,000 population or more. The latest comprehensive tabulation of sewage treatment plants in the United States (30) gives a total of 5,580 plants, of which 97% or 5,403 provide sludge digestion, and 3,522 or 63% have some form of sludge dewatering and disposal. Citation of these figures indicates how much more important and apropos the Symposium would have been if some papers had been included on plants serving populations of 20,000 to 200,000, which group would include a large percentage of the sewage treatment plants in the United States. For example, (M) data indicate that for sewage plants serving populations of 50,000 to 200,000 sludge digestion and drying on sand beds should be considered in comparison with dewatering by vacuum filters and incineration, based on type of treatment by which the sludge is produced, quantity of sludge to be disposed of, dependability of operation, and related factors.

The plant operation cost data presented in the Symposium leave much to be desired for better comparison and analysis. Cost of sewage treatment alone, exclusive of cost of sewage collection, should be furnished, on a million gallon basis and a dry ton sewage solids basis. In addition, cost of filtration should be given on a dry ton sewage solids basis, as well as cost of incineration, and other treatment unit operation costs as well, so that a definite dollars and cents value is presented; also a percentage of the total treatment cost should be made available for each unit.

As the (M) paper illustrates both in presentation of data and in stressing the point, studies can be made profitably, at all sewage plants, of economics of operation of present installation, possibilities of effecting economies by enlargement of present facilities at some future date, and economical rates for different types of sludge for the benefit of designers of future plants.

It is well to note that year after year at least one sewage treatment plant is presenting irrefutable data of the value of trained professional sewage treatment plant supervisors and operating personnel. The author of the (M) paper attributes satisfactory operating results to the relatively large number of professional engineers and chemists in supervising positions at his plant, necessitated by greater complexity of sludge filtration and incineration processes; to maintenance at high level at all times of interest and conscientiousness of entire personnel—particularly filter and incinerator operators; by control of filtration by Buechner funnel tests; hourly calculations of chemical dosages; shift competition; and utilization of new ideas. The splendid data presented in the (M) paper make one wonder whether other sewage treatment plants have done as well as they could, and should, in the employment of a number of qualified professional engineers and chemists as supervisors and in the training of plant operators.

Mr. Van Kleeck summarizes data on the conditioning and application of sewage sludge as fertilizer, a most important and promising phase of disposal of sewage sludge. Sufficient attention to this phase has not been given heretofore on an extensive cooperative basis. The progress made, especially since about 1928, indicates a successful solution with sound development.

Langdon Pearse,[12] M. Am. Soc. C. E.—The range of procedure presented in this Symposium illustrates the rapid advance in the practice of handling sewage sludge since the early 1920's, and particularly in the technique of conditioning, dewatering, and heat-drying sludge. The discovery of the value of ferric chloride as a conditioner by Mr. Palmer and the extended study by Mr. Dundas and his associates in heat-drying and incineration are among the most important advances in the art. The first stage of the development related to design; the second, to operation and maintenance.

Mr. Velzy has described operating conditions at the Buffalo installation, in which primary sedimentation produces a sludge that is treated by partial digestion, vacuum filtration, and incineration. Mr. Fuhrman discusses the plant of the District of Columbia, where the primary sludge is digested and elutriated before vacuum filtration, the cake being dumped. Mr. Schroepfer analyzes the Minneapolis-St. Paul plant, in which sludge from primary settling is concentrated, dewatered, and incinerated. The maintenance problems in each are somewhat different: Buffalo uses the flash dryer and Minneapolis-St. Paul, the multiple hearth; Mineapolis-St. Paul does not employ digestion, Buffalo uses partial digestion, and the District of Columbia has complete digestion with elutriation of sludge. The problem of The Sanitary District of Chicago has been the design and operation of apparatus to dewater, heat dry, and incinerate excess activated sludge, as described by Messrs. Dundas and McLaughlin.

---

[12] San. Engr., The San. Dist. of Chicago, Chicago, Ill.

If the end product is fertilizer, certain additional costs are incurred from the need of fuel to replace the heat otherwise supplied by the sludge itself when burned. These costs have been estimated at \$2.50 to \$3.00 per ton of dried sludge. In the operation of the equipment, a drier filter cake can be secured if incineration follows. This affects the output of the equipment, measured in dry weight. Furthermore, the rates of filtration on a vacuum filter are considerably lower, measured in pounds of dry solid in cake per hour, for activated sludge than for fresh or digested sludge, and the moisture content of the cake is higher.

For filter cloths Buffalo and Minneapolis-St. Paul use canton flannel. The District of Columbia and Chicago use woolen cloth. At Chicago wool was chosen, despite the higher first cost, because with a life of three months the total cost of the woolen cloth in place was less per ton of product. Because of war conditions, various materials have been tried for winding wire. However, a method of crimping the cloth in place with grooves and wooden splines is proving satisfactory, without any use of wire. The pipe drainage system of the filters is being replaced with plastic or glass pipe. Wooden backing has proved superior to wire mesh.

Heat-dried activated sludge at Chicago is sold only in bulk in carload lots, based on analysis, under a 5-yr contract with an exclusive buyer. The material is distributed chiefly in the southeastern United States. The output has varied. Prior to World War II, the equipment was worked at a higher rate than proved feasible under war conditions. The sales are shown in Table 20.

TABLE 20.—SALES OF HEAT-DRIED ACTIVATED SLUDGE AT CHICAGO

Year	Tons	PERCENTAGE, DRY WEIGHT	
		Ammonia	P_2O_5
1939	11,303	6.00	....
1940	58,464	6.40	2.25
1941	56,597	6.24	2.27
1942	51,729	5.97	2.45

The ammonia content at the Southwest Works at times is as high as 8.1%, but at no time has it fallen below 4.37%. The Calumet sludge is consistently lower in ammonia than the Southwest sludge.

At present there is considerable demand for organic material for mixing purposes. Milwaukee and Chicago are currently selling all they can produce. Milwaukee markets about half its output in bags through jobbers and retailers. This is practicable because of storage facilities of about 25,000-ton capacity. At Chicago, shipment is made as manufactured.

The status of the conversion of sewage sludge to fertilizer is apparently a matter of economics. At present, with the rigid control over chemical nitrogen, organic nitrogen is in demand. From 1910 to 1920, the trend of the organic nitrogen market was upward, reaching a peak in 1920. It then turned downward, largely because of the competition of chemical fertilizers. The trend was reversed about 1932 and rose until 1937, then dropped slightly, and finally stabilized at a somewhat higher level for the war period under ceiling control. Undoubtedly organic matter or humus is required in many soils. Heat-dried activated sludge is the most valuable of the sludges. However, other sludges properly prepared offer a useful source of humus and nitrogen of lower grade. In general, the distribution of sludge in agriculture is limited largely by economic reasons. Air-dried digested sludge is suitable for local use, as a substitute for manure, whereas heat-dried activated sludge may be shipped as far as 1,000 miles.

Because of the uncertainty of prices for organic nitrogen in postwar times, the planner of large activated sludge works should certainly provide another outlet than fertilizer. The plants of the Sanitary District are designed either to burn the heat-dried sludge or to sell it as fertilizer. Because war conditions prevent any present installation of additional equipment, the Sanitary District has just completed a 16-in. sludge pipe line, 4⅔ miles long, from the Southwest Works feeding a system of lagoons, covering 78 acres, divided into 16 units. The working depth averages 16 ft. This will handle excess activated sludge seeded with Imhoff digested sludge.

The use of digestion tanks as a buffer between the settling tanks and the vacuum filter may be necessary in many projects to average the solid load and reduce the equipment for vacuum filters and incinerators. However, situations may arise in which digestion may prove undesirable, particularly in handling industrial wastes from the brass industries, containing copper, which tend to slow up or stop the digestion of sludge. In such cases the designer should consider taking the raw sludge direct from the settling basin to the vacuum filter, with suitable conditioning followed by incineration.

Although the Sanitary District has given considerable thought to the disposal of fly ash, as yet nothing has developed which replaces the pumping of a wet slurry of fly ash to a neighboring lagoon. At the Southwest plant the fly ash is practically all derived from the burning of coal in making steam as well as for drying.

From the standpoint of operation and maintenance, there are still opportunities for improvement in the details of design. Both capacity and life of equipment should be increased, with a minimum of expensive or hard-to-get material. In the conditioning of sludge, elutriation has come forward, particularly for handling digested sludge. In the field of conditioning agents, ferric chloride still is preeminent. Thus, the chemical industry has materially aided sewage treatment development by substantial reductions in price since 1925.

C. R. VELZY,[13] M. AM. SOC. C. E.—The Symposium and the discussions describe the problems of dewatering and incineration, show where improvements and economies can be achieved, and indicate the possible direction of future developments. In general, conclusions are not drawn but rather experiences are stated with the inference that study and development should be continued.

---

[13] Asst. Engr., Greeley & Hansen, New York, N. Y.

The disposal of sludge thus far has been a necessary expense of sewage treatment. Disposal processes do not affect the quality of treatment plant effluent, and the value of sludge has never been more than that of a by-product. In some cases, utilization of sludge for fertilizer has yielded an income, and this use will develop as costs of dewatering and handling are reduced and as the demand increases for sludge as a soil conditioner. Efforts toward improvements in sludge disposal in existing plants, therefore, have had, as a final objective, reduction in cost of the processes.

Attention is called to the need for a high degree of ability in the directive personnel, and skill and interest on the part of operators, of dewatering and incineration plants. This need is obvious, not only on account of the complexity of the processes, but also in order to carry on the research and development necessary to continued progress.

The description of the problems of dewatering and incineration, and the comments on utilization of sludge are instructive but do not point to any common procedure for sludge disposal which may be followed in all cases. Designing engineers must still make careful analyses for each new design. For small plants, the use of sand-drying beds is most economical, with utilization of sludge for fertilizer dependent largely on local demand. In some sea coast cities, disposal of sludge at sea is still the least costly procedure. For the large group of cities not in either of these classifications, a thorough analysis of each case is required. Location of the plant, availability of space, and other factors will affect the selection of sludge disposal processes, but the over-all cost of sludge disposal is likely to be the controlling factor.

Experience in existing plants indicates that design should always provide adaptability for future developments. One important item in this connection is the possibility of the use of sludge for fertilizer. The economy of this development may depend upon cost of auxiliary fuel and the market for fertilizer. An incinerating plant which has flexibility in operation as between incineration and drying of sludge for fertilizer has an advantage in being able to follow market conditions. Other possible developments, such as better temperature control in incinerators, heat recovery, and improvements in mechanical equipment, should be considered in design so that observations may be made and adjustments effected, as indicated by the operating experience.

GEORGE J. SCHROEPFER,[14] ASSOC. M. AM. SOC. C. E.—Many of the problems arising in connection with various types of sludge disposal are presented in the papers of this Symposium and in the discussions. Some solutions have been suggested. Years ago an eminent sanitary engineer made a statement to the effect that "Sewage treatment is sludge disposal," indicating that the controlling problem is the disposal of sludge resulting from various processes of sewage treatment. A reading of these papers renews the conviction of the writer that this statement is still apparently true. Frank discussion of some of these problems, as in this Symposium, is leading to their satisfactory solution, and toward even further improvement in the art of sewage treatment.

---

[14] Chf. Engr. and Supt., Minneapolis-St. Paul San. Dist., St. Paul, Minn.

The writer enjoyed reviewing the various discussions, and was particularly pleased by Mr. Genter's thorough consideration of the results of the Minneapolis-St. Paul operations. Mr. Genter has accumulated a mass of valuable information on sludge disposal which he presents very effectively, from his point of view, in Table 19. He uses the results of this analysis as the basis of a major part of his discussion. Unfortunately, Mr. Genter bases his comparisons on per capita values which the writer will attempt to show are not scientific and in accordance with the facts. For this reason, the writer's review of Mr. Genter's discussion is limited to showing the fallacy of the method of comparison used.

Every one conversant with the field of sewage treatment realizes that there are variations, affected by a number of factors, in the quantity and quality of sewage from various municipalities. Furthermore, and in addition, there is a large variation in the removals accomplished by different plants. A comparison of costs and efficiencies of sludge disposal on a per capita basis penalizes a plant with a treatment process that is more effective than another or which by chance happens to receive a relatively stronger sewage. Since the per capita quantities of solids removed may vary as much as tenfold between two plants, the per capita basis of comparing sludge disposal is improper and unsound. Although this method of comparison may have a place in commercial literature, or in general comparisons for popular consumption, its usefulness or propriety in scientific analysis is open to serious question.

In Table 21 some of Mr. Genter's data from Table 19 are included, and, in addition, but using the basic data, other comparisons are shown (with items such as Nos. 2a, 26a, 26b, and 28a). Considering the various data (see item No. 2a), the quantity of sewage in gallons per capita per day varies for the plants listed from 77 to 234. The suspended solids content (item No. 3) varies from 155 to 329 ppm. The percentage removal of solids by the plants listed varies from 34.8% to 74.6%. All of these factors combine to cause a large variation in the quantity of solids removed and to require disposal in the various plants, ranging from 33.4 to 89.5 lb per capita per yr. In the same manner the quantity of sludge filtered varies from 12.3 to 89.5 lb per capita per yr. By the writer's method of comparison the latter six plants in Table 21, using elutriation, are shown to be particularly efficacious. The writer insists that to compare, on a per capita basis, six plants employing elutriation, and filtering an average of about 15 lb per capita per yr, with the Buffalo plant (which filters 33.5 lb per capita per yr) and with the Minneapolis-St. Paul plant (which filters 89.5 lb per capita per yr) is unscientific and fallacious.

On a per capita basis (item No. 24, Table 21), the costs at Minneapolis-St. Paul are the highest, $9.64 per capita per yr, compared to an average of $5.60 for the six plants employing elutriation. However, on the more proper basis of tonnage of solids removed or disposed of, the order of economy is reversed. Thus, the filtration cost per dry ton of raw solids is $2.23 at the Minneapolis-St. Paul plant compared to a $2.60 average for the six plants employing elutriation. Furthermore, even the tonnage of raw solids removed by the settling tanks is not a proper basis for comparing the costs of sludge filtration in several

TABLE 21.—COMPARISON OF ESSENTIAL ITEMS THAT CONTROL DEWATERING COSTS (1941 DATA)

26b	Filtration cost per ton of digested solids	2.23	....	4.63	4.92	7.83	8.33	11.45	10.40
	(c) CHEMICAL COSTS FOR SLUDGE FILTRATION								
27	Total spent (dollars per yr)	33,410.70	18,382.43	8,500.00	2,060.90	1,108.00	3,803.74	2,300.00	178.70
28	Actual cost, in cents per capita	4.15	3.06	1.06	1.37	0.852	1.49	1.59	0.714
28a	Actual cost per ton of filtered sludge	0.93	1.83	1.24	1.59	1.17	2.30	2.59	1.03

plants in some of which digestion is employed and in others not utilized, since, in a particular plant, costs of such a major item as chemicals vary directly with the quantity of chemicals actually filtered. For this reason, the cost per dry ton of solids actually filtered (item No. 26b) is a more proper method of comparison of filtration costs. At the Minneapolis-St. Paul plant, the cost per ton of solids filtered is $2.23, compared to an average of $7.78 in the other six plants (lowest $4.63, highest $11.45). Thus, on a more proper basis, the costs at the Minneapolis-St. Paul plant are less than one third of the average costs at the six plants employing elutriation, instead of twice as much as Mr. Genter's basis of comparison implies. The writer concedes that costs at a large plant, such as that at Minneapolis-St. Paul, should be markedly lower than those at a smaller plant filtering as little as one thirtieth of the quantity handled at Minneapolis-St. Paul. The writer also admits that under certain conditions elutriation will result in reduction of chemical requirements for conditioning (possibly at the expense of the treatment process). However, he does not agree that elutriation is the panacea for all sludge disposal "headaches," and in this discussion is using Mr. Genter's own data to show that comparisons on an unsound basis may be very misleading.

The chemicals required for sludge conditioning vary with the tonnage of sludge filtered. In fact, the chemical requirements are based, as the usual "yardstick" (see Table 19, items Nos. 17, 18, and 19), on the percentage of chemicals as related to the dry sewage solids filtered. Per capita quantities of chemicals have no place in plant comparisons nor in the comparison of year-to-year operation of a particular plant. As a result of the war effort, there has been a marked increase in tonnage of solids received at a particular sewage plant, all out of proportion to the increase in population of the community. Mr. Genter's basis of comparison being on a per capita basis would imply that the engineer or superintendent responsible for the operation of a plant receiving, say, twice the load of solids it formerly received, is operating his plant inefficiently because the quantity of chemicals doubled. Chemical requirements must be based on the tonnage of solids disposed of. Referring to Table 21, and basing the comparison on the costs of chemicals in cents per capita, as Mr. Genter does (item No. 28, Table 19), the costs at Minneapolis-St. Paul are shown to be 4.15¢ as compared to the average of the six plants employing elutriation at 1.18¢. Since these six plants filter only about one sixth of the quantity of solids per capita of the Minneapolis-St. Paul plant, the unscientific nature of this method of comparison will be evident. Basing the comparison on the actual cost of chemicals per ton of solids filtered, the picture is exactly reversed. As compared to a cost per ton of $0.93 at Minneapolis-St. Paul, the average costs for the six other plants shown is $1.64. This difference would possibly represent more the variation in size of the plant with attendant higher unit costs of chemicals than it would the effect of elutriation.

All of the foregoing comparisons have been based on Mr. Genter's data which of necessity were restricted to the period up to 1941. In the case of the Minneapolis-St. Paul plant, further economies in the use of conditioning chemicals have been effected. Thus (see Table 22), as compared to 1941 costs of $0.93 per dry ton for chemicals, costs in 1942 were reduced to $0.75, and further lowered for the first ten months of 1943 to $0.72. This is less than one half the costs in the other six plants listed. Similar reductions may have been accomplished in other plants, but these additional data are shown to indicate that, as a basis of comparison, chemical requirements, even in 1942, had not hit "rock bottom" at this plant.

TABLE 22.—ANNUAL COMPARISON OF CHEMICAL REQUIREMENTS AND COSTS OF SLUDGE DISPOSAL

Year	Percentage of Dry Weight		Actual cost of chemicals per dry ton	Total Operation and Maintenance Cost per Dry Ton		
	Ferric chloride	Lime as Ca O		Vacuum filtration	Incineration	Total
1938	3.17	10.30	2.65	4.92	2.05	6.97
1939	2.10	5.68	1.56	2.64	0.99	3.63
1940	1.83	4.51	1.11	2.19	1.34	3.53
1941	1.53	3.77	0.93	2.16	1.23	3.39
1942	1.20	3.44	0.75	2.10	1.17	3.27
1943[a]	1.10	3.12	0.72	2.05	1.19	3.24

[a] January 1, 1943, to October 31, 1943.

It is desirable and important that the sludge disposal process employed should not have a deleterious effect on the treatment process. In other words, it is important that solids once removed by the treatment process not be returned as a result of the failure or inability of the sludge disposal process to handle such solids. Within limits, of course, it is reasonable that finely divided solids be returned to the treatment process in the expectation that they will again be removed. In reviewing the data in Table 19, it was observed that in the plants employing elutriation the number of pounds per capita per year removed by sedimentation averaged 45.1, whereas the number of pounds remaining after digestion and elutriation averaged only 14.7 lb. This raises a question of the reason for the disparity between the quantities of sludge actually filtered and the quantity of sludge normally to be expected following digestion but without elutriation. For example, at the Winnipeg plant a total of 69 lb of raw solids per capita per year were removed by sedimentation and discharged into the digestion tanks. However, a total of only 13 lb were filtered, instead of the 35 to 45 lb which might ordinarily be expected with the normal destruction of solids by digestion. Another possible explanation is that some of the solids were disposed of by other means. At one inspection of the Winnipeg plant, this possible explanation was rejected, since no solids were disposed of by any means except filtration. The only remaining possibility, therefore, is that an extremely large part of the solids entering the digestion tanks was "lost" by heavy supernatant pumping from these tanks, or that in the elutriation process certain fine solids were washed out and returned to the raw sewage from which they failed to settle out again. As shown in Table 23, in the six plants employing elutriation following digestion, the average loss of solids was 58.5% of the solids actually filtered, ranging up to 165% in the case of the Winnipeg plant.

All of the foregoing is intended to show that comparisons of sludge disposal should be based on the work done by such processes, that the tonnage basis accurately measures such work, and that a sludge disposal process which adversely affects the treatment process should even be penalized for such effect in a proper basis of comparison.

In the paper by the writer, the advantage of skilled engineering and technical personnel throughout the various grades of a staff in a large plant was emphasized. This observation was commented upon by several of the discussers. When the paper was being written (1941), the Minneapolis-St. Paul plant had been in operation for slightly more than three years, and operating and cost data were included only to October 31, 1941. Since then more data on sludge disposal operations have become available, and these are presented in Tables 22 and 24. In Table 22 it is shown that sludge filtration costs have

TABLE 23.—COMPARISON OF EXPECTED AND ACTUAL QUANTITIES OF SLUDGE AT VARIOUS PLANTS, IN POUNDS PER CAPITA PER YEAR

Location	Types filtered[a]	Raw solids	Actually filtered	Expected quantities[b]	AMOUNT UNACCOUNTED FOR	
					Pounds	Percentage of actual
Minneapolis-St. Paul	R	89.5	89.5	89.5	0	0

17	Cost of chemicals to filter 110 tons of dry solids, in dollars per day	104.50	86.90	79.20

[a] To October 31, 1943.

been reduced to $2.05 per dry ton and incineration costs to $1.19. As shown in Table 24, the costs of chemicals, on the basis of 110 tons per day of dry solids and fixed unit costs of chemicals, have been reduced from $242.00 per day in 1938 to $79.20 in 1943. This is a result of continued and expected reduction in chemical dosages, which, as shown in Table 22, have been reduced from 3.17% of ferric chloride and 10.30% of lime in 1938 to 1.10% of ferric chloride and 3.12% of lime in 1943. This reduction of approximately $2.00 per dry ton for chemicals, when it is remembered that an average of about 35,000 dry tons are filtered annually, will result in a saving of considerable magnitude.

The statements of Messrs. Van Kleeck and Rudolfs concerning the practicability of using raw sludge as a fertilizer were particularly interesting to the writer in relation to present practice at the Minneapolis-St. Paul plant. Raw sludge has certain objectionable characteristics including a possible health hazard. To obviate some of the difficulties presented in the use of raw sludge, this district has adopted the policy of allowing farmers to haul and use the filter cake only during the fall and early winter months from October to January, inclusive. No raw sludge is allowed to be hauled after February 1. As a matter of convenience the farmers apply the filter cake as it is hauled. The storage of the material, even for several days, creates odor problems and changes the characteristics of the sludge so that it is no longer workable. The use of fresh filter cake is not permitted on lawns and gardens within the city. Instead, the district stores filter cake for a period of two years, and this material (which is very workable and odor free) is made available for interurban use. Several years of experience have shown that at least two years of storage are necessary to place the material in a satisfactory condition for use. Shorter periods of storage result in a sticky foul-smelling mass.

This policy of the district, and the fact that, to the present time, the material is furnished without charge has resulted in a steady and rapid increase in the tonnage of material used as a fertilizer. The following are the quantities of filter cake used for such purposes:

Year	Tons
1939	21
1940	2,756.8
1941	3,678.3
1942	6,867.3
1943	11,580.3

Although use in 1943 represents only about 10% of the annual production of filter cake, there should be an even greater demand in future years.

In a very systematic and orderly manner, Mr. Mendelsohn gives an analysis of the operating experiences and improvements at the various plants. Such information permits some interesting comparisons.

The Symposium with its discussions has presented a rather complete picture of the field of sludge disposal. The tone of the discussions indicates that it has been thought provoking, and, if no other purpose was served, this alone would justify the presentation of the Symposium.

GEOLOGY IN HIGHWAY ENGINEERING

By Marshall T. Huntting,[1] Esq.

With Discussion by Messrs. W. W. Crosby, Carl B. Brown, F. H. Kellogg, Berlen C. Moneymaker, E. F. Bean, A. T. Bleck, Lyman W. Wood, Philip Keene, Jacob Feld, H. E. Marshall, K. B. Woods, D. J. Belcher, R. Woodward Moore, George E. Ekblaw, Allen S. Cary and Ade E. Jaskar, Karl Terzaghi, D. P. Krynine, Robert F. Legget, Irving B. Crosby, Hyde Forbes, A. A. Eremin, and Marshall T. Huntting.

Synopsis

Within recent years engineers and geologists have worked to bring about a closer bond between their respective professions. Engineering geology studies have been conducted in many parts of the world by goverment agencies, engineering societies, and independent workers.

Geology has entered into highway engineering problems in many ways, and study of geological features has helped to solve many highway construction and maintenance problems. However, many more such problems could be solved profitably by the use of geologists' services. Twelve of these problems will be treated in this paper, and examples will be given to show how some of them are being solved through the cooperative work of geologists and highway engineers. It is the purpose of this paper to help both engineers and geologists to recognize more frequently those situations in which geology does enter into highway engineering.

Introduction

In contrast to the rapid advance of engineering sciences in the fields of statics, dynamics, and hydraulics within the past century, there was a general lag in advancement of those phases of engineering involving earth materials and earth processes, which together constitute the basis of the science of geology. Comparatively recently, however, has come a fuller appreciation of the value of scientific study of the earth materials upon which must rest the foundations of the structures planned and constructed by engineers. As a result many engineers have worked to perfect a better bond between geology and engineering.

Note.—Published in December, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Formerly Geologist, State Div. of Geology, State College of Washington, Pullman, Wash.

Engineering geology studies, many of which are applicable to highway engineering problems, have been initiated in Europe and in America by governmental and municipal agencies, by engineering societies, and by individual workers. Reports of the influence of geology on roads appear in English publications as early as 1888. Since that time, especially within the past few decades, the results of geological investigations into specific highway engineering problems have been published both in Europe and America, but apparently no treatment of the subject as a whole is available.

The work of the geological surveys of several of the states in the United States will be used to illustrate some geological applications to highway engineering.

PROBLEMS

Of the multitude of problems confronting highway engineers many involve geologic factors and thus should command the attention of geologists. No attempt will be made herein to present a complete study of any of the problems; instead, the purpose is to indicate some of those instances in which geologists' services might be profitably engaged. These follow:

(1) Locating suitable road-surfacing material pits and quarries;
(2) Determining the suitability of various earth materials for surfacing, concrete construction, and other highway uses;
(3) Subgrade treatment and classification;
(4) Frost-heave problems;
(5) Predicting the character of material to be excavated;
(6) Preventing and correcting landslides;
(7) Appraising the competency of materials for bridge foundations;
(8) Judging the desirability of bridge sites and road sites with respect to possible changes of stream channels;
(9) Investigating proposed tunnel sites;
(10) Investigating and predicting subsurface water conditions and locating underground water supplies;
(11) Evaluating mineral lands to be bought or condemned for highway location; and
(12) Acting as witness in litigation.

Although highway activities have always claimed some attention from geologists, many, if not most, of the foregoing problems have been insufficiently considered. Economic and other factors will determine the importance of many of them, and some will be relatively more important than others, depending upon several factors, of which the geologic character of the terrain traversed by a given road is probably the most significant. In some instances geological investigations have been made by independent consulting geologists called in for specific assignments, and some have been made as a part of the routine duties of men who were an integral part of the state highway departments, but more frequently they have been made by the state geological surveys in response to highway department requests for consultory advice on special problems.

LOCATION OF SUITABLE ROAD-SURFACING MATERIAL PITS AND QUARRIES

Probably the most obvious and certainly the most widely recognized application of geology to highway engineering is in making materials surveys, which involve locating, and determining the quality, quantity, and the natural features which affect the exploitation of gravel, stone, clay, and other types of material for subgrade construction, surfacing, and concrete construction. Of the

> "* * * total annual expenditure of $500,000,000 [for roads in the United States], probably over half is spent for materials and their transportation to the construction projects, and it is in the cost of these materials that the largest savings can be effected" (1).[2]

The possibility of effecting financial savings and of obtaining better road materials through materials surveys is almost universally recognized, as are also the advantages of having the surveys made by men who have specialized in geology and have made the study of earth materials their profession. Obviously earth materials surveys can best be made by specialists, who, after learning from the engineers specifically which rock types have the physical and chemical specifications best suited to given needs, can then apply their understanding of the geological phenomena controlling the origin, subsequent alteration, and present physiographic expression of those rock types to locate, classify, and delimit commercial deposits for highway use. The geologist, through his knowledge of the glacial, stratigraphic, petrologic, and physiographic history of a given area, should be able to locate, easily, bodies of any type of rock present, without resorting to the too often used method of haphazard test pitting, which is an expensive and tedious process at best.

In some sections of the United States crushed rock is used to a large extent for surfacing and other construction and maintenance work. Selection of sites in rock to be quarried and crushed has been guided in some instances only by the character of plant site available, distance to place the crushed rock, and other such factors, without sufficient regard for the geologic factors involved. The extent, continuity, and uniformity of rock, where not exposed, are features predictable only on a geologic basis. The degree and extent of jointing and of weathering or other alteration are other such features.

Similarly, the nature of a deposit of sand, gravel, or other nonconsolidated material is determined by its geologic origin and so is predictable only when that origin is known. Geologists have been most widely employed in highway work for locating and testing such deposits.

Among the state organizations conducting materials surveys is the Louisiana Geological Survey, which locates and maps deposits of sand, gravel, rock, and shell, and which, in 1941, published a bulletin (2) on sand and gravel deposits of Louisiana. This work was financed partly by the State Highway Department and has since been put to considerable use not only by that department but also by various military groups in the state for building roads in the vicinity of the army cantonments.

In Texas the Bureau of Economic Geology of the University of Texas, in Austin, has cooperated with the State Highway Department in the location of road materials. On most of their projects geophysical prospecting apparatus of the resistivity type has been used to determine the thickness of sand and gravel beds.

The Areal and Engineering Geology Division of the Illinois Geological

---

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix)

Survey has conducted comprehensive studies in cooperation with, and for the benefit of, the Highway Division. One such study was of the limestone resources of the state, the results of which (3) were published in 1925. Another was a study of sources of material, particularly gravel and thin limestone deposits, for use on local roads. Maps of clay deposits in part of southwestern Illinois were made for use in obtaining clay materials for stabilized roads.

Wisconsin is a pioneer and leader in materials survey programs. As early as 1907 its Geological Survey was appropriated $10,000 by the state legislature for investigations and experimental work in road building. This work has been continued, and the survey now assists the highway engineers in every way possible, including the following, quoted from a letter by E. F. Bean:

> (*a*) Road materials surveys. For nearly all construction projects, surveys are made for surfacing materials, sand-gravel fill, and clay binder for gravel.
> (*b*) Classification of excavation. In some cases division engineers are consulted on classification of material to be excavated.
> (*c*) Subgrade treatment. Conferences and consultations in the field have been held.
> (*d*) Litigation. The state geologist has been a witness for the state on cases involving excavation, gravel, and limestone.

The road materials surveys have been especially fruitful, and for this work the Wisconsin Geological Survey is given an appropriation of $15,000 per yr.

Wisconsin Materials Survey Procedure.—The Wisconsin Highway Department has mobile crushing, screening, and washing plants which are moved to sites located by Geological Survey men at the request of the county highway departments. The highway department gives to the state geologist the exact specifications of the rock required, the quantity needed, the road on which it is to be used, and the use to which it is to be put. A geologist immediately goes into the field to investigate road materials in the near vicinity of the work to be done. He locates a number of pit sites in material which will meet the highway specifications. He then examines in detail each site selected to determine tonnage available, amount of overburden, cost of quarrying, and the pertinent geological features. Of each site he makes maps on which his findings are illustrated. Out of a probable eight or ten sites to be selected, the geologist may recommend two or three which will then be more extensively explored by an engineer to determine which deposit shall be developed.

Suitability of Various Earth Materials for Surfacing, Concrete Construction, and Other Highway Uses

Physical tests to determine the suitability of rocks for road surfacing are many and varied, and in the main they are sufficient in themselves. It is in determining the reason why certain rocks are durable and others are not that the geologist can be of service. This is not a question of academic interest only; on the contrary, it is one of considerable practical value, in that through recognition of the critical factors the geologist, by petrographic examination, can indicate quickly whether or not a given rock is likely to be satisfactory for a specific use.

High toughness is usually associated with traprock, and, in general, the fine grained volcanic rocks are harder and tougher than the coarser grained plutonic rocks. The sedimentary rocks vary widely in physical characteristics, but they are generally softer and less tough than the igneous rocks. Limestone and dolomite have greater toughness and are equal in hardness to the average sandstone, as determined by the standard tests. Of the metamorphic rocks, marble is generally neither as hard nor as tough as its unmetamorphosed equivalent, limestone. In most instances the foliated metamorphic rocks are comparatively soft and of low toughness, and as a rule they are rendered unsuitable for most road building purposes by their characteristic tendency to crush into long, thin, or flat fragments.

The hardness and toughness of these rocks are dependent upon the following fundamental properties: (*a*) Mineral composition (relative abundance of various minerals) and chemical composition (hardness, toughness, and cleavage of individual minerals); (*b*) texture (size and shape of grains and porosity); (*c*) freshness of minerals (degree of weathering or hydrothermal alteration of original minerals); and (*d*) jointing and fracturing. These fundamental properties are easily observed by the trained eye alone or with the aid of a good hand lens or petrographic microscope.

Failure of concrete by disintegration presents problems in which the importance of investigating the properties of the aggregate rocks has been minimized far too greatly. Attempts to prevent concrete failures were originally concentrated on varying the water content of the mix, experimenting with different types of cement and various cement-aggregate proportions, and adding special ingredients to the mix. Little attention was paid to the characteristics of the aggregate rocks. Since 85% to 90% of all concrete consists of aggregate, the quality of the concrete undoubtedly is governed to a marked degree by the quality of the aggregate, and the recognition of this fact has stimulated some fruitful research along this line. In 1931 Oliver Bowles reported (4) that failure of some concretes had been traced to physical defects in the rock aggregate, and in this connection he stated,

> "Physical tests of abrasion resistance and crushing strength should be supplemented by microscopic examination to determine soundness and the presence or absence of undesirable minerals. Microscopic examination is particularly valuable in recognizing partial alteration of the original minerals, which is accompanied by the formation of secondary minerals, usually of inferior quality."

More specific are the warnings of J. C. Pearson and G. F. Loughlin in 1923 (5) reporting the failure, in less than a year and a half, of concrete using the plagioclase feldspar labradorite for aggregate. Microscopic examination showed that the feldspar was largely altered to the minerals, laumontite, kaolin, and calcite, in decreasing order of abundance; and it was indicated that these three minerals were responsible in the same order for the disintegration of the concrete. Feldspar aggregate which did not cause failure was found to be unaltered. Strength tests applied to test specimens failed to indicate the unstable nature of the altered feldspar aggregate, thus emphasizing the advisability of having petrographic analyses made of questionable aggregate material previous to its use.

Further recognition of the rôle of inferior aggregates in concrete failures is noted in a highly informative paper (6) by Thomas E. Stanton, M. Am. Soc. C. E., Materials and Research Engineer for the California Division of Highways. Extensive tests conducted by him demonstrated that some concrete failures result from excessive expansion of concrete caused by chemical reaction between high alkali cements and certain mineral constituents in some aggregates, such as some shales, cherts, and impure limestones. Opaline silica, apparently the trouble-causing mineral, was identified in aggregates of the defective concretes. The mineral identifications were made with the microscope by a geologist, Allen H. Nicol, Mineral Technologist for the Aggregate and Soils Department of the California Division of Highways.

In 1941 the Washington State Department of Highways engaged H. A. Coombs as consulting geologist to determine the cause of failure of highway concrete at several places in the state. Late in the year Mr. Coombs reported (7) the results of his investigations into the cause of disintegration of the concrete in several bridges near Ohanapecosh on the White Pass Highway. Test procedures patterned after those developed by Mr. Stanton in California were used to prove the failures to be the result of excessive concrete expansion. The expansion was thought to result from chemical reaction between cement and aggregate. Thin section study with the petrographic microscope combined with fluorescent tests with ultraviolet light proved the reactive aggregate material to be pebbles of andesite. Further work should indicate what percentage of the deleterious andesite can be used in aggregate without causing undue expansion, and all rock deposits exceeding that percentage of andesite should be condemned as sources of aggregate for concrete.

Subgrade Treatment and Classification

Since the weight of traffic is supported not on the pavement but rather on the subgrade, it is obvious that the properties of the subgrade materials will exert a tremendous influence on the success or failure of the surface. The most common subgrade material is "soil," a term which, depending upon its definition, may mean only that part of the mantle which supports plant roots, or it may be used to cover a wide variety of unconsolidated earth materials ranging from gravel through sand, silt, and clay, and including organic deposits. The term will be used in its broadest sense to include all the unconsolidated mantle overlying solid bedrock.

It is well known that soils possessing obviously different physical properties give equally different performances as road building materials. Recognizing this the Public Roads Administration (PRA) and most state highway departments have set up soil testing divisions whose work has been to classify soils, to test their physical properties, to correlate test determined physical properties with performance records, and to make recommendations on the basis of their findings. Soil studies conducted by them and other interested organizations since the 1920's have brought forth a wealth of information which has been successfully applied to the solution of subgrade problems. Most valuable, perhaps, have been their soil classifications based on physical properties and correlated with performance records.

A general soil classification such as that developed by the PRA (8) is satisfactory for most applications of soil mechanics to highway engineering as pointed out by K. B. Woods, Assoc. M. Am. Soc. C. E., and R. R. Litehiser, M. Am. Soc. C. E. (9), but in exceptional cases there is found need for a more specific classification such as one based on mineralogical composition of soil. Some of the effects of mineral composition on the behavior of clays and soils were reported in 1940 by G. E. Ekblaw and R. E. Grim (10). They classify the clay minerals under the three groups—(*a*) kaolinite group, (*b*) montmorillonite group, and (*c*) illite (11) group of sericite-like minerals. Each group has well-defined but vastly different capacities to absorb water, possess exchangeable bases, and break down into extremely small particles which will determine to a large degree the plasticity and permeability of soils containing these clay minerals. Plasticity and permeability in turn are extremely influential in determining compaction, soil slippage, and frost heave—features of considerable importance to the highway engineer.

In other instances where a soil classification based on physical properties is not entirely adequate, a supplementary classification may be useful, based on the soil's origin such as the following:

I. Residual soils.
II. Colluvial soils.
III. Organic soils.
IV. Transported soils—*A*, alluvial; *B*, lacustrine; *C*, marine; *D*, glacial; and *E*, aeolian.

The soils falling under a given heading in this classification will not have all their physical properties alike, but it will be found that some of their properties will be remarkably uniform over wide areas.

Nothing can replace the engineers' physical tests to identify soil types and to determine their suitability in subgrades on the basis of performance, but testing and sampling will be most effective and economical only when something is known of the soil strata's probable uniformity and regularity—features which are dependent in large part upon the origin of the soil, and the closely related mineralogical and chemical composition of the soil, soil particle size and shape, local topography, subsurface water conditions, and climatic conditions. The geologist's understanding of these features will help in interpreting sample test results and will enable him to suggest where samples should be taken. Thus, the direct economy in the use of geologists is in reducing the number of actual tests.

Geologists have played a leading rôle in the soil testing divisions of many state highway departments and have lent substantial assistance in others.

Outstanding is the work of the Illinois State Geological Survey's Areal and Engineering Geology Division, established in 1927 and headed by Mr. Ekblaw. According to R. F. Legget, Assoc. M. Am. Soc. C. E. (12*a*), this organization is unique in being the only state or national geological organization to recognize, to such an extent, the interdepending relations of geology and engineering. In a letter, Mr. Ekblaw states that his division has given advice on scores of problems involving landslides, rockfalls, slump, sod creep, and similar movements of earth above, beside, or beneath highways; heave and collapse of various kinds of pavements; "mud pumpings"; stability of fills, both as regards material in and foundation below the fill; treatment of peat bogs; foundation material for piers and abutments for bridges, overpasses, and underpasses; quality and location of aggregate material for concrete or other types of pavements; all kinds of drainage conditions; and location of highway routes to avoid undesirable conditions. Some of the advice has been preventive, given before construction was undertaken, and some has been curative, given after damage occurred.

Formerly the Michigan Geological Survey Division had direct cooperative relations with the State Highway Department. It conducted surveys for road gravel and road material and made test borings for swamp and marsh fills. The latter work in 1925 was transferred to the newly created Soil Engineering Branch of the State Highway Department's Testing Division. The soil classification used by them is that of the international system, described in the 1938 *Yearbook of Agriculture*, Soils and Men.

In Ohio two geologists are employed in the soil sampling and testing work of the Soil Section of the State Highway Testing Laboratory. The data and recommendations resulting from the soil, foundation, and geologic studies made on all projects involving federal aid funds and on all major state projects are thought to result in savings to the state amounting to several times their cost. Detailed description (13) of the work of their geologists and soil engineers may be found in the *Proceedings*, Purdue Conference on Soil Mechanics and Its Applications, which also includes articles describing the aims and methods of soil investigations in several other states.

H. A. Buehler, State Geologist for Missouri, believes that his state's highway department probably utilizes geology to a greater extent than any other highway department in the nation. The state geologist has been an ex-officio member of the State Highway Commission since its inception. The department's testing division organized a geological investigation branch, which has been the center around which soil stabilization has grown. Using one geologist for every two field divisions, the headquarters office has five geologists, all of whom are field experts in stabilization work.

Frost-Heave Problems

Frost heave might properly be discussed under the previous heading ("Subgrade Treatment and Classification"), but it is thought to be a problem of sufficient weight to merit separate treatment. Frost heave is a phenomenon to be dealt with in highway construction and maintenance over a large part of the United States, and with improved facilities for snow removal annually increasing the mileage of road left uncovered and open to frost attack, the need for frost-heave studies becomes more and more apparent.

Obviously the features of climate, rainfall, and temperature will broadly control the limits of the area in which frost action is of consequence. Recognizing this, J. A. Sourwine, Senior Highway Engineer, PRA, in 1930 concluded from a study (14) of climatological records that the area subject to frost damage to highways includes Maine, New Hampshire, Massachusetts, Rhode Island, Connecticut, New Jersey, New York, Pennsylvania, Ohio, West Virginia, Kentucky, Indiana, Michigan, Wisconsin, Iowa, Illinois, Missouri, northern Oklahoma, northern New Mexico, northern Arizona, Utah, Colorado, Kansas, Nebraska, South Dakota, North Dakota, Wyoming, Montana, Idaho, eastern Oregon, and eastern Washington. Within this area frost heave will be a problem only in those places where drainage conditions and soil characters are so combined as to make excessive differential frost action possible.

Laboratory and field studies in connection with frost heaving have been active for many years and much information on the subject has accumulated. The first explanation of the true nature of frost heaving appeared in 1918 when Stephen Taber (15), State Geologist and Professor of Geology at the University of South Carolina, at Columbia, showed that heave was the result not of expansion of water on freezing but of growth of lenses or layers of ice crystals at the frost line. He found that in order for ice to accumulate in layers a supply of water must be maintained to the zone of freezing either by a water table so high that it is above the frost line, or by capillary rise from a source below. The first source of supply can be removed comparatively easily by drainage, but the second is not so easily disposed of.

It has been shown that in many, if not most, instances of frost-heave disturbances clay is a major constituent of the subgrade material. The clay acts as the medium through which water rises from the water table by capillarity until it reaches the frost line, where it freezes and causes an irregular upheaval of the road surface. The subgrade soil profile ordinarily varies widely within small areal limits; consequently the amount of water available for freezing under the road surface will vary in a short distance, thus causing differential uplift and a rough road.

A comparatively recent suggestion is that mineral content is an important factor influencing the physical properties of clays subject to frost heave. It is known that two clays may have the same ultimate chemical composition and the same grade size distribution and yet possess quite different physical properties if their mineral compositions differ. Obviously then, a knowledge of the effects on the physical properties of a clay attributable to each constituent mineral is necessary in order to understand exactly why a given soil acts as it does. Such knowledge can then be applied to the planning of effective preventive measures. So far as the writer is aware, no research to determine the relation of clay mineral composition to frost heaving has yet been completed, but in this connection Mr. Grim has made some preliminary studies (16).

Suggested preventive methods against frost-heave damage have been many and varied. During the period from 1928 to 1933 the PRA, cooperating with the highway departments of Minnesota, Wisconsin, and Michigan, conducted a survey to correlate the various methods of different engineers. In the resulting report (17) Henry Aaron gives three classes of preventive measures. Additional preventive measures have been suggested in reports by H. F. Winn (18) and A. Scheidig (19). Selection of the best preventive measure in any given case must depend on economic considerations and on the soil profile in the area being considered; thus it must depend directly or indirectly on information furnished by soil surveys.

PREDICTION OF CHARACTER OF MATERIAL TO BE EXCAVATED

Probably more disputes have arisen in civil engineering contracts through inadequate classification of material to be excavated than through any other feature. The cost of digging solid rock may be ten times or more the cost of digging an equal amount of earth (Fig. 1); consequently, a contractor should have the most accurate available estimate as to the volumes of each he will have to move, and the classification should be made in terms of the methods to be used to excavate the material. On large jobs estimates made by pure guesswork or by rule-of-thumb methods are certainly inadequate. Yardage estimates of solid rock and of unconsolidated material will be most reliable where the estimator, knowing the geologic processes operative in the accumulation of those materials, makes his estimates on the basis of that knowledge.

FIG. 1.—THE COST OF DIGGING ROCK MAY BE TEN TIMES THAT OF DIGGING AN EQUAL VOLUME OF EARTH

In excavating intrusive igneous rocks, such as granite, it may be assumed that the rock will remain quite uniform both at great depths and for long distances laterally with respect to properties affecting excavation, except for jointing and weathering. Jointing is generally best developed along the sides and top of the intrusive rock mass, near its contact with the intruded rock. However, a granite mass which has been deeply eroded and covered by sedimentary rocks probably would not be more jointed near its contact with the surrounding rock than elsewhere, thus illustrating the need for knowing the geologic history of a rock to be excavated. The degree and depth of weathering of granite, as well as of every other rock, depend upon the rate of weathering and rate of erosion which carry away the weathered rock. Glaciated areas generally show little weathering in their rocks, owing to the comparatively recent vigorous scouring action of the ice.

Extrusive igneous rocks, such as basalt, may be extremely varied in nature over short distances laterally or vertically, or they may be quite uniform, depending upon their chemical composition, their mode of origin, the type of topography over which they flowed, their rate of cooling, and the amount of deformation, erosion, and weathering they have suffered. In basalt, jointing may be almost entirely lacking or may be very well developed, depending on the foregoing determinants. The degree of jointing very largely controls the cost of excavating such rock, and can be predicted fairly safely.

Unconsolidated earth materials (soils) may vary considerably according to their origin, but they are nearly all easily excavated. The important factor in considering such deposits is their depth to underlying solid rock. Within limits, the depth and shape of such deposits are reliably predictable by competent geologists.

The various sedimentary rocks and unconsolidated sedimentary deposits vary widely with respect to ease of excavation, but each variety has its own set of characteristics developed at the time of its deposition and altered by its post-depositional history. The origin of the deposit—whether alluvial, marine, lacustrine, glacial, or aeolian—very largely controls the nature of the unconsolidated sedimentary deposits as well as the original nature of the sedimentary rocks. The latter, however, may be deformed, metamorphosed, and weathered so as to be more difficult to predict where not exposed. It is the task of the geologist to learn the geologic history of such a rock, and to base his prediction of its properties affecting excavation on that history.

Of the metamorphic rocks, those formed by regional deformation or by load metamorphism at great depth may be expected to be uniform over comparatively great distances laterally, but in some cases they may change abruptly with depth. Such changes at depth are the result of original variations in the rock before it was metamorphosed, and they are predictable to a certain extent. Rocks of contact metamorphic origin are not to be expected to occur over large areas and may be found to grade into their unmetamorphosed equivalents within short distances.

In a study of excavation problems erosional, glacial, sedimentary, igneous, deformational, and weathering histories should all be considered, since the present condition of the materials to be excavated is entirely dependent upon them.

PREVENTION AND CORRECTION OF LANDSLIDES

Treatment of landslide problems may be divided into two categories, preventive and curative. All too often the opportunities to apply comparatively inexpensive preventive measures are passed by during highway construction, and as a result there occur traffic-disrupting, and sometimes catastrophic, slides that could have been prevented had the proper precautions been taken. The necessary curative measures are generally costly and are seldom completely effective.

In laying out the route for a new highway it is important to watch for places where the probability of landslides is great, and such places should be avoided in locating the highway. Where economic or other factors make it necessary to build a road in an area of probable landslide occurrence, careful preliminary surveys should be made in order to plan proper preventive measures. The preliminary survey must first determine which areas are likely to be subject to landslides. It should then discover the nature of the possible slides and show the factors, geologic, climatic, and man-made, which will initiate rock or soil movement. The investigators should be thoroughly familiar with geology and its rôle in landslide occurrence.

The surface of the earth is constantly undergoing changes in shape. Most of these changes involve the transfer of enormous quantities of material from the highlands to the lowlands and to the sea by erosion and deposition. Quantitatively less important but of far greater direct interest to the engineer are those changes in shape which involve landslides. "Mass movement of earth or rock on hill slopes, at an appreciable rate of speed," will be used as the meaning of the term "landslide"—a definition more inclusive than that generally accepted by geologists but well suited to engineering purposes. The rocks and soil of the earth's crust are under the influence of gravity, so that even in only slightly hilly terrain they are in an unstable state of equilibrium. Highway construction through blasting, altering natural drainage, and transferring earth materials from their normal resting places to new positions upsets temporary stability and initiates many landslides.

Old landslides can usually be recognized by their characteristic irregular, hummock-and-hollow topography in the debris situated at the base of slopes on which the scars of the slides usually may be seen. Where no characteristic topography or landslide scar is detectable, old slides are sometimes indicated by tilting trees or trees with tilted bases and vertical tops.

Landslides may involve enormous masses of solid rock broken from steep faces under their own great weight, or they may involve only loose surficial detritus. Rockfalls, not properly classed as landslides, comprise small quantities of solid rock precipitated from steep slopes. The movement may be in the form of mass sliding or slipping, or it may be in the nature of a flow. In any case it will be conditioned by some or all of these features: (*a*) Presence of clay or decomposable shale, (*b*) underground water, (*c*) topography, (*d*) stratigraphy, (*e*) structure, (*f*) joints, (*g*) foundation, and (*h*) shape of rock particles.

The sliding of rock strata along lines of stratification, sliding of surficial detritus over rock foundation, and flow of detrital masses are all facilitated by the presence of clay or shale which softens when wet. Decomposable shale where overlain in a cut or cliff by rocks more resistant to weathering often causes slides by weathering and sloughing, allowing the overhanging rock to break and slide of its own weight.

Abundant underground water decreases the stability of hillside accumulations of soil and facilitates slides, particularly where clay is present.

A topography of great relief, of course, is most subject to slides, but gentle slopes also are the sites of troublesome slides under some conditions.

A stratigraphic relationship frequently causing trouble is that in which pervious rocks overlie impervious strata, especially where the impervious layer is clay. Percolating water, on reaching the impervious layer, is stopped in its downward movement and is forced to flow laterally to an outlet. Where the outlet is a cliff, slides are quite likely to occur along the upper surface of the water-soaked clay layer.

Unjointed igneous rocks are generally capable of standing vertically without sliding, and hard, unjointed, horizontally stratified rocks are relatively stable, but rock strata dipping toward a steep face are subject to slippage along the planes of stratification. Slides in such rocks seldom give any warning previous to the time of their occurrence. Jointing weakens any rock, and jointed rocks already weakened by stratification are especially likely to cause slides. Rock masses often slip along old fault planes where movement previously occurred.

The angle of repose for rounded rocks is less than that for angular rocks which offer more resistance to slippage and flowage; therefore it seems logical to assume that detritus high in rounded rock and sand grains is less stable and more likely to slide than angular detritus. This assumption has been borne out by the observations of G. E. Ladd (20), Associate Economic Geologist, PRA.

Different combinations of geological, climatic, and man-made conditions can produce slides of quite different natures. Preventive measures should be planned on a basis of a slide's causes, and those causes can usually be discovered by geologic investigation and recognition of the type of slide. The following landslide classification is a modified form of one proposed in 1927 by Mr. Ladd:

(*a*) Slope adjustment of surficial material;
(*b*) Rock strata slides;
(*c*) Rockfalls; and
(*d*) Artificial fill slides.

Slope Adjustment of Surficial Material.—This very common type of slide may involve either flowage or slippage or both. Individual slides vary in size from very small to several thousand feet in length and width. Movement is sometimes rapid and complete within a few minutes or hours, but more often it is slow and intermittent and continues for years. Rate of movement is increased by steep slopes, by the lubrication furnished by clay, and by high water content. Also contributory to sliding are rounded rock and sand grains in the detritus. A smooth, lubricated rock foundation below detritus in many cases forms the base on which slippage takes place, but flowage is comparatively independent of foundation conditions.

Rock Strata Slides.—Rock strata slides range in magnitude from small slips in road cuts to huge, sometimes disastrous slides in which millions of tons of rock are dislodged. An example of the latter is the most disastrous slide in North America, which on April 28, 1903, covered more than a mile of highway and killed more than 70 people in the town of Frank, Alberta, Canada. The town was at the base of the steep face of Turtle Mountain, composed of a great thickness of steeply dipping Paleozoic limestone overlying softer cretaceous sandstone and shale. The limestone was highly jointed at right angles to the bedding, and it was along this series of joints that the failure occurred. The joint cracks weakened the rock; coal mining in the cretaceous rocks near the base of the mountain may have weakened its foundation; and severe freezing and thawing of water in joints in the rock probably furnished the force which made the entire side of the mountain tear loose and crash down into and across the valley at its base.

Rock strata slides occur most commonly along highways where construction or stream erosion has left steep faces of highly jointed stratified rocks or where it has cut across the stratification of rocks dipping toward the face. Combinations of jointing and alternating hard and soft beds are especially dangerous.

Rockfalls.—Rockfalls are seldom individually large, but on account of their wide and frequent occurrence they constitute a persistent problem in highway maintenance. They consist of a more or less steady dribble of rock fragments which increases during wet or freezing and thawing seasons. Hard, jointed rocks are especially subject to rockfalls, and any rock face at the base of which a large talus slope has accumulated should be avoided if possible.

Artificial Fill Slides.—Slides in artificial fills are by far the most prevalent, and they are the source in some states of the most serious highway problems to be met. Sliding conditions arise from the use of improper design, unsuitable materials, poor compaction, unfavorable water conditions, and weak foundations. Test procedures for the purpose of recognizing these slide-causing conditions have been developed and are used to a considerable degree in many states.

The State Geological Survey of Illinois has investigated several particularly troublesome landslides near Peoria (21). One slide caused a 5-ft movement out of line of a 200-ft slab of the highway along the west side of Illinois Valley. Sliding was believed to occur in an impervious clay zone kept wet by seepages from an overlying porous sandstone stratum. Drainage was suggested as the only cure for the slides.

In 1935 W. C. Morse reported (22) a saving of perhaps $100,000 to the State of Mississippi and the nation resulting from his condemnation of a site for a new bridge to cross the Yazoo River at Yazoo City. The proposed site was such that the eastern highway approach to the bridge would have had to be built for from a half mile to a mile over landslide terrane which was so old as to mask its true identity and accordingly might not have been recognized as such had not a careful examination been made.

An excellent discussion of landslide preventive measures by Mr. Ladd (23) in 1928 includes statements of costs and effectiveness of various methods. A most important conclusion resulting from his study of slides in Ohio and West Virginia was that, in most cases, retaining structures, seldom entirely effective, should be replaced by surface and underground drainage systems to keep moisture below the critical point at which rock masses are unstable.

Competency of Materials for Bridge Foundations

A bridge of any but the smallest size represents a considerable investment. Consequently its location should be considered as permanent, or at least as permanent as the location of the highway of which it is a part. To be permanent a bridge should be designed to meet changing natural and man-made conditions as well as present conditions. It has been said that a chain is no stronger than its weakest link, and this general thesis is certainly applicable to bridge design. The superstructure of a bridge can be no more sound than its piers and abutments, whose soundness in turn is dependent upon their design and upon the nature of the rock or soil foundations on which they rest (Fig. 2).

Fig. 2.—The Superstructure of a Bridge, Its Piers and Abutments, Can Be No More Sound Than the Rock or Soil Foundations on Which They Rest

The weight of the bridge and its traffic load must ultimately be supported by the earth foundation, making it imperative that bearing capacity of the foundation be known so that proper design and spacing of piers can be determined.

Ordinarily economic factors combined with limitations set by the highway route location are the first considerations in selection of bridge sites; foundation materials usually are not considered as limiting factors, the assumption being that the design of the piers can be made to fit the foundation conditions. For this reason bridge sites selected sometimes present difficult foundation problems which require unusually detailed investigation preliminary to construction. Precise information as to the strength, attitude, and water-bearing characteristics of local materials should be obtained for all bridge sites.

Exploratory methods to determine these characteristics may be classed generally as geological, geophysical, and mechanical sampling. A purely geological exploration of a proposed bridge site is seldom productive of enough detailed and precise data to be sufficient in itself, but a field study of a given site combined with a knowledge of local and general geology should be the basis for rather reliable estimates of probable foundation conditions and should precede choice of more detailed exploration methods. The geological investigation is of particular value in predicting such conditions as depth; structure; and lateral extent of sand, gravel, or soil overlying bedrock.

More precise information of this kind may be obtained through the use of geophysical test methods of several types, the most applicable to engineering work of this kind being the earth-resistivity (electrical) method and the seismic method. A knowledge of geology, especially of stratigraphy and of geologic structures, is indispensable in interpreting the results of any geophysical test.

Taking samples of foundation materials by one of many mechanical means is the most commonly employed exploratory method; the advantage being that in this way subsurface materials can actually be seen and examined, and, when undisturbed samples are taken, tests of crushing and shearing strengths, as well as other physical property tests, can be made. The geologist's sphere of usefulness in mechanical sampling lies in examining samples; in helping to interpret the samples in terms of dimensions, structures, water-bearing characteristics, and load-bearing capacities of subsurface formations; and in combining his interpretation of subsurface conditions with features of general and local geology to form the basis for recommendations for further sampling and testing.

Although in most cases the location of bridge sites is determined primarily by considerations other than foundation conditions, the final selection of sites for the largest bridges frequently is made only after detailed sampling programs have revealed the location of the most satisfactory foundation conditions. In this respect, the San Francisco-Oakland Bridge (San Francisco, Calif.), built at a cost of more than $73,000,000, and one of the largest bridge projects ever undertaken, stands as a monument to the worth of careful preliminary foundation investigations. Before the design or the location of the bridge was selected, the engineers decided on a program of borings and soil tests, the results of which would guide them in selecting (*a*) the most desirable location for the center line of the bridge, (*b*) the best location for individual piers, and (*c*) a logical basis for the design of the piers (24). Samples obtained by several methods were tested mainly in laboratories at the University of California, at Berkeley, and center-line location, pier location, pier design, and construction methods were made to conform to the conditions indicated by the tests.

The too frequent occurrence of bridge failures caused by inadequate foundations indicates that thorough foundation investigations should be conducted for the sites proposed for all bridges, large or small. The following example of a bridge failure should serve to emphasize this point.

In 1912 a $80,000 bridge was built in a west coast city to span a deep cut through which a transverse street passed. The excavation for the cut was entirely in horizontally, thin-bedded, blue clay. Recognizing the unstable nature of such material in the steep banks of the cut, the engineers designed the 95-ft steel cantilever arms and the 171-ft simple steel span so that the arms were strong enough to carry their load without support at their outer ends. The piers supporting the outer ends accordingly were not anchored to the superstructure. The advisability of such a design was proved when in 1915 a slide at the north end of the bridge carried away the piers supporting that cantilever arm without damaging the bridge. Thus, recognition of unstable foundations was the basis for effective superstructure design to meet those conditions; the inadequacy lay in not using the same basis for design of the piers. This was proved on February 26, 1917, when a slide caused the failure of one of the north main piers, badly buckled the lower chords in the south cantilever arm, and caused the collapse of about 150 ft of the timber approach on the south. More soundly anchored piers of proper design very likely would have prevented this bridge failure.

Bridge foundation investigations are conducted regularly by the state geological surveys of several states. Notable in this connection is the work of the Michigan Geological Survey Division in examining the core samples obtained preliminary to plans for a "Straits Bridge" to cross the five-mile-wide Straits of Mackinac between Mackinaw City, Mich., and St. Ignace, Mich.

Desirability of Bridge Sites and Road Sites with Respect to Possible Changes of Stream Channels

Permanency of bridge piers and abutments is dependent not only upon design of the structures and load-bearing capacity of the foundation, but also, to a considerable extent, upon the permanence of the stream channel at the bridge site. The shifting or meandering of a stream channel may dictate long spans and deep piers across the entire width of the flood-stage channel even though the normal channel be only a small fraction of that width. In most instances meandering streams operate to increase maintenance costs rather than first cost of construction. In any case, a careful study should be made for bridge sites on meandering streams, and conditions conducive to the permanence of a channel should be a deciding factor in the final selection of the crossing. The yearly destruction of many miles of highway by shifting stream channels indicates that more emphasis also might well be put on locating highways with more regard to possible channel changes.

Because most changes in the shape of the earth's surface resulting from stream erosion take place so very slowly, people often fail to recognize the tremendous erosive power of most streams. The effects of erosion are emphatically impressed upon the mind of the observer who, standing upon the brink of the thousands of feet deep and miles wide Grand Canyon of the Colorado, sees the muddy river still actively eroding a deeper channel.

The development of the valleys of all rivers, including that of the Colorado, passes through a series of stages (25) recognizable by the consequent topography. During the stage of youth streams have steep gradients and steep sided V-shaped valleys, and they erode rapidly, dominantly downward. During successively later stages the streams' gradients decrease, valleys widen and become less steep sided, and downcutting is largely replaced by lateral cutting. The ultimate development is the peneplain, where erosion has virtually ceased.

Climate and rock types and structures act to modify the effects of erosion. In arid regions much or most of the drainage is interior; that is, streams flow into closed basins and do not connect with the sea. Thus, all material eroded by a stream in such a region is redeposited on land, usually directly in the bed of the stream. Highways in arid regions, where streams flow only during infrequent storms, must be built with due consideration not only to the erosive power of the streams but also to the inevitable and sometimes extensive deposits of sand, gravel, boulders, and mud left in the wake of the flood waters.

Erosion in humid regions is less erratic, and its effects are more easily predicted. In the youth stage erosion is dominantly downward and is most rapid where velocity of current is greatest, at rapids and at constructions of the waterway. Rapids, as a result of accelerated stream bed erosion under them, move upstream, deepening the channel as they go. During later stages lateral cutting widens valleys and allows flood plains to form. Streams near base level on broad flood plains are subject to comparatively rapid lateral shifts of channel, especially when the rivers are at flood stage. Lateral erosion is greatest on the outside bank at a curve in a stream. Consequently, the broad loops of a meandering stream tend to migrate bodily downstream.

Hardness and chemical reactivity of rocks have obvious effects upon erosion. In regions of sedimentary rocks the tendency is for the hard sandstone strata to resist erosion and form ridges while the somewhat softer and much more soluble limestone beds and the soft shale beds, because they are more easily eroded generally, are the rocks in which the valleys form. In arid regions, where there is little opportunity for solution, limestone is resistant to erosion and is commonly a cliff-forming rock.

Rock structures act to control erosion and in so doing they exert considerable control over stream patterns. The structural features most effective in guiding erosion and most essential to recognize in a bridge-site survey are folds, faults, and joints. Faults and joints provide planes of weakness along which erosion is easily accomplished. Folding governs stream pattern by forcing parallel bands of hard and soft rocks into flexures so that upon erosion the tilted hard strata are separated by nearly parallel softer strata.

The effects upon shifting of streams attributable to stage of erosion and to modifications imposed by climatic and rock structural conditions are recognizable in advance through geologic investigation. Such investigation should precede final selection of every bridge site. In the case to be described briefly preliminary geologic investigation very probably would have condemned the bridge site chosen as liable to dangerous changes of channel, a condition proved to be true after the bridge was built.

In September, 1914, a 280-ft through steel span highway bridge was built across a certain river in the State of Washington. It was built by the county and state at a cost of $22,818. The north end of the bridge was anchored to solid rock, but the south abutment rested on river gravel and sand. High water in 1920 shifted the channel of the river and washed out the south approach. The bridge itself was not damaged, so to cross the new channel a second steel span of 240-ft length was built to connect with the first. The second span was completed in November, 1920, at a cost of $39,402. Later high water again shifted the channel farther southward and this time washed out the south approach of the second span. A third steel bridge was connected to the second to cross the newly formed channel. The third span, completed in 1934, was built at the cost of $36,284. Thus, an unfortunate original selection of bridge site was responsible for later construction cost increase of 331% over the cost of the original construction.

Investigation of Proposed Tunnel Sites

Probably in no other phase of highway engineering can the study of geology be more fitly and profitably applied than in locating, designing, and constructing tunnels. Increasingly higher standards for newly constructed highways necessarily result in the construction of more and more tunnels in order to meet the maximum grade requirements. Each tunnel built presents problems unique to that tunnel alone as well as problems common to all such projects. This fact, in addition to the high cost of tunneling, emphasizes the need of obtaining as much information relative to rock conditions as possible before construction is begun.

As in bridge building, the general location of the highway limits the possible locations of the tunnels to be built, and economic factors further govern tunnel design and construction. As in bridge building, however, geologic conditions play a large part in determining those governing economic factors. After a preliminary survey for a new highway has established the general location of a tunnel, a careful geological investigation should be made in conjunction with a drilling campaign. This investigation should reveal the existing geological conditions at the tunnel site, and those conditions should then be the basis for selection of (*a*) the final location of the tunnel, (*b*) the construction methods used, and (*c*) the design of the tunnel. An example to illustrate how a geologic survey can be of value in the final selection of a tunnel site is the case of a tunnel built obliquely across the line of an active fault. A flow of water in a wide zone of fault breccia and gouge caused trouble by lubricating the soft material and allowing it to drop into the tunnel. A geological examination of the site should have revealed the presence of the fault previous to construction and should have shown the advisability of locating the tunnel so as to avoid the fault.

After a tunnel site has been selected, an investigation should be made to discover as many as possible of the geological features that will affect the method of construction and the design of the tunnel. Unconsolidated materials such as sand, gravel, and mud require tunneling techniques entirely different from those of solid rocks, and variations of the main methods used also depend upon details of rock characters, most of which can be determined in advance of construction. These details of rock characteristics have a bearing upon (*a*) overbreak of rock in excavation beyond the limits specified by the design engineer, (*b*) hazards of construction, and (*c*) necessity of lining the tunnel.

Overbreakage.—It is practically impossible to excavate a tunnel to the exact dimensions called for in the specifications, and the material excavated beyond those dimensions according to most contracts must be moved by the contractor without pay. Accordingly, the extent of overbreakage to be expected is an important consideration. Plutonic igneous rocks, because of their general textural and structural uniformities, usually break closer to the theoretical section than do sedimentary and metamorphic rocks. The foliation and jointing of metamorphic rocks and the jointing and bedding of sedimentary rocks act to control the directions of breakage during excavation, the breakage being easiest along the lines of weakness furnished by these structural features.

Hazards.—The chief hazards in tunneling operations are the possibility of encountering large flows of water, the danger of cave-ins in soft rock and unconsolidated material, and the danger of blocks of rock falling from the roof of tunnels in solid rock. An additional inconvenience frequently met in deep tunnels is increase of rock temperatures at depth. Temperature increase with depth is variable and its causes are not entirely understood, and so cannot be predicted with any great degree of accuracy. The 12-mile Simplon Tunnel in Europe, with a maximum rock cover of 7,000 ft, encountered rock temperatures as high as 132.8° F.

The greatest likelihood of encountering large flows of water is found in tunnels in alluvial deposits. Permeable sediments of any kind may carry large flows, as might also permeable extrusive igneous rocks; but large flows of water are not to be expected in intrusive igneous rocks except along faults or joint planes.

Cave-ins and rockfalls are conditioned by the degree of consolidation, the presence of clay or soft shale, vertical and lateral earth pressures, underground water, and textural and structural features of rock.

Necessity of Lining.—The walls and roof of a highway tunnel must be competent to stand without danger of failure for the life of the tunnel. If rock is such as to be hazardous during construction, it probably will require an artificial lining to make a safe tunnel for traffic; but, just because a rock does not give trouble during construction, that is no assurance that it will remain safe and not require lining. Long exposure to air and water causes some rocks to expand and causes others to decompose and lose their strength. Anhydrite and some clays and shales are especially subject to failure in this manner and must be treated accordingly.

Accurate and complete records of the geological data collected prior to, during, and after construction should be kept for every tunnel built. In this way a valuable collection of information may be made for future use.

INVESTIGATION AND PREDICTION OF SUBSURFACE WATER CONDITIONS AND LOCATION OF UNDERGROUND WATER SUPPLIES

Subsurface water, an entire branch of geologic study, can be only barely mentioned. The subject has been treated comprehensively by C. F. Tolman (26). Additional information may be had from the publications of the Water Supply Branch of the United States Geological Survey, two papers by O. E. Meinzer (27)(28) being especially valuable.

Subsurface water may be divided into vadose water and ground water. The line of demarcation between the two is the water table, the upper surface of the zone of saturation in which ground water fills all the interstices in the rock. Vadose water is that subsurface water which lies above the water table, in the zone of aeration. Movements of ground water are predominantly lateral, whereas movements of vadose water in the zone of aeration above the water table are predominantly downward. Upward movements of vadose water are also of some interest to highway engineers, especially in connection with frost-heave control as previously discussed. Subsurface water has a further important bearing on previously discussed highway problems encountered in open excavations and fills, tunnels, landslides, and bridge foundations. Except in frost-heave problems, vadose water has little effect upon highway projects; the trouble-causing water in most instances is that encountered when highway construction penetrates below the water table.

State highway maintenance stations require supplies of potable water, and many highway construction and maintenance operations require large quantities of water. In some instances where surface supplies are not available this involves locating and developing ground-water sources, and locating a sufficient supply as near as possible to the surface may be quite an accomplishment. A man versed in geology should be competent to make a scientific prediction, within limits, of quantity available, rate of flow, and depth to satisfactory supplies of water in any given area. The geologist's prediction is not infallible, of course, for the reason that it is made on at least three extremely variable bases, any or all of which may not be entirely dependable in every instance: (*a*) Past experience of others; (*b*) the individual's education and experience; and (*c*) his interpretation of subsurface rock conditions.

Movements of subsurface water are controlled by geologic conditions, chief of which are character, distribution, and structure of the rocks enclosing the water. Areal and vertical extent of a rock formation; details of its general structural features such as abundance, size, and attitude of stratification, joints, and faults; and textural details governed by size, shape, assortment, and arrangement of individual rock grains—are all factors governing subsurface water conditions and all reflect the complex geologic history through which the rock has passed. In general, well sorted, unconsolidated, clean gravel has the highest water-yielding capacity of the rock formations. Other rocks that yield much water, under favorable conditions, are sand, sandstone, limestone, and basalt. Poor water-bearers are hard, unjointed igneous and metamorphic rocks, and most unproductive of all are the clays, which although porous are nearly impervious to water.

The state geologists of several states have been given the responsibility of locating wells to supply highway uses. The Florida Geological Survey suggests the locations for water wells, identifies formations and water horizons, and makes geologic well logs for the state's road camps. The Geological Survey Division of Michigan assists the Michigan Highway Department in the development of water supplies at its roadside parks, and also locates new wells for home sites where homes are necessarily moved as the result of rerouting or widening of highways.

Evaluating Mineral Lands for Highway Purposes

The right-of-way division of a state highway department has the task of securing by purchase, or where necessary by condemnation, rights of way, pit sites, and stock-pile sites as needed. Increased activity in improving old roads and building new ones in late years has greatly increased the volume and complexity of the work of the legal staffs of those divisions, and the expert testimony of economic geologists has been of assistance in a number of situations where mineral lands have been acquired for highway construction.

Owners of mineral lands are prone to overestimate the value of their own property; likewise, people unfamiliar with mining enterprises tend to underestimate the value of such property, although in some instances they have been duped by high-pressure salesmanship into accepting unwarrantedly high values set by promoters for practically worthless property. The unbiased consultory advice of a geologist could be a real aid to a right-of-way legal staff confronted with such situations.

A second use for geologic advice in evaluating mineral lands arises in connection with the construction of mine-to-market roads. The setup in the State of Washington will serve to illustrate this point.

In 1939 an act was passed creating a Mine-to-Market Road Commission, consisting of three members—the Director of Conservation and Development, chairman; the Director of Highways; and the Executive Officer of the Washington State Planning Council—the purpose of which was to act on all matters pertaining to the establishment, location, construction, and financing of mine-to-market road projects. A project can be initiated under this act by a petition which states the known facts pertaining to the occurrence of mineral deposits in the area to be served, the extent of explorations and development, and approximate length, termini, and route of the proposed road. All petitions are investigated by members of the commission, and the properties to be made accessible by the proposed roads are examined by geologists of the Department of Conservation and Development to check the statements made in the petition and to determine the worth of the proposed roads.

Witness in Litigation

Because highway engineering involves earth materials in most of its phases, it is not surprising that a large number of the cases brought to court by or against highway organizations arise from disputes concerning those earth materials. Likewise, it is not surprising that geologists have been called in on many such cases to give expert testimony on geologic matters involved. In passing it might be said that had the geologist's advice been asked earlier many court actions could have been prevented by eliminating the points of contention.

A court case in which geologists' testimony played a significant part was that in which a railroad sued a state for disruption of traffic and repair of immediate damage, and for destruction of stability along 700 ft of filled grade. The damage, actual and claimed, was caused by an avalanche of rock initiated by a large dynamite blast shot on November 22, 1927, by a contractor building a part of a state highway. The estimated 165,000 cu yd of rock removed by the blast was precipitated from the cliff, down a talus slope at its base, across a muck-filled valley for a distance of about 1,500 ft to and over a section of a long railroad embankment in the valley. A total of 700 ft of track was destroyed. The railroad asked for the $20,000 on the basis of their claim that not only the tracks but also the entire rock fill in the embankment was carried away by the movement. The plaintiff's thesis, substantiated by the testimony of a well-known geologist, was that the movement was in the nature of a slide or flow of a mixture of rock and soil talus and of soil in the valley, the effect of which was to push the rock fill out into the river beyond the embankment, leaving in its place a heteorogeneous mixture composed 35% of rock and 65% of muck and silt decidedly inferior to the original rock as an embankment material.

In opposition to this was the state's contention, as presented by the testimony of Harold E. Culver, State Geologist, that the movement was not in the nature of flowing or sliding of blasted rock, talus, and valley fill, but rolling and tumbling of blasted rock only, the effect of which was to fill a part of the valley and to overflow the embankment taking part of the track with it, but not disturbing the stability of the embankment itself. The evidence presented in Mr. Culver's testimony was influential in the court's decision to disallow the railroad's $20,000 claim.

CONCLUSION

The task of the engineer is to overcome, by his ingenuity, the obstacles presented by nature. His works are becoming increasingly more complex and of greater magnitude and consequently require the use of highly technical information in an increasingly wider range of fields. It has become impossible for any one man to command a knowledge of much more than the bare fundamentals of all of the many highly specialized lines of endeavor involved in the successful completion of many engineering projects. This increased complexity in all fields has given rise to a so-called age of specialization, in which specially trained men in many fields combine their efforts to produce the best possible results. Highway engineering is sufficiently broad to include a great number of varied kinds of work and so has involved specialization in many fields, among them that of geology, dealing with the earth materials and the forces that act upon them—features which in one way or another enter into almost every phase of highway engineering.

Some of the services already rendered to engineering by geologists have been stated in this paper, with the hope that in this way engineers and geologists alike may be helped to recognize more frequently those situations in which the geologist may be of assistance to the highway engineer.

DISCUSSION

W. W. Crosby,[3] M. Am. Soc. C. E.—The plea in this paper for active cooperation of geologists in highway work interests the writer, not because he has any awareness of the lack of such cooperation, but because he personally recollects fundamental contributions by geologists to the establishment and the development of highway engineering. Long ago, the foundations were durably laid by these men who are so often forgotten when the structure is completed. Mr. Huntting's earliest reference (15) is dated 1918, and only one other (5) of the twenty eight antedates 1924.

More than two decades before, N. S. Shaler, a noted geologist and professor at Harvard University, at Cambridge, Mass., wrote "American Highways" (29) which resulted in the creation of the Massachusetts Highway Commission in 1893. It is unnecessary to detail here the outstanding leadership of that body, of which Professor Shaler was an active member.

Only a few years later (in 1898), at the suggestion of William Bullock Clark, Professor of Geology at Johns Hopkins University (Baltimore, Md.) and State Geologist, the Maryland Geological and Economic Survey was authorized to investigate "the question of road construction" in that state. The seven reports (30) of this survey (four on the "Highways of Maryland" and three on "State Highway Construction") were published in the years 1899 to 1910, inclusive, and widely distributed. The 1899 Report has been commended "as the most complete statement ever issued by any State." These reports cover in detail most, if not all, of the "problems" listed by the author and much else of at least equal importance.

Of the nine men on the "Scientific Staff" of the Maryland Geological and Economic Survey for the 1899 Report, the following were geologists: William Bullock Clark, Harry Fielding Reid, Edward B. Matthews, Charles S. Proesser, and George B. Shattuck.

Contemporaneously, the late Joseph Hyde Pratt, M. Am. Soc. C. E., as State Geologist, set the standard for modern highway work in North Carolina. Wisconsin followed the Maryland work closely with W. O. Hotchkiss, M. Am. Soc. C. E., State Geologist, supervising the groundwork. The late Logan Waller Page, M. Am. Soc. C. E., at one time Geologist for the Massachusetts Highway Commission, directed the U. S. Office of Public Roads from 1905 to 1919.

The writer has probably mentioned herein only a very few of the geologists who did so much for highway improvement, and he has scarcely hinted at the enduring character and widespread effects of what they accomplished. However, time gives a great appreciation of the fundamental, although often overlooked, importance of the work of geologists in highway engineering.

There are doubtless numerous geologists who have been, or are, contributing most valuably to the advancement of highway engineering. Indeed, a highway department cannot function without such advisers.

---

[3] Cons. Engr., Coronado, Calif.

Carl B. Brown,[4] Esq.—The professions of engineering and geology will both benefit by a paper that calls attention to the many aspects of highway engineering in which the training and viewpoint of the geologist can be of service to the engineer. A list as extensive as that of Mr. Huntting could be readily developed for railroad engineering, flood control engineering, military engineering, and, in fact, any engineering field dealing with the surface configuration of the earth, earth materials, or dynamic geology.

Unfortunately, many engineers, seemingly, have not learned to appreciate the aid that can be rendered to them not only by geologists, but by soil scientists, climatologists, agronomists, and specialists in numerous other fields. If some engineers seem noncooperative, this may be due, in part, to the failure of geologists, figuratively, to "come down to earth" or, literally, to evaluate their "stock in trade" on the basis of what is important in terms of the life of engineering works.

Although most of the paper shows an excellent appreciation of engineering needs, under the heading "Desirability of Bridge Sites and Road Sites with Respect to Possible Changes of Stream Channels," the conventional, and not too applicable, geological interpretation of erosion cycles and causes of stream-channel changes is given as follows:

> "Climate and rock types and structures act to modify the effects of erosion. * * * Hardness and chemical reactivity of rocks have obvious effects upon erosion. * * * Rock structures act to control erosion and in so doing they exert considerable control over stream patterns. * * * The effects upon shifting of streams attributable to stage of erosion [youth, maturity, or old age] and to modifications imposed by climatic and rock structural conditions are recognizable in advance through geologic investigation."

These statements all refer to processes and effects that act or result so slowly that they are generally of little importance in considering engineering structures expected to last 100 years or even 500 years.

Throughout most of the United States, especially in the humid sections, accelerated soil erosion is a far more critical factor in highway and bridge construction and maintenance than geologic structure or rock type. Many instances could be cited of stream channels that once ran over rock shoals with high banks sufficient to confine all but the largest flood flows, and that today are filled with sand to within a foot or two of the top of the banks. As a result, even moderate flows are causing severe bank erosion, washing out bridge approaches, and covering highways with sand and silt.

The streams of the Southern Piedmont, in a geological sense, are degrading. The region as a whole is in a stage of geologic maturity of the second or later cycle, being perhaps half finished with the process of downcutting from a former peneplain surface to a new peneplain level. Many of the streams today, however, are not degrading their beds but are rapidly aggrading, because of the overload of coarse sediment produced by widespread sheet erosion and severe gullying of the deep soil mantle—a result of the clearing and cultivation of the land. The rate of slope erosion has been drastically accelerated, and the response has been stream-channel and valley aggradation. The rate of acceleration, itself, has fluctuated widely during the past 150 years with the ups and downs of agriculture. The future channel regime at any point where a bridge is to be built will depend more on future land use and the extent of soil conservation in the watershed than on the relatively immutable geologic factors of rock type, structure, and climate.

---

[4] Head, Sedimentation Section, SCS, U. S. Dept. of Agriculture, Washington, D. C

Engineers will find considerable information of value on the effects of erosion on stream-channel changes in two technical bulletins issued in 1939 and 1940 by the U. S. Department of Agriculture (31)(32).

F. H. Kellogg,[5] M. Am. Soc. C. E.—In furnishing a comprehensive view of the diverse factors involving applications of geology to highway engineering, the author has made a valuable contribution. By treating the various headings in the paper from a standpoint of what is actually being done by highway engineering organizations, he approaches the subject from a practical standpoint. Considering the general nature of the paper, one can scarcely take issue with the statements and conclusions. However, a more definite indication of the limitations of geological work in this field would increase cooperation and reduce antagonisms engendered by divergent viewpoints. With no intention of trying to act as a qualified critic of geological methods, the writer suggests some possible limitations.

Obviously, as emphasized by the paper, the more time taken for a geological study, and the more drilling, laboratory, and geophysical information available, the more complete and reliable will be the conclusions. An illustration of the danger of geological study without a sufficient background of detailed exploration is furnished by the experiences in connection with the Moffat Tunnel in Colorado (33)(34). There, a condition not anticipated by preliminary investigation was a fault zone of "rotten granite," which tended to cave into the tunnel bore, costing a number of lives and raising the cost of the project from an estimated 7 million dollars to more than 17 million dollars. The complaint was made that, although the geologists had given an elaborate report, "the voice of prophecy was not upon them." Under more modern conditions, nobody would expect any prophecies, but a vastly greater amount of time and money would be spent on gathering specific data on the rocks in the tunnel site before starting construction on a project of such magnitude.

There are specialists among geologists just as there are among civil engineers and among highway engineers, and so it is questioned whether many of the functions treated by Mr. Huntting could be performed by the average geologist. Particularly in connection with subgrades, slides, and ground waters, a wealth of firsthand experience is a prime requirement for most professional work, and an acquaintance with the elements of elasticity, hydrodynamics, and soil mechanics is often desirable. Doubtless, members of state geological surveys working closely with the highway departments, and some geological engineers, possess these qualifications. Many other geologists do not.

A type of rock slide which has been overlooked by geologists on some construction jobs occurred on the Madden Dam Project in Panama. A shallow key trench was cut in a bluff rising steeply from the Chagres River to a height of nearly 200 ft. The rock showed almost no signs of seams, crevices, or bedding planes. Soon after the excavation, however, it began to crack and masses of rock threatened to fall on the operations at the base of the bluff. The cracked material was removed until, once more, only smooth, solid rock was exposed. In another day or so, more cracks appeared and the danger of rock slides increased. The situation grew steadily worse until a geologist was called in consultation. He immediately diagnosed this condition as a case of overstressed rock. The very fact that the rock was so solid, so free of any strains which would have relieved the stresses, was the cause of the trouble. The geologist showed that the same rock across the river was well jointed, and never acted this way. Thereafter, no more rock was removed from that area without immediately replacing it with concrete, so that the stress balance was undisturbed, and no more "popping rock" was encountered. This case illustrates the value of a geologist with wide experience in practical excavation and construction problems.

---

[5] Senior Materials Engr., TVA, Knoxville, Tenn.

An engineer dealing with rocks and soils must gain some knowledge of geological principles from the very nature of his work. A geologist could advance, substantially, the cause of understanding between the two professions by avoiding conclusions that would be apparent to any one with the slightest knowledge of geology. In general, delineation of alluvial and residual soils, lengthy observations as to the dangers of cuts through rocks with a shaley cleavage dipping toward the road, and detailed descriptions of readily identified rock formations and aquifers—all would fall in this category.

Mr. Huntting has mentioned the possibilities of the geological approach to problems of subgrades and slides in artificial fills. Although the writer does not believe that engineering work in soils must be a highly restricted specialty, or that any particular group has a monopoly on statistical development and mathematical physics, he contends that the value of the geological approach to these problems is limited. For example, in the paper under the heading, "Frost-Heave Problems," the statement is made that soils with a high clay content are likely to show considerable frost heaving because they have small pore spaces, which cause high capillary rise. On the other hand, clays usually have such low permeabilities that only a small quantity of water is involved in this capillary action. Soils with pore spaces sufficiently small to permit a high capillary rise, yet large enough to involve appreciable quantities of water, are the worst offenders as regards frost heaving. These offenders can be identified quickly and economically by simple physical tests. Again, the statement is made in the paper under the heading, "Prevention and Correction of Landslides," that sands with rounded grains are less stable than those with angular grains. This is obvious, but it gives no basis for determining the slope required for a given fill under given conditions of compaction and pore pressure.

The writer once made a study of the effect of mineral composition on the mechanical properties of soils by concentrating individual minerals, grinding them to certain grain-size distributions in a colloid mill and performing various physical tests on the monomineralic soils thus produced. The minerals were selected with the help of C. S. Ross, of the U. S. Geological Survey, who pioneered in the field of clay minerals and their identification. Observing the tremendous effects of small admixtures of certain minerals in the finer fractions of a soil, and those of the intimate mixtures of various minerals in many of the soils studied, the conclusion was reached that a purely physical approach would be more rapid and practical for most control work. The complex petrographic and X-ray techniques involved in identification of the clay minerals do not favor the mineralogic approach to problems in soils engineering except in the fields of research and development. In these fields, this approach has great promise, particularly in connection with studies of chemical and physico-chemical processes (35)(36)(37). In applying the results of this research, however, rapid and simple physical tests based on performance experience appear preferable.

The foregoing comments seem warranted because there are engineers and geologists who would let geological analyses supplant, rather than supplement, purely physical investigations of the problems in the paper. Evidently Mr. Huntting is not of this opinion, and the writer strongly concurs with his basic conclusion that geology is a powerful tool in many highway engineering activities and that there is not a sufficiently general realization of this fact.

Berlen C. Moneymaker,[6] Assoc. M. Am. Soc. C. E.—The twelve problems listed and discussed in this paper include nearly all the major geologic problems involved in the construction and maintenance of highways. Many of the same geologic problems are also concerned with the construction and maintenance of railroads.

Mr. Huntting's treatment is rather general, on the whole, and few professional engineering geologists are likely to challenge, seriously, either his statements or his conclusions. Engineers, however, might be inclined to feel that he tends to "oversell" the importance of geology and to underestimate the engineer's knowledge of geologic problems. As most colleges and universities require their engineering students to complete satisfactorily one or more courses in geology, most engineers embark on their professional careers with some geologic background. Engineers who specialize in field work—constructing and maintaining highways, building dams, driving tunnels, etc., learn much about geologic problems by actual experience. Admittedly, some of this knowledge is gained the "hard way" and occasionally a disastrous failure results from ignorance of geologic conditions. Nevertheless, minor geologic problems, such as the determination of slopes in excavations, etc., may ordinarily be handled satisfactorily by engineers.

Mr. Huntting's paper raises a number of questions, among which are the following:

1. Should All the Work Included in the Twelve Problems Be Performed by Geologists?—These problems involve several distinct earth sciences, some of which are not geologic in the strictest sense, and it is debatable whether geologists should enter the fields of related or allied sciences. The Geologic Division of the Tennessee Valley Authority (TVA), for many years the largest staff of engineering geologists ever assembled, may be cited as an organization in which a high degree of specialization, even in geology, is recognized. The work done by this group is geologic in the very strictest sense, and work in the related or allied sciences is performed by other staffs of specialists. The actual testing of materials is left to materials testing specialists; the testing of soils is left to specialists in soil mechanics; geophysical work is left to geophysicists, and so on. The Geologic Division of the TVA is sufficiently large to include specialists in several branches of geology. Specifically, the activities of this staff include the following: Engineering geology for dam sites and tunnels; the location and geologic study of quarry sites; the collection of samples for testing; petrographic studies of foundation rocks, concrete aggregate, and riprap materials; study of ground-water problems in areas adjacent to reservoirs; examination and appraisal of mineral lands; the presentation of testimony in court at condemnation trials; and miscellaneous geologic work, such as studies of bridge foundations, deep highway and railroad cuts, and drainage projects for malaria control.

---

[6] Chf. Geologist, TVA, Knoxville, Tenn.

In the opinion of the writer, geophysics, soil mechanics, and the testing of materials should not be considered in the field of geology. However, many excellent geologists have become specialists in these related sciences.

2. How Should a State Highway Department Provide for Its Geologic Work?—As the author has shown definitely that geologic information may be used advantageously in the construction and maintenance of highways, it might seem that each state highway department should equip itself with a geologist or with a small geologic staff. However, the matter is not as simple as that. If geologic advice is to be of any great value, it must be that of a specialist. In this day of specialization, no geologist is sufficiently versatile to qualify as a specialist in each branch of the science involved in the author's twelve problems. It would be difficult to assemble a small staff of two or three men capable of even moderately reliable work on all these highway engineering problems. A well-rounded staff, qualified to perform specialized work in all branches of the earth sciences involved, would require the personal services of the following specialists, some of whom are not geologists: Engineering geologist, petrologist, ground-water hydrologist, economic geologist, materials testing specialist, soil mechanics specialist, and geophysicist. Obviously, most state highway departments cannot justify the maintenance of such a large staff.

Although Mr. Huntting notes the close cooperation that exists between certain state highway departments and state geological surveys and mentions the engagement of special consultants, he makes no specific recommendation as to how a state highway department may best obtain geologic advice of high quality. Considering the great variety of geologic and related investigations required for the construction and maintenance of highways, the state geological surveys can afford the best and most economical assistance. In states where the geological surveys are small or inactive, the faculties of state universities may supply able geologic advisers.

3. Is the Geologic Examination Sufficient of Itself?—In some instances, a geologic examination may afford all the information necessary, but in many cases a mere examination is not sufficient.

A geologic examination of a tunnel site without a considerable amount of exploratory core drilling may not yield much precise information. The writer examined the Garzas-Peñuelas power tunnel site in Puerto Rico before construction was undertaken and was unable to predict the geologic conditions with desirable precision. However, a very thorough study of the stratigraphy and the orogenic and geomorphic history of the area enabled him to predict accurately the nature of the geologic problems.

The Garzas-Peñuelas tunnel is 11,674 ft long and extends in a north-south direction across the rugged Cordillera Central, which forms the insular divide of Puerto Rico. Rock decay has progressed to such great depths (200 ft) below the surface that bedrock was exposed only at the intake portal and in the channels of two small streams that cross the tunnel location. Moreover, the entire tunnel site was covered by a luxuriant growth of tropical vegetation. By a painstaking study of the residuum along the location, the character of the underlying rock could be predicted with accuracy. A study of the only rock exposures in the area revealed the location of a few faults. Although it was expected that hundreds of faults were to be crossed, there was no way of determining precisely either their location or magnitude or their importance as geologic problems.

Fortunately, little serious trouble was experienced in the actual driving of the tunnel but this was due to the excellence of the engineering supervision rather than to lack of difficulty. As predicted, hundreds of faults were encountered but most of them were small and presented no problems. Many of them were marked by shear zones and occasioned appreciable overbreakage. For support, these structures required timbering during construction and lining afterward. Two major faults, both apparently active, were crossed with some difficulty and after considerable delay. Both yielded copious quantities of water under considerable head. One of them resulted in the caving of the heading and the partial filling of the bore with 1,000 cu yd of fine gouge and 500 cu yd of broken rock. This fault zone was 152 ft wide and yielded 1,300 gal of water per min. The other fault also resulted in the failure of the heading and the partial filling of about 40 ft of the bore with broken rock and gouge. The fault zone was only 21 ft wide and yielded 200 gal per min of water under a head of 160 lb per sq in. Five months were required to tunnel through the 173 ft of ground represented by these two fault zones.

At the time the geologic examination was made, the tunnel site was definitely fixed by engineering and other considerations, and preliminary construction activities were already under way. No geologic exploration of any type was made along the tunnel location. Although the geologic conditions could have been determined in advance only from drill holes on 25-ft centers, from a few feet to 640 ft deep along the tunnel site, the cost of the program would have been prohibitive.

The Garzas-Peñuelas tunnel is an instance in which the engineer in charge handled difficult practical geologic problems remarkably well.

The Moffat Tunnel through the continental divide in Colorado represents another instance in which a geologic examination, without exploration, was highly inadequate. Numerous other instances in which geologic examinations, without the advantage of exploration, proved inadequate or entirely misleading could be mentioned.

One geologic condition not mentioned by the author in his discussion is the silicosis hazard involved in the quarrying or tunneling of siliceous rocks. Rocks containing more than 10% free silica are likely to cause silicosis among workmen unless the dust count per cubic foot is kept below 10,000,000 particles of two microns (0.002 mm) or smaller in size. The free silica content of the rock to be tunneled or quarried may be readily determined by petrologic studies. The silicosis hazard is very largely eliminated by adequate ventilation, the use of wet drilling methods, and the spraying of the broken rock during such operations as loading and crushing. Failure to control siliceous dust invites serious trouble. The contractor on the Hawk's Nest Tunnel in West Virginia was sued by some 600 former employees who claimed to have contracted silicosis while at work on that project.

This paper is an excellent and timely contribution on the relation of geology to highway engineering. Geology is a valuable tool that is used advantageously in several branches of civil engineering. Its limitations, however, should be emphasized as strongly as its advantages. The most reliable geologic work, in any branch of the science, is done by a specialist, and even a specialist, in many instances, must rely on data made available by exploration.

E. F. Bean.[7]—A brief paper cannot be comprehensive in coverage. Thus, the following notes reflect a desire for a longer paper rather than adverse criticism of this paper, which is an excellent review of the work that has been accomplished.

The "Wisconsin Materials Survey Procedure" would be more accurately described if the first sentence under that heading were omitted, and the following statement were added at the close of the paragraph:

> "This information makes it possible to let contracts at lower figures, or for the county to perform the work at lower cost since the uncertain factor, source of road aggregate, has been eliminated."

The State Highway Department does not own and operate any local plants.

The list of investigators of inferior aggregate in concrete (see heading, "Suitability of Various Earth Materials for Surfacing, Concrete Construction, and Other Highway Uses") should be expanded to include, in addition to Mr. Stanton, A. T. Goldbeck, Stanton Walker, and W. J. Emmons, Members, Am. Soc. C. E., and Fred C. Lang and M. O. Withey.

Of course, the Bibliography cannot include all pertinent references but at least five others might well be included (38)(39)(40)(41)(42). Perhaps, also, reference should be made to the *Annotated Bibliography of Economic Geology*, published semiannually, which contains a section devoted to engineering geology.

A. T. Bleck,[8] Esq.—The conclusion of the paper is a very succinct summary. As the author states, highway engineering is sufficiently broad to include many varied kinds of work requiring specialized knowledge, which the engineer should avail himself of as the occasion arises.

In exploration for materials deposits, complicated bridge foundation problems, classification of excavation materials, tunnels, etc., consultation on geological formation appears to be an obvious need. However, considering problems arising in connection with the soil mantle of the earth, highway engineers in general possibly have relied on, or sought for, soil mechanics data to too great an extent and to the exclusion of other factors, such as the geological formation and subsequent development of soils. This opinion is based on not only personal observations but also the apparent controversial tenor of the literature on the general subject of soils in their relation to highway and airport construction.

[8] Constr. Engr., State Highway Commission of Wisconsin, Madison, Wis.

If geology, to a reasonable degree of certainty, can be applied to predict the probable exposure to moisture to which the soil in given locations will be subjected, the engineer can then correlate these data with those supplied by the science of soils mechanics and effect an adequate design without sacrificing economy. Perhaps a greater mutual understanding, on the one hand, of the problems encountered, and on the other, of the knowledge and counsel that could be made available, is necessary and Mr. Huntting's paper seems at least to be a step in that direction.

LYMAN W. WOOD,[9] ESQ.—The twelve problems, listed by the author, constitute an adequate statement of a geologist's duties with the Iowa State Highway Commission. In subsurface explorations of bridge sites, the procedure is perhaps more advanced than that used by other highway organizations. Test borings are made for all bridges where foundations are expected to extend below stream bed. The boring records are reviewed by a geologist and become part of the final bridge plan, supplemented in many cases by geological sections of the strata penetrated and by results of physical tests on samples of critical materials. Valuable information on excavation conditions, as well as on probable pile bearing, is thus made available to contractors.

Road material resource surveys, to be of greatest value, must be continuous. The Iowa Highway Commission has followed a plan for periodic reexamination of all material deposits, with provision for revising estimates of quantity or commenting on quality, as advisable. The more important deposits are examined annually; others are examined less frequently. Proper maintenance of a file of material resource information in an up-to-date condition will require a considerable annual outlay of time, but experience indicates that the results are worth while.

PHILIP KEENE,[10] ASSOC. M. AM. SOC. C. E.—In the United States, highway work has attained the category of "big business," and highway engineering is replacing many of its rule-of-thumb practices with scientific solutions. As the author has demonstrated, geology is an important scientific aid to proper design, construction, and maintenance of highways.

Probably geology in Connecticut highway work today is most useful in determining depths of the various soil strata overlying bedrock when making borings for bridges and structures and in soil surveys. As the author indicates, knowledge of the geology of a bridge site, before or after some borings are made, permits economical and judicious selection of subsequent bore hole locations and depths. Soil surveys have been made by the department since 1942 on all cuts and swamps, on the larger projects. The surveys in cuts are intended primarily to locate rock surface for determining probable yardages of rock and earth excavation, inclination of cut slopes, and width of right of way to be purchased; but they also enable the engineer to determine definitely, or tentatively, the need for subbase, underdrains, and slope drains, the suitability of soil for fills, and the treatment of special features which occasionally are encountered.

---

[9] Formerly Geologist, Iowa State Highway Commission, Ames, Iowa.

[10] Soil Mech. Engr., State Highway Dept., Portland, Conn.

The bedrock and ledge of Connecticut consist chiefly of ancient complex metamorphic and igneous formations which are very difficult to decipher. However, covering a strip that is from 15 to 25 miles wide and extends throughout the middle of the state in a north-south direction are traprock and sedimentary "brownstone" formations which form part of the Newark series of the Triassic Period. These formations dip from 15° to 30° in an easterly direction, forming definite characteristic ridges in numerous localities. In this Triassic strip the depths to rock surface can be predicted quite accurately for an area, especially on these ridges, before or after a bore hole has been completed. This characteristic dip also permitted definite calculation of the location of the contact plane between the traprock sill and the underlying red sandstone between bore holes for the proposed tunnel at West Rock, New Haven, Conn.

A use for geology, not mentioned by the author and needed only rarely, is in the examination and interpretation of soil or rock cores to determine the plane or zone of rupture of a slide. Such cores might have many small faults and distortions caused by old disturbances, in addition to those caused by the slide being studied. In such a case, geology would be indispensable in distinguishing between the old and the new movements.

JACOB FELD,[11] M. AM. SOC. C. E.—Undoubtedly a knowledge of geology is helpful in solving the twelve problems enumerated in this paper, most of which are specialized problems of soil mechanics. If the author's statements are taken at face value, soil mechanicians (or is it soil "mechanics") as well as foundation engineers are daily encroaching on a restricted field. Since soil control and analysis has always borrowed information from the science of geology, uses and has used knowledge contributed by the sciences of physics and chemistry, and also employs analogies from electricity and hydraulics, the encroachment on the field of geology is not unique.

To be expert enough to handle the twelve problems properly, the geologist should be a well trained highway engineer, a specialist in soil mechanics, an expert in tunnel design and construction, and a divining rod operator, as well as an expert witness. Might it not be simpler to take a highway engineer who has had the necessary training in soil mechanics and insist that he obtain sufficient training in geology than to expect the geologist to understand the engineering problems enumerated?

Suitable gravel pits generally may be located by the application of geology, but the writer has found in practice that the only way to know the characteristics of sand or gravel deposits is to take samples while digging is in progress. Even boring samples do not give the complete answer. On a recent large project where almost one million cubic yards of run-of-bank gravel was needed, approximate locations of available supply within a radius of ten miles had been determined from topographic and geological considerations. When the time came to use this gravel, almost every one of the locations was found to be a disappointingly thin cover of gravel overlying sand. In a number of locations the gravel was covered with glacial till, the cost of the removal of which made the supply of gravel very expensive.

---

[11] Cons. Engr., New York, N. Y.

The author's statements concerning the suitability of various earth materials (in which he includes concrete aggregates) fail to take into consideration the fact that standards have been set up by the American Society for Testing Materials, American Concrete Institute, the Bureau of Public Roads, and forty-eight state highway departments, in the form of specifications listing not only the requirements of physical and chemical characteristics but also, in great detail, the methods of testing the compliance with such requirements. Most of these specifications are based on an accumulation of empirical information which may be determined in some instances by geological considerations. However, the wealth of experience indicates that empirical data based on prior performance is a safer guide to the highway engineer.

On U. S. route No. 9, north of Peekskill, N. Y., there is a monument to a contractor who undertook the excavation through a hillside, definitely glacial in origin according to all geological information available, which, when exposed, was found to be a thin skin of glacial till and boulders overlying nice hard solid rock. The unclassified excavation unit price in the contractor's contract applied to the excavation of this cut, more than 100 ft deep in solid rock, put him in the class of an ex-contractor. In this instance, somewhat too great a reliance on "known" geological characteristics of that area were disastrous, to the contractor.

Under the heading, "Prediction of Character of Material to Be Excavated," Mr. Huntting states:

> "The cost of digging solid rock may be ten times or more the cost of digging an equal amount of earth (Fig. 1); * * *."

In more than one instance, the writer has had actual experience, where the cost of digging rock would have been much less than that of the type of earth encountered. The writer also wishes to dissent from the statement (see heading, "Competency of Materials for Bridge Foundations") that:

> "The superstructure of a bridge can be no more sound than its piers and abutments, whose soundness in turn is dependent upon their design and upon the nature of the rock or soil foundations on which they rest (Fig. 2)."

The soundness of a superstructure has no relation to the type of rock or soil encountered in the foundations.

Under the heading, "Prevention and Correction of Landslides," some mention should be made of the slide that occurred in Pittsburgh, Pa., in 1922 and also of the landslides in Los Angeles, Calif., and Fort Peck, Mont.

When discussing bridge foundations, the author seems to indicate that taking and testing soil samples is entirely the work of geologists. In all his soil mechanics studies on that subject, the writer has never heard this claim.

The writer's experience in 1943, when searching for an available supply of gravel, afforded an interesting side light on the evaluation of mineral lands with gravel pockets. He found buying farms, including the houses and livestock, less costly than buying gravel pits. No amount of test pit probing or boring data would give a true indication of the amount of gravel available, except at a most unreasonable cost. Evaluating the land based on expected yield of gravel involved so many factors of both time and exploratory costs that it was much more expedient to buy the land. For sites where agreement as to the amount of available gravel could not be reached, experts were called in to analyze the situation from the geologist's point of view. The result was testimony in the form of reports of one geologist against another; and, as in the litigation examples given in the paper, one geologist gave testimony which was accepted and the other geologist gave testimony which was not accepted. So the score was even.

The writer's objection to this paper is again demonstrated by the "Conclusion." The attempt to delegate all questions "dealing with the earth materials and the forces that act upon them" to geologists, on the plea that highway engineering is sufficiently broad to include this overspecialization work by geologists, seems an attempt at overspecialization.

A quotation from a paper written by Edwin G. Conklin (43) is quite pertinent:

> "The extreme specialization of science has tended to obscure the larger aspects of Nature, as a whole. It has been said that modern science consists in knowing more and more of less and less. Certainly it is concerned largely with analysis and always more analysis.
>
> "Of course, analysis is necessary, but so also is synthesis if we are to see organisms as living beings. We lose sight of these larger aspects of life in the process of analysis, unless we reverse this procedure from time to time and consider organisms and environment synthetically.
>
> "Life has been compared to a beautiful tapestry, woven in intricate design of many threads and colors. By means of physics, chemistry, physiology, anatomy, embryology and genetics we unravel this texture, separate its constituent threads and colors, but lose the pattern as a whole. These analytical sciences have enormously increased our knowledge of life's constituent elements and processes, but the pattern of the tapestry is usually neglected or ignored."

In a similar sense, the writer makes a plea that the subject of highway engineering be considered as a unit and, if the highway engineer needs training in the science of geology to properly solve the problems encountered, he should have that training. If he delegates the soil problems to geologists, why not also delegate such chemical problems as those of cement and its uses to chemists and static problems on the design of pavements and bridges to physicists, and thus leave no place for the highway engineer.

H. E. MARSHALL,[12] ESQ.—The subject of this paper is worthy of the careful attention of both engineers and geologists interested in the efficient operation of a highway system. It presents a comprehensive, up-to-date description of the numerous but often unrecognized problems with which engineers must deal in the design, construction, and maintenance of a highway system in which the application of geological data and methods of study are necessary.

---

[12] Geologist, Bureau of Tests, Ohio Dept. of Highways, Columbus, Ohio.

The value of utilizing the services of trained geologists in its highway department has long been realized in Ohio. The department, created in 1904, established the testing laboratory in 1909. The first assignment of the laboratory was to make a geologic study of the sources of aggregate, both developed and undeveloped. The report, prepared by the geologist at that time, has been valuable for the comparison of the wide range of aggregates available in Ohio.

In more recent years studies of the mineral composition of a number of aggregates for service records of portland cement concrete have been made using the petrographic microscope. Although this work has been discontinued at present because of the shortage of trained personnel, it is hoped that it can be continued after the war and that it will indicate a method whereby certain aggregates containing minute quantities of deleterious material, whose effect is not clearly enough recognized by the usual tests, can be identified.

When fourteen dams were constructed for the Muskingum Valley flood control project, approximately 150 miles of highway relocation was necessary. Since much of this relocation involved the construction of fills, a part of which would be inundated, the slopes of these fills had to be protected from erosion by wave action. To find suitable rock for this purpose a considerable amount of geological surveying was done by highway department geologists in the various flood control basins. In addition, the various stones available (principally sandstone) were studied by the use of the petrographic microscope to determine their composition and probable durability when exposed to the various agencies of weathering on the fill slopes. The location of sources of suitable stone close to the projects has resulted in a considerable saving in the cost of highway work in the district. Similar studies were also made in connection with reconstruction of highway fills damaged by the 1937 flood of the Ohio River.

Geologists have been employed continuously in the study of soils and related problems by the testing laboratory since 1937. Much soil testing for highways consists essentially of an engineering analysis of the physical properties of soil, its strength, and the influence of moisture on its performance. Furthermore, the engineer's training in advanced mechanics and mathematics is a necessity for the testing of the stability of soil by shear and consolidation tests and especially for the application of data obtained from these tests to the solution of problems in the supporting strength of soils for structures and embankments. However, the geologist's working knowledge of the historical processes which have led to the development of soil deposits gives him a picture of their character and distribution which is frequently of more immediate value in dealing with routine questions of soil stability than some of the more elaborate methods of theoretical soil mechanics. For a reasonable and well-rounded study of soils for highway work both the geological approach and the engineering approach must be used.

In the Ohio organization geologists have been found particularly valuable in making field surveys of the soil and rock conditions which will be encountered in the construction of proposed new highways. The mapping of soil profiles, particularly in hilly regions where deep cuts extend into the bedrock, can only be done intelligently if the general geology of the region is understood. Frequently, a detailed study of the geology of the area will be necessary in connection with the soil survey for the project.

In areas where landslides are common, detailed information on the character and structure of the bedrock, in addition to data on the physical properties and thickness of the soil overburden, is necessary to a proper evaluation of the conditions which may cause sliding or under which slides have already developed.

To illustrate the influence of local geology on a specific landslide, the following brief report of a slide which occurred in the southern part of the state is given. A section of the Ohio River Road lying just below a long sweeping curve in the river, where lateral erosion of the channel has kept the river against the valley slope, had been settling and sliding periodically for many years. This section is founded on talus near the toe of the slope. Investigation along the line of the old road showed the depth of poorly consolidated detritus composed of clay and boulders to be so great as to preclude the possibility of satisfactorily holding the road on this line by any practical means. A new road was constructed higher on the valley slope so that most of its length was on a prominent sandstone ledge. However, because of the considerable excavation necessary to obtain a roadway of sufficient width on the bench, a part of the roadway was constructed of fill extending beyond the old sandstone cliff and resting on the same talus slope occupied by the old road. Several years after construction a slide occurred in this overlapping fill in which about 400 ft of the roadway settled a distance of 5 to 10 ft within a period of two weeks. Investigation of the conditions leading to the development of this slide showed not only that the fill was resting on a great thickness of clay and rock talus but also that water had been flowing through the sandstone stratum down the dip of the rock from a tributary valley which parallels the river at this point about one-half mile away (see Fig. 3). The probability that water saturating the fill adjacent to the old rock cliff was coming through this porous sandstone eliminated from consideration any permanent corrective procedures which did not either cut off entirely the water from this source or place the full roadway width on top of the solid rock ledge. The potential water bearing nature of this sandstone was evident only when the inclination of the bedrock as determined from a geological study of the area had been made.

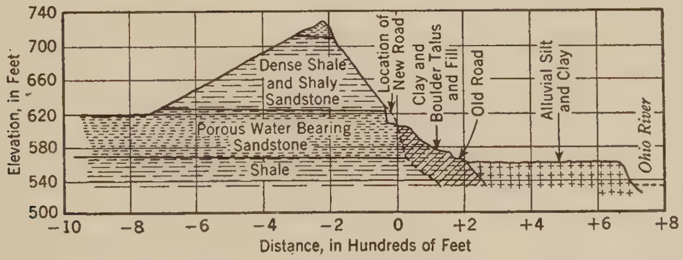

Fig. 3.—Water Seeping through a Dipping Sandstone Bed Contributed to the Saturation of the Talus Slope and Fill on Which a Highway Was Constructed in Southern Ohio

As Mr. Huntting has shown, the geologist by the application of his science can contribute much to the solution of many highway engineering problems, particularly those involving earthwork. However, for engineering purposes, detailed and accurate data must nearly always be obtained by such procedures as test borings and laboratory tests to supplement the more general data obtained from a geological examination. Exact information necessary for the safe construction of an improvement cannot be secured in many cases without detailed investigation. The geologist's services in these problems will be of the greatest value in indicating the need for, and extensiveness of, these studies and in interpreting the results.

K. B. Woods,[13] M. Am. Soc. C. E.—The approach used by the author in discussing the relationship of geology to highway engineering by citing typical cases can be extended indefinitely. The periodic recording of these experiences can constitute a valuable addition to engineering literature. The significance of this procedure is emphasized by the fact that highway engineers generally are not familiar with, and lack an appreciation of, the usefulness of geological literature in solving a wide variety of their problems.

Most states do have, or have had, a geological survey organization which has produced many geological publications containing a vast store of information that can be used to practical advantage by the engineer. Added to these should be other available publications, including in particular the maps and reports produced by the soil surveys of the various states. Pedology and geology go hand in hand and can be useful tools to the highway and airport engineer, particularly in such soil areas as the glacial drift, the great plains, the coastal plains, and in some residual soil areas—including such parent rocks as limestones and shales. In mountainous and semimountainous areas, a knowledge of the rock conditions usually is a primary requirement for satisfactory design and ultimate good performance of the completed engineering structure.

Failure to use available geological information and talents is not entirely the fault of the highway engineer. There is a fundamental difference in the perspectives of geologists and highway engineers. A concrete example is the time element. The geologist thinks in terms of hundreds, thousands, and even millions of years, whereas the highway engineer, in his endeavor to keep pace with the mechanical developments of the automotive industry, is fortunate indeed if he can build and design a highway useful for 50 or even 25 years. The first essential for widespread use of geology in highway engineering is a blending of the two perspectives. The geologist should endeavor to acquaint himself with the broader aspects of engineering and the engineer in turn should decide what phases of geology are applicable to his problems. The engineering and geology schools of the educational institutions in the United States might well be ideally situated to initiate this common understanding.

Referring to the section on "Problems," the following comments will be directed to four of the first six items, namely: (1) Locating suitable road-surfacing material pits and quarries; (2) determining the suitability of various earth materials for surfacing, concrete construction, and other highway uses; (3) subgrade treatment and classification; and (6) preventing and correcting landslides.

---

[13] Associate Prof., Highway Eng., Asst. Director, Joint Highway Research Project, Purdue Univ., West Lafayette, Ind.

In regard to Problem (1), two factors are of major importance—namely, certain land forms and bedrock geology. The geologist well knows that prospecting for gravels and sands in the glacial drift area can be limited to certain land forms including kames, eskers, river terraces, outwash plains, and sand dunes. The engineer is not generally familiar with the geological history of these land forms and as a result his quest for possible sources of granular materials is all too often hit or miss. The geologist, on the other hand, may not be familiar with the engineering requirements of items such as base courses, for instance, and may locate for the engineer's use only those deposits that may yield commercial aggregates. Many states already have available geological maps which show these land forms. The author has listed several of these. A more recent publication than those in the "Bibliography" is the report by H. W. Leavitt and E. H. Perkins (44) which contains granular materials maps of Maine.

Recent developments in the use of aerial photographs for locating available granular deposits, as well as for interpreting the engineering characteristics of soils, have increased the possibilities of a combined engineering-geological approach to the problem (45). The trained eye can locate granular materials in such photos by noting the drainage patterns, color tone, topography, vegetation, etc., with unfailing accuracy. All deposits of this type are good potential sources of granular materials for highway base courses or even for commercial aggregates in many instances. A knowledge of geology and pedology in this technique is necessary for a correct and accurate interpretation of the evidence included in the photograph.

Another important consideration in the use of information concerning land forms and their effect on highways and airports is that of location. River terraces, for instance, frequently are excellent airport sites because of the granular texture of the soil which provides adequate drainage without the use of many additional man-made appurtenances. Soil survey reports should not be neglected in this respect since detailed maps frequently are available and they can be used to establish grades and to locate highways and airports on the best available materials. Likewise, these same maps, when available, do show the locations of available granular materials.

In regard to Problem (2), the author stresses the fact that research and physical testing of aggregates, used in portland cement concrete construction, have not kept pace with the developments in concrete construction in general. The aggregate has been considered more or less as an inert material, the active ingredient being the cement. As stated by the author, available information disproves this idea. Performance surveys of concrete roads in Kentucky (46) indicate that certain river gravels produced pavements much inferior in quality to those made with other aggregates. Some surveys recently completed in Indiana show that a large mileage of concrete pavements made with one particular aggregate always produced inferior concrete, regardless of the time of year of construction, the underlying subgrade soil, the traffic conditions, the type of cement used, the fine aggregate used, and any other variables that may have occurred in connection with a construction program involving this aggregate during the 12-yr period in which it was used. Other aggregates employed for short sections on these same contracts were invariably more satisfactory. Since the results of physical tests on such aggregates are not particularly alarming, there appears to be much need for the development of better tests for acceptance. As suggested by the author, the study of thin sections by a competent mineralogist might at least be helpful in determining the suitability of such aggregates in concrete construction. In this respect, the approach used by D. G. Runner (47) promises to give considerable assistance in solving such problems.

In regard to subgrade treatment and classification, a "pin-point perspective" seems to have been taken in many instances in correlating pavement performance with soil areas. In any given large geographical area, well-defined geological boundaries can be used to distinguish one soil area from another. Since the soil profile either is the product of disintegration and weathering of underlying bedrock or consists of transported materials primarily derived from rock, it follows that similar soil profiles should be developed from similar materials provided the weathering has been of the same duration and that at least similar conditions of climate, topography, and vegetation have prevailed. From this it can be deduced that standard designs of the highway—particularly the base course, pavement, subgrade treatment, and drainage—can and should be made for each large uniform soil area. The only variable to be considered, then, would be the amount and weight of traffic loads that are to be anticipated. Many performance surveys made on flexible pavements in Indiana (48) lend support to this thesis.

Approximately 2,000 miles of secondary pavements in Indiana were surveyed during the 1943 spring breakup, yielding many interesting results. For instance, about 50 miles of traffic-bound gravel or stone bases with a bituminous top (total pavement thickness of 6 to 8 in.) located on gravel terraces suffered no noticeable ill effect from the combination of a severe winter and traffic. Similar pavements in silty clay soil areas suffered severely even with pavements as thick as 12 to 15 in. Another soil area in north-central Indiana consists of shallow sands on till, the sand being of variable thickness. Much pavement distress was encountered in this soil area, particularly where the shallow sand was 3 ft thick or less. Such an area may escape the engineer's attention since sand is normally an excellent subgrade material. However, a combination of traffic with adverse water and temperature conditions was sufficient during this particular spring to cause havoc with many miles of pavement, including some primary types. Obviously, a standardization of design with particular reference to grade and drainage is essential for proper pavement performance in this particular soil area.

Another pavement problem that can be studied on a geological-soil-area basis is that of pumping of rigid pavements. This action consists of the ejection of muddy water from beneath the pavements through cracks, joints, and along the edge of the pavement. Within a short time a void develops beneath the pavement, leaving the slab unsupported in certain places. Ultimately, cracking and complete disintegration of the pavement result (49). In the Middle West this problem prevails on heavily traveled roads located in lacustrine soil areas, such as in the Lake Chicago (northern Illinois and Indiana) and Lake Maumee (northern Ohio) soil deposits and in deep cuts in moraines. The extreme importance of the type of soil as a factor in pavement pumping cannot be overemphasized. The highly plastic coastal plain clays of Georgia, Alabama, Arkansas, and Texas, for example, produced badly pumping pavements where traffic loads are heavy. The engineer will be able to cope with this problem in the design of his pavement, but, since this new design may be more expensive than the older design, he should know where pumping pavements are likely to occur. The correlation of pavement performance with the geological-soil areas is a feasible approach to this type of problem.

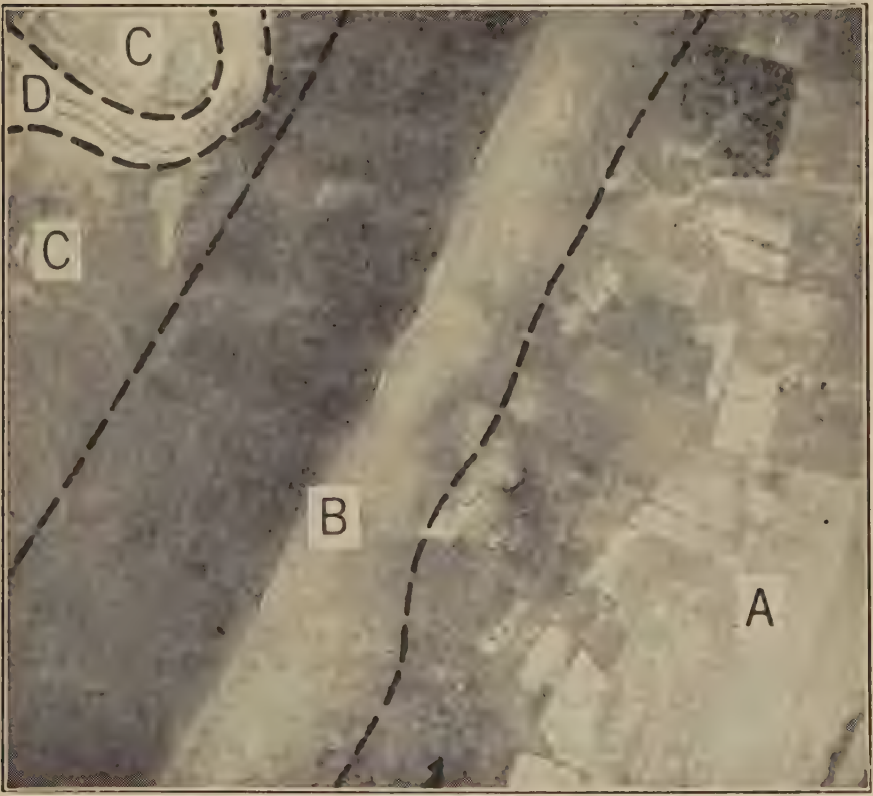

FIG. 4.—AIR PHOTOGRAPH OF A BEDROCK AREA—A IS LIMESTONE, B IS SANDSTONE, C IS SOFT SHALE, AND D IS RECENT RIVER ALLUVIUM

Landslides may be studied frequently on a geological-area basis. The Conemaugh formation of the Pennsylvanian system, for instance, in some areas contains dozens of landslides, particularly in the "red-bed" outcrops. The Ordovician system outcropping in southeastern Indiana, southwestern Ohio, and north-central Kentucky is another landslide-producing geological area. Corrections for landslides in such areas can almost be standardized, and certainly precautionary measures can be employed in the original road layout when it is realized that the geological strata in question have caused trouble repeatedly during and after previous construction operations. However, it should be emphasized that landslides will not necessarily prevail in other outcrops of Ordovician or Conemaugh rocks since this geological age classification does not require a similarity in rock textures.

In correlating pavement performance with geological areas, one of the important weaknesses of geological literature is the stress that is placed on substantiating data showing similarity of age rather than similarity of texture of the particular strata in question. Age is important to the geologist in reconstructing the sequence of geological events. On the other hand, texture and composition of the rocks are of major importance to the engineer, particularly if he is to use geology in applying the results of experience gained in one area of the world to a similar area elsewhere. This difficulty is fast being overcome by the analysis of the patterns of aerial photographs. Experienced technicians can use such photos and predict with remarkable accuracy the type of rock strata. A typical bedrock pattern is shown in Fig. 4. Even the inexperienced can see the contrasting patterns of the limestone, sandstone, and shale, designated as A, B, and C. The continued development and use of these techniques will require even greater coordination between the engineer and the geologist. In turn, active association of the two groups should do much to create a better understanding between them.

D. J. Belcher,[14] Jun. Am. Soc. C. E.—The general thesis that geology is applicable to the solution of many highway engineering problems marks this paper as one to be read and considered by every engineer engaged in highway and airport engineering. It is hoped that some significance can be attached to this apparent trend toward a more diversified treatment of the various branches of endeavor classified as civil engineering.

The writer wishes to approach the discussion of this paper from a different direction—that of the engineer looking at geology. Without question, Mr. Huntting is representative of the progressive group of geologists that are contributing to the improvement of engineering practices in the construction field. That geology can contribute immensely to highway engineering is becoming more apparent each year. In fact, there are few, if any, who have explored the complete significance of geologic principles to these civil engineering problems.

The situation today is one in which the over-all work of the highway engineer is complicated by new and less tolerant standards. The influences and new problems should be met by recourse to available information and skills that may help to solve them. Unfortunately they are often unsolved. For example, many design engineers, field engineers, project engineers, and inspectors, who have opportunities to apply a knowledge of soils engineering, overlook opportunities to make corrections that will save time and money and prolong pavement life. Knowing the principles of soil formation, they can solve simple problems and recognize the potential problems that require the services of the soil engineer or soil scientist.

So it is with geology and the geologist; too few engineers realize the usefulness of geologic principles in everyday problems. Can they then see its application to larger problems?

As a science (and an art) geology is complex and requires a specialist's skill, but engineering is not geology and therefore does not often require the details or terms common in strictly geologic work. Having had the opportunity to examine geology in the light of engineering use in many of the states from east to west the writer has formed the personal conclusion that geology is very important in many areas and relatively unimportant in many others. Where it is important in the bedrock areas, the existing information and methods can be vastly simplified for their application to engineering work. Areas such as those covered by coastal plains sediments, great plains materials, glacial, and aeolian deposits are here considered separate from the general field of geology. Some difference in opinion may occur in the definition or scope of geology. However, the fact remains that soil forming processes in most of these areas create problems not amenable to geologic treatment. The official geologic map of the United States Geological Survey does not always concern itself with surface deposits but presents information on bedrock that is buried at depths of from 5 to 500 ft below the surface in the areas mentioned. Obviously the highway engineer is concerned with the character of the surface or near-surface materials.

---

[14] Research Engr., Joint Highway Research Project, Purdue Univ., West Lafayette, Ind.

The development of a second point is somewhat contingent upon the attitude taken on the scope of geology. If the field of the geologist is all inclusive, as it may well be by liberal definition, the situation is aggravated when one insists that a competent geologist is always essential. A competent geologist is a highly trained person whose talents may well be wasted on engineering problems in many states. Substitute instead a practical knowledge of geologic processes and principles in a number of the state highway department's engineering personnel and a greater potential improvement is in view.

Specialists can advance their field at a much greater rate by sharing their knowledge, acquainting others with their work, and thereby stimulating an interest in its application. The services of trained geologists will be in greater demand when there are more engineers with an interest in geology working in the field. That potential interest can be developed or retarded by the teachers of applied engineering geology in the colleges and universities.

If the average highway engineer does not use geology it is because he has not been shown the usefulness of the subject. The subject is not often deliberately and wilfully ignored. The fault lies largely with the geologists and the teachers of geology because they are not well acquainted with the problems of engineering. From this situation three conditions have developed:

(*a*) In their natural enthusiasm, the geologists have endeavored to apply the unmodified science to engineering problems;

(*b*) The situation, so common in many specialized fields, arises in which it is felt that only a highly trained geologist can deal with these problems; and

(*c*) The application of geology to highway engineering suffers when the specific engineering problems make the geologic concept seem both vague and general by comparison.

At this point it is well to make it clear that this commentary seeks first to advocate a greater application of geologic principles to the solution of highway problems to which they are pertinent, and then to add to and modify certain phases of Mr. Huntting's paper in the light of personal experience. To that end the following comments are offered:

Problem (1) Location of Pits and Quarries.—There can be no reasonable disagreement with the premise that sands and gravels as well as rock strata are predictable on the basis of a pattern or mode of occurrence that is in part geologic. These facts are seldom if ever taught in the classroom and it is indeed rare to find them presented to engineers in technical literature. The methods are simple and their mastery well within the capabilities of a competent materials engineer. There will be instances in which the special skills of the geologist are necessary, especially in bedrock areas, but the bulk of the work will not require the specialist.

Problem (2) Suitability of Various Earth Materials for Surfacing, Concrete Construction, and Other Highway Uses.—The original presentation under this heading deals with a very significant phase of concrete aggregates that has a much more promising future than it has had a fruitful past. Unfortunately engineers have often chosen highly irrelevant test procedures as a means of testing aggregate quality for specific uses. The problems can be solved only when the origin, mineralogy, and chemistry of the aggregates are studied by competent persons. Obviously these skills can be found among the geologists, mineralogists, and chemists. It is suggested that this phase might be given additional consideration, whereas its inclusion with the less definite "earth materials * * * and other highway uses" to some extent detracts from the importance of the subject.

Problem (3) Subgrade Treatment and Classification and Problem (4) Frost-Heave Problems.—Since these are included in the writer's field of special endeavor, the manifest interest in Mr. Huntting's paper is understandable. These are problems that contain considerations other than geologic. In these two items the geologist may find himself far afield. The broad approach of the geologist has not demonstrated any appreciable suitability in dealing with problems of subgrade treatment or frost action despite the studies of crystal growth conducted by Professor Taber (15) and the resulting contributions to the knowledge of frost action. In the solution of field problems, frost action is a complex problem. It occurs as a product of the whims of ground water as well as of soil texture and is found more often in sands (shallow deposits on till), silty sands, and silts, rather than in clays as indicated.

The writer feels that ultimately a geologic method of classification suitable for engineering usage will form the basis of soil classification, but to date it has not been fully developed. When offered initially, engineers in general may express little sympathy for such a classification because of their classroom impressions of geology.

Returning to the geologist's present method of soil classification—residual, colluvial, organic, transported—it may be cited as an example of unrelated standards of classification. In terms of engineering problems this method lacks realism because:

Residual soils range in texture from the common clays (limestone, granite, basalt, etc.) through the silts, sands, and sandy clays (sandstones, schists, granites, etc.) to residual gravels.

Colluvial soils occupy relatively insignificant areas, vary so widely in texture, lack uniformity, occur on steep slopes, and are so highly susceptible to wide variations in water conditions that little of engineering significance can be said in the general terms necessary to a classification.

Organic soils, all significantly associated with a high water table, are worthy of distinction as a separate class and a further subdivision should probably differentiate between organic-sand mixtures of the glacial outwash areas and the mucks, peat, and muskeg swamps.

The term, "transported soils," like other classifications, is broad and includes all textures and all ground-water conditions. To illustrate:

An alluvial soil area, for example Mississippi River alluvium, varies in texture from medium sand in Minnesota through silts in Illinois to clays from Missouri to the Gulf. At any one point in the flood plains (south of the Wisconsin State border) one may expect sand on the natural levee and silt or plastic clay in the "slack water" areas. Since these alluvial soils vary in texture with the size of the stream and the nature of the soil in the watershed, the method of classification cannot be too general and remain cogent.

Lacustrine soils are uniform by comparison since they are generally of silt or silty-clay texture, whereas marine sediments (of the coastal plains) provide highly plastic clays as well as sands and silts. Likewise glacial soil as a classification embraces the plastic silty clays of the till plains, sands of outwash plains, and gravels of the valley plains, kames, and eskers.

The aeolian group, if subdivided into sand and loess, provides two remarkably uniform soil materials.

It has been acknowledged (see heading, "Subgrade Treatment and Classification") that "The soils falling under a given heading in this classification will not have all their physical properties alike * * *" and that, "Nothing can replace the engineers' physical tests * * *." Physical tests show similarity among the vast areas of lacustrine silt in the glacial lakes Agassiz, North Dakota and Minnesota, Maumee, northern Ohio, Lahonton, Utah, and Bonneville, Washington; in the loess in Mississippi, Tennessee, Illinois, Minnesota, Iowa, Indiana, Kansas, Missouri, Nebraska, Idaho, Washington, and North China—to cite a few; and in the alluvium in Ohio, Indiana, Illinois, and Iowa; and some residual soils derived from fine-grained sandstone. Obviously the engineering problems in these different areas are not all similar, so physical tests alone are often misleading.

This is more a criticism of engineers relying on test data than of the geologic approach, and the geologist will more readily understand it. The engineer relying on test data alone often finds himself standing on one leg (technically and figuratively), and his designs are continually off-balance because other conditions upon which good performance is contingent do not appear in design formulas.

If the geologist's approach is too broad and the contemporary engineer's too narrow, the solution may then be found in a blending that can be obtained by a better mutual understanding. Add geologic principles to highway (soils and materials) engineering. Combine test data and the soil position or land form. Consider the natural position, the soil structure, the profile horizons, the drainage, and the climate. The solution lies largely in the hands of the geologist-engineer-professor—not the geologist, not the engineer, not the professor.

Problem (5) Prediction of Character of Material To Be Excavated.—This is an important phase of highway location and planning. Many engineers familiar with a few fundamentals of rock weathering and geology react unfavorably to the implication that a competent geologist is always required to perform these services.

In the "Prevention and Correction of Landslides," Problem (6), the geologist can render his most valuable service in many afflicted areas. In rapid succession all can approve the listing of his value in tunneling operations, Problem (9); evaluation of mineral lands, Problem (11); and as an expert witness in related court actions, Problem (12). However, the cause suffers when the geologist presumes to render comparable service for highway engineers except in special cases in judging bridge foundations, Problem (7); predicting channel changes, Problem (8); and underground-water supplies, Problem (10). In each of these it is felt that the descriptions offered do not substantiate the positive character of the statement of the problem.

R. Woodward Moore,[15] Esq.—The twelve cases discussed in this paper constitute important problems continually confronting the highway engineer wherever road construction and road maintenance are undertaken. The writer was particularly interested in the references to geophysical methods of test applied to their solution. The possible value of such exploration methods to the geologist and engineer alike should be emphasized.

For some years the Division of Physical Research and Tests of the Public Roads Administration has been engaged in research on the use of geophysical methods of test in highway engineering. Conclusions resulting from these studies and the work of several of the state highway departments, as well as of other agencies in the United States and elsewhere, indicate that the methods of test mentioned by the author—the earth-resistivity and the refraction seismic tests—may have considerable economic value in the solution of many of the problems listed by Mr. Huntting. Specifically, Problem (1) and Problems (5) to (10), inclusive, appear to be susceptible of solution or partial solution by geophysical tests. The following paragraphs are submitted in amplification of the information concerning geophysical tests as presented by the author in the belief that such methods of subsurface exploration may prove to be increasingly useful to the geologist in further demonstrating the usefulness of geology in highway engineering.

Problem (*1*).—The location and delineation of deposits of road-surfacing materials by earth-resistivity tests have been described by various investigators during the ten years since 1934 (50)(51)(52). In a letter to the writer, Henry C. Porter, M. Am. Soc. C. E., reported rather favorably on such tests by the State Highway Department of Texas. Investigations conducted by the Public Roads Administration have further established the usefulness of this test in such work.

---

[15] Associate Civ. Engr., Public Roads Administration, Federal Works Agency, Washington, D. C.

Problem (*5*).—Both the refraction seismic test and the earth-resistivity test have been found to be applicable to the classification of excavation materials (53). The resistivity test has been applied rather successfully in the study of highway grading projects by the Missouri State Highway Department, the test data obtained being of considerable aid in predicting the character of the materials to be encountered (54).

Problem (*6*).—Although little work has been done, as yet, in determining the usefulness of geophysical tests in connection with landslide areas, it would seem highly probable that such tests could be of appreciable value in disclosing potential slide areas. The refraction seismic test has been used in preliminary investigations to determine the presence of impervious shales beneath talus slopes which constitute potential sliding surfaces upon which the overlying porous material may move (55). The earth-resistivity test should be of practical value in locating impervious strata of shale or clay beneath less consolidated and more porous soils. Where such conditions exist, road structures may be benched into the impervious layer instead of being built entirely upon the porous materials subject to slipping along the lubricated surface of the underlying impervious stratum. In the case of large fill structures in highway construction routine resistivity tests made over the fill immediately after construction and at intervals thereafter may prove of value in disclosing variations in moisture content. In this way abnormal increases in moisture may be detected within the fill where increasing hydraulic pressures may cause a slip-out requiring costly reconstruction work and causing considerable inconvenience to an established flow of traffic. No data are at hand to substantiate such a conjecture, however.

Problem (*7*).—Both methods of test may be used in the study of bridge foundation materials, the seismic test being more positive in its identification of solid rock formations in areas where either solid rock or gravel formations may be expected. The low cost involved and the rapidity with which these tests can be executed make them of particular value in preliminary surveys, often eliminating the need for the time-consuming and costly methods ordinarily used in direct explorations of the substrata. Where conditions warrant, the direct methods of exploration may be used on the final location selected.

Problem (*8*).—The earth-resistivity traverse or constant-depth test should be of aid to the geologist in locating buried river channels throughout a given area, particularly where sand and gravel are concentrated within such channels and where rapid erosion might conceivably occur during flood periods. The determination of the presence, depth, and lateral extent of such deposits might well influence decisions as to the desirability of a particular bridge or road location.

Problem (*9*).—Earth-resistivity tests have been used successfully in connection with explorations involving a tunnel site in a hydroelectric development in Canada (56)(57). The use of this test in explorations on highway tunnel sites is likely to be largely influenced by the depth and character of the overburden. However, the presence of faulting and zones of shattered and highly altered or weathered rock where water may prove troublesome in tunnel construction should be rather easily determined by the resistivity test. The refraction seismic test has been used in several instances by the Public Roads Administration in surveys made in connection with the location of proposed highway tunnels. The data obtained from these surveys have not been published but are contained in the files. In such studies the broken and weathered rocks have seismic wave velocities considerably different from the characteristic velocity in the solid rock sought for the portal construction. Predictions as to the need for a lining for a particular tunnel may be made, based upon intermediate seismic wave velocities indicating a fractured, jointed rock mass through which the tunnel is to pass.

Problem (*10*).—There have been numerous instances in which the resistivity test has been used successfully in the search for underground water supplies. References (58)(59)(60) are examples of such studies. At times the water may be located more or less directly by reason of low resistivity resulting from various salts carried in solution, but more often it is located through its association with some stratigraphic or structural formation such as clean sand and gravel or a rock formation conducive to the entrapment and storage of water.

George E. Ekblaw,[16] Esq.—The purpose of this paper (see "Synopsis") is "to help both engineers and geologists to recognize more frequently those situations in which geology does enter into highway engineering." How extended or complete the discussion should be is an open question—it could range from the extreme minimum of a single statement of obvious fact to a maximum of volumes in which all known or possible examples were cited. Whether or not the length and style of this paper is sufficient for the purpose, therefore, is largely a matter of personal opinion and hardly subject to technical discussion.

The author has chosen to subdivide the topic into twelve "problems" ("classes of problems" might be a more appropriate term). By inference these comprise the entire field of cooperative endeavor. Actually there are numerous other classes of problems which are equally or more important—such as (*a*) selecting the most desirable of two or more alternative routes for a highway, either locally or regionally, from the viewpoint of geologic conditions, (*b*) locating or alining a highway to avoid undesirable local conditions, (*c*) peat-bog problems, and (*d*) grade-fill problems—to cite from experience in Illinois alone.

Mr. Huntting has cited incidents to exemplify these "problems." Naturally these examples are those with which he is personally familiar or which have impressed him. Any one working in the dual field of geology and highway engineering could supplement these by other incidents, perhaps even more striking or typical. The number and variety of such incidents would be determined by geographic and temporal range and variety of experience, but to a greater or lesser degree Mr. Huntting's examples could be duplicated anywhere, so they may be considered sufficient to illustrate the classes of engineering problems discussed.

Within the limits of the paper, Mr. Huntting has done probably as well as any one could. Because of the brevity of the paper, many generalized statements have been made which, like all generalities, may not be universally true and to which exceptions of limited application could be made. Excluding such exceptions, experience in Illinois would corroborate all the statements applicable within the state, in a general way, except one: In Illinois it has been observed that silt, not clay, is the major constituent of subgrade material most affected by frost heave, and the writer does not subscribe to the opinion (see heading, "Frost-Heave Problems") that "The clay acts as the medium through which water rises from the water table by capillarity until it reaches the frost line, where it freezes and causes an irregular upheaval of the road surface." The presence of some clay in the silt may add to the effective capillarity and to the ice-layer expansion which is the principal cause of frost heave, but material that has a large percentage of clay seems to favor neither capillarity nor ice-layer expansion. Theoretically, because of the smaller grain size of clay, capillary water should rise higher in clay than in silt, but other factors apparently operate to offset the grain size.

[16] Geologist and Head, Areal and Eng. Geology Div., State Geological Survey, Urbana, Ill.

Allen S. Cary,[17] Assoc. M. Am. Soc. C. E., and Ade E. Jaskar,[18] Jun. Am. Soc. C. E.—Geology contributes to the solution of airport engineering problems as much as to those of highway engineering. The author has presented twelve possible problems in which a geologist's services might be profitable in highway design. Most of these have been of major importance in airport design for several years. The urgency of the military airport program, the heavy wheel loadings, and the tremendous amounts of construction materials involved have forced the designing engineers to obtain a large quantity of accurate data in a minimum length of time. In many, but not enough cases, the services of full-time geologists have been requisitioned.

In the preparation of soil profiles, in procurement of truly representative soil samples, in exploration for fill materials and aggregates, and in providing drainage data, the geologist has been like the man who charged one dollar for fixing the typewriter in a few moments. Objection elicited the statement that he charged only one cent for the fixing, but ninety-nine cents for knowing how. The geologist has been able to minimize extensive "pattern" explorations involving test pits, auger borings, etc., by his professional knowledge of probable extents of uniformity in sediments (both horizontally and vertically) and his understanding of ground-water behavior.

In addition to advising on the design of the runways, the geologist has been of inestimable aid in water supply and building foundation problems.

The author has so ably discussed the various applications of geology to highway engineering that it is not necessary to enumerate further examples. However, the relation between the engineer and the geologist does deserve elaboration. By far the best single publication available on this subject was written by R. F. Legget in 1939 (12).

It is satisfying to note that the constructive service of the geologist is more appreciated now than at any time in the past and bids for further recognition in the future. A review of civil engineering in the past, and its status in the present, demonstrates that the future trend is inevitable. In the earliest years of modern civil engineering, when most projects were of small or moderate scope, the engineer was able to cope with his problems by being his own geologist or by considering a large factor of safety (more correctly, factor of ignorance) in his work. When modern society began to demand larger and more elaborate structures, it became necessary for the civil engineer himself to specialize. Today a civil engineering graduate may have such a subtitle as structural, sanitary, railroad, highway, irrigation, commercial, municipal, hydraulic, or materials engineer. These special fields may even be subdivided further. Many years of general experience are required before a man can qualify for the title of civil engineer.

[17] Geologist, Soils Laboratory, U. S. Engr. Dept., Univ. of Washington, Seattle, Wash.

[18] Associate Geologist, Soils Laboratory, U. S. Engr. Dept., Univ. of Washington, Seattle, Wash.

Upon resuming responsibility for the design of major projects, the civil engineer is so busy with general aspects that he has neither the time, nor, possibly, the training in details, necessary to obtain the geological data for design. He must either delegate this responsibility to specialists or gamble. The latter course has been taken too frequently as is demonstrated by failures in the past (12). Too often the principal use of consulting geologists is in determining the causes of failure of important engineering structures.

As stated previously, the constructive service of the geologist is becoming more appreciated, and bids for higher recognition in the future. This prophecy is supported not only by the results of mistakes that have been made in the past, but also by the fact that the most favorable sites for engineering projects are gradually being "used up." The ingenuity of the civil engineer is being taxed to the utmost by the design of large concrete and earth-fill dams, long-span bridges, large airports (often built on the poorest foundations), intricate highway systems, elaborate water-supply systems, and many other projects. Thus, the geologist is needed more than ever.

Where to find the experienced engineering geologist, who can fulfil such responsibilities, and devote full-time service to the engineer, is an important consideration, but one beyond the scope of this discussion.

KARL TERZAGHI,[19] M. AM. SOC. C. E.—This review of the relation between geology and highway engineering deserves the attention not only of highway engineers, but of every engineer who deals with rock and soils. The influence of geologic factors on the success or failure of engineering operations is so manifold and decisive that it cannot be overemphasized. Hence, the writer agrees with Mr. Huntting on this subject. However, the manner in which soil mechanics has been treated, or rather ignored, calls for some comments regarding the competency of the geologist to express an opinion on the design of structures and regarding the circumstances which brought soil mechanics into existence.

In his college days the writer enjoyed the benefits of a specialized training in geology and petrology under the guidance of prominent experts in these fields. His first professional papers were devoted to purely geological subjects and throughout his subsequent professional career as a civil engineer he never ceased to draw upon whatever geology and experienced geologists had to contribute toward the solution of his problems which, in his early days, were primarily connected with hydroelectric power developments. However, as his engineering experience increased, the writer became painfully aware of the existence of a large group of engineering problems in the region between the domains of geology and of applied mechanics. These were the problems involving the mechanical effects of loads and seepage pressures on soils. Geology furnished valuable information regarding the origin, sequence, and shape of the individual soil strata, and applied mechanics made it possible to compute the stresses in the soil produced by given systems of forces. However, there was no method of evaluating the corresponding deformations and of defining the stress conditions for failure. The empirical rules used for bridging the gap were sadly inadequate. Since this fact was continuously impressed on the writer by observation, he became more and more obsessed by the desire to remedy the intolerable situation.

---

[19] Cons. Engr., Lecturer on Eng. Geology, Graduate School of Eng., Harvard Univ., Cambridge, Mass.

His first impression was that the no man's land between geology and engineering could most successfully be invaded from the geological viewpoint because he thought that definite relationships might exist between the geological character and the petrographic character of the soil strata in the field and their reaction on the forces which act on them during and after construction. To discover the existence of such relations, it is necessary to proceed in a purely empirical manner, by correlating construction experience with whatever can be ascertained by methods of field geology at the sites of construction. After the writer had spent several years collecting data of this type at random, he found the process too slow, and he decided to take advantage of what at that time was the boldest and most promising experiment in engineering geology ever made—namely, the construction of dams, open cuts, and tunnels, under extremely different geological conditions, by the U. S. Reclamation Service. During 1912 he visited practically every one of the larger construction camps of the Reclamation Service. With the active cooperation of the late F. H. Newell, M. Am. Soc. C. E., Director of the Reclamation Service, who was keenly interested in the writer's quest, geological data pertaining to the observed sites were secured. After the voluminous material was assembled, the writer tried to extract from it whatever definite relations may exist between the geological character and strength and bearing capacity of the different strata. The results of his labors were so utterly disappointing that he did not even consider it worth while to publish them. They can be condensed into a single sentence. There are no definite relations, because, for a given geologic origin and petrographic character of a stratum, the strength of the material, rock, or soil depends on conditions that are not, and cannot be, recognized by a purely geological investigation. For almost every geologically well-defined stratum the possible scattering of its physical properties from the statistical average is so important that one cannot even make an acceptable guess based on precedent.

At that stage of his investigation—a stage of bitter disappointment and disillusionment—the writer became interested in what is now known as soil mechanics. During the following 25 years he spent most of his time on observation and experimentation in this particular field. He aimed to develop suitable experimental methods for investigating the physical properties of soils and to explain the behavior of soils under the influence of load and seepage pressure on the basis of the laws of mechanics of solids and fluids. Between

1926 and 1929, the writer spent much time and labor on advocating the purely empirical procedure of correlating soil constants and soil profiles with the observed performance of the road surface in the field. Since the relative merits of the different methods of soil mechanics are already evident by their success or failure in connection with design and construction, their legitimate place among the tools of the practising engineer is no longer a matter of personal opinion.

Soil mechanics, without the assistance of geology and general statistics, can be used only in those rare instances in which a structure must be built in, or above, fairly uniform and homogeneous soil strata. In every other instance reasonably accurate values for the soil constants and information on the vital details of the structure of the subsoil can be obtained only by combining the results of soil tests with the results of investigations on the geological origin of the subsoil. However, the results of these investigations merely represent the prerequisite for solving the engineering problem. The solution itself requires an evaluation of the mechanical effect of the forces acting on the soil during and after construction. This major item in the solution is far beyond the domain of the geologist. As a matter of fact, many geologists know so little about the mental equipment necessary for this decisive part of the design that they consider themselves competent to make positive recommendations. Since this fact is often ignored even by engineers, its practical implications deserve serious consideration.

Although a competent geologist knows more about rocks than any engineer, no engineer would expect him to prepare an adequate design for a stone arch bridge, because the design of such a bridge requires a thorough training in mathematics and mechanics. Nevertheless, it is not uncommon for engineers to consider seriously the opinion of a geologist regarding the safety of a dam foundation, and this is a serious mistake. Few dam foundations can be designed on a purely mathematical basis, because generally the foundation conditions are too complex to permit an accurate forecast of the mechanical effects of load and percolating water. However, precisely because of this complexity, the design of such a foundation requires a far more thorough training in the mechanics of solids and fluids than does the design of a stone arch bridge, because the capacity for evaluating correctly the mechanical implications of various geological details without any computation does not develop in the human mind until a stock of subconscious knowledge has been accumulated as a result of the habitual application of the laws of mechanics to the solution of a great variety of problems. Since the geologist has neither the training nor the opportunity to acquire such a background, his forecast of a mechanical effect can be very misleading. The following example should serve to illustrate this fact.

In 1915, the National Academy of Sciences in Washington, D. C., appointed a committee of distinguished scientists to report on the causes of slides on the Panama Canal. Since one of the members (a prominent geologist) had previously acquired some knowledge of mechanics, he presented his findings in mathematical terms, involving an elaborate theory of the relation between the compressive strength of the rocks and the stability of the slopes. The basis of his theory was "that the tension T, acting along an arc δs of the surface of sliding is equivalent to a normal pressure $T\ \delta\psi$." To justify his statement the geologist referred to a classical textbook on mechanics. Since the writer was not aware of the propriety of applying this principle to the mechanics of solids, he consulted the reference and found that the statement refers not to solids, but to the relation between the surface tension and the normal pressure at the boundary between gases and liquids.

This incident demonstrates that an acquaintance with the literature of mathematics and mechanics, a necessary tool to the engineer, is not sufficient to establish competency as an engineer. Professional training has recognized the need and wisdom of following the acquisition of scientific knowledge by an apprenticeship for the purpose of developing the art of the profession. Competency for the practice of a profession is measured by both education and experience. Neither one alone is sufficient. The experiences necessary to become a competent geologist are not likely to be the same as those necessary to become an engineer. Hence, it would be dangerous for the engineer to accept an opinion of a geologist on a question of engineering. In science, a serious error in computation or judgment merely constitutes a blunder, but in civil engineering it may lead to a catastrophe.

Several geologists have published instructive descriptions of landslide preventive measures. However, if the reader of these discussions is familiar with the subject, he will notice that almost all these measures were developed, practised, and described by civil engineers prior to 1880. The geologists merely discovered that successful preventive means had already been used by civil engineers at a time when the landslides had not yet aroused the interest of the members of their own profession. As a matter of fact, there are exceptions to this rule. About 1935 a German engineering geologist proposed preventing slides on the slopes of a deep cut in stiff, fissured clay in northern Germany by grouting the fissures in the clay with portland cement. This procedure was entirely new. The writer saw the cut after the grouting was done, the cut was made, and the slopes had failed by sliding.

Under the heading, "Investigation of Proposed Tunnel Sites," Mr. Huntting discusses the influence of geological factors on tunneling. Essentially the same information was published in 1874 by F. Ržiha (61) and since that time no new material has been added.

Mr. Huntting implies (under the heading, "Frost-Heave Problems") that the danger of frost heave increases with increasing clay content of the soil. This and several other statements indicate that he does not pay as much attention to the laws of physics as these laws deserve. However, it would be preposterous to blame him, because he is a geologist and not an engineer. His deficiencies in physics are more than compensated by his broad vision in the field of geology, and merely indicate that the field of competency of every professional man, the geologist included, has certain limitations. If the geologist is careful enough not to trespass, his potential usefulness in connection with civil engineering cannot be overestimated.

Because of the obvious value of reliable geological information, large construction organizations, such as the Tennessee Valley Authority or state highway departments, are inconceivable without a staff of competent geologists. However, a vast amount of construction work is still being handled by very small staffs or by individual engineers. The success or failure of some of these jobs may depend to a large extent on a correct interpretation of the geological conditions. Thus, one may ask whether or not the investigation of the geology of a given site requires the services of a professional geologist. The answer to this question depends quite obviously on the nature of the job and a reliable answer can be expected only from an engineer who is thoroughly familiar with the elements of physical geology and with the influence of geological factors on the mechanical effects of loads and seepage pressures. Any other engineer might ignore the existence of geological complications on the job or overestimate the soundness of his own judgment in connection with problems in the domain of the professional geologist. Therefore, an elementary training in geology should be considered an essential prerequisite to the practice of highway, tunnel, or foundation engineering. In recent years most of the universities in the United States and abroad established courses in soil mechanics. This fact alone makes it necessary to teach engineering geology. The reason is obvious. Soil mechanics, as taught and practised at present, is likely to create the dangerous illusion that the processes in natural soil strata are always, or at least usually, as clear and simple as those in the cylindrical specimens subject to investigation in the laboratory. This idea, however, is due not to an inherent defect of soil mechanics, but to the incurable tendency of the human mind toward unwarranted generalization. Soil mechanics is not a substitute for engineering geology but a supplement to it. Sometime in the future when its novelty has worn off and its extravagances have been forgotten, soil mechanics may even turn into a useful tool in connection with purely geological research. Pending this future development, a course in engineering geology is needed as an antidote, and Mr. Huntting deserves the gratitude of his readers for his apt presentation of the manifold practical values of purely geologic information.

D. P. Krynine,[20] M. Am. Soc. C. E.—The predominant industry in the United States is agriculture, the construction business ranking second. Of the two billion dollars spent on public construction in 1938, about 45% was invested in roads and highways. The nation makes a considerable effort, financially, to keep its highways in tune with requirements of its life. The user wants a highway located where he needs it; he wants good riding conditions; and he wants low taxes. Hence, the major problem of the highway engineer is by no means a technical one. First, the highway engineer thinks of the purely human part of his problem, including human relations and economics, and for this purpose good planning is necessary. Again, this planning is not primarily of a technical nature. When finally the time comes for technical planning, the problem is again broken into two parts—what to build and on what to build. The former part of the question, of course, is more important than the latter. When a proper design of the superstructure and a proper choice of pavements (including materials) has been made, according to the needs of traffic, the question of the subgrade and of the foundation arises, and here the advice of the soil mechanician and of the geologist is necessary. Essentially, the highway engineer asks the soil mechanician and the geologist to advise him whether the soil, near the surface or remote from it, will support a given structure safely.

---

[20] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

Soil Mechanics, Soil Science, and Geology.—The engineering study of the properties of earth masses began with the early construction of fortifications in France, perhaps in the sixteenth century. The term "geology" in its present sense was probably first used sometime in the seventeenth century. Thus, the engineering study of earths (later termed "soil mechanics") and geology are approximately of the same age—about three hundred years old. Only recently did these fields begin to approach each other, in scope and content, to the mutual benefit of each. In this connection the purpose of this paper as defined in the "Synopsis" is timely and appropriate.

Near the beginning of the twentieth century, a group of geologists and agriculturalists started a new branch of knowledge which they named "Soil Science," and this particular branch of human knowledge, concerning the agricultural study of topsoils and their properties, has become an independent one. Highway engineers and soil mechanicians can find many interesting ideas in the field of agricultural soil science, such as the capillary moisture in soils, which is exceedingly important to those interested in the structural properties of soils (62). Geologists, particularly hydrogeologists, are more interested in free or gravitational water.

Thus, whereas soil scientists study topsoils mostly for agricultural purposes, geologists are interested in the earth as a whole, including the mantle covering the solid rock—with the exception, perhaps, of topsoils. Highway engineers and soil mechanicians are interested in the upper part of the mantle (about 300 ft thick), including any rock within that range of depth. At greater depths, stresses caused by the heaviest engineering structures are insignificant, and, in a practical sense, there may be no measurable strain from additional loads. Topsoils must be considered when simple earth roads are being built; but neither geologists nor soil scientists can advise the highway engineer effectively about topsoils.

Engineering and Geological Points of View.—There is considerable difference between the engineering and geological approach to the study of that part of the earth mantle which is important to engineers. Three differences are basic: (*a*) Relative scale of outlook, (*b*) relative appreciation of the strength of a material, and (*c*) relative concept of the time element.

The geologist tends to characterize a locality in broad terms whereas the engineer needs data concerning a particular point. In other words, the geologist thinks on a wider scale than does the engineer. Even excellent geological maps cannot be used for engineering purposes directly (except for preliminary studies) without supplementary borings and other soil investigations. An experienced boring contractor or foreman should make the borings rather than an average geologist or an average soil mechanician. Of the latter two, the person best qualified to do so must supervise the borings, interpret the results, and conduct the laboratory and field tests. If there is a geologist who is familiar with the test technique and who in addition understands the function of engineering structures, he may well be entrusted with the tests. In a general case, however, a well-trained soil mechanician is preferable because of his specialized and intimate acquaintance with the strength of soils.

The third difference between a geologist and an engineer is in the relative concepts of time. The geologist's unit for measuring time is large—the geological "age." Ancient and medieval engineers also tried sometimes to build for eternity. The modern engineer, however, has a feeling that in a relatively much shorter time every structure built by man must outlive its usefulness and be replaced. Hence, as a rule he builds for a limited time only, generally for the period of amortization (dams with silting reservoirs, apartment houses, etc.). Especially is this true of highway pavements, for which there is a certain maximum service life (63).

Right Type of Geologist.—The impression gained by a reader of this paper is that a geologist can perform a great number of useful tasks in highway engineering. Granted that this may be so, the question still remains as to the choice of a proper geologist. An experienced Swiss engineering geologist, M. Lugeon (64), has stated (writer's translation):

> "A geologist who works with the engineers must remain a naturalist and must use the methods of natural science only. This is not only to avoid assuming the rôle of an engineer with subsequent conflicts, but mostly because geologists have been trained in schools of naturalists * * *. A geologist who has only studied the history of the earth and of those who have lived on it is of no use to the engineer * * *; but, if this man was also preoccupied in studying the mechanics of the formation of earths and seas, if he tried to know the creative and destructive agencies of the mantle, then practical men will take him from the ranks and use him."

The chief engineer of a highway project is usually a man with wide general interests and technical experience. He will accept no statements which in his opinion are too abstract and cannot be used immediately in practice. Thus, the geologists must know something about the behavior of structures and pavements to speak the highway engineer's language. In addition, considerable previous practice and a certain degree of reorientation will be needed.

Through intimate contact, the writer has come to look upon geologists as exceedingly fine scholars and useful people. In all frankness, however, it should be admitted that in everyday highway practice the services of a geologist, as such, are not essential. Excellent results are attained by engineers with some construction practice and school training in soil mechanics and elements of geology. However, in exceptional cases (for instance, if there are important structures such as tunnels or large dams or if a considerable number of landslides occur), it would be a serious mistake not to seek the advice of an able and competent geologist.

True Value of Soil Investigations.—As a matter of course, whoever is in charge of the preliminary soil investigations must furnish correct results and must report a true picture of both surface and subsurface soil conditions. Nevertheless, the accuracy of soil investigations is not a guaranty of the safety of a given structure. An excellent proof of this statement is furnished by Mr. Huntting himself (see heading, "Competency of Materials for Bridge Foundations") when he mentions an $80,000 bridge that failed due to poor design although presumably soil conditions were fairly well known. Structures stand successfully either because they were adequately designed and built by skilful engineers or purely because they have been lucky enough to escape critical conditions. The writer disagrees with the statement that the San Francisco-Oakland Bridge "stands as a monument to the worth of careful preliminary foundation investigations." If that bridge is to be considered as a monument, it is a monument to the ability of its designers and builders. During the period of most active railroad construction, many structures were built practically without soil investigations. If many of them still stand, can they be considered as monuments to the absence of soil investigations?

Uncertainties.—Superficially, one would conclude that in any investigation of the physical properties of a pavement subgrade an extremely meticulous study of all hard and soft spots should be made. On the contrary, Francis M. Baron, Assoc. M. Am. Soc. C. E., has shown (65) that a hard spot corresponding to a 25% reduction in computed deflections results in the rather small reduction of about 18% in the computed critical stresses.

In some cases, therefore, the study of the pavement subgrade may be simplified and standardized considerably if in a given locality there are only a few types of soils to deal with in the subgrade. In such cases simple auger borings, to a depth of, say, 4 ft, are made, and the thickness of the pavement is determined from practical observations of the behavior of existing pavement slabs on similar soils.

Frost-Heave Problems.—Under the heading, "Frost-Heave Problems," Mr. Huntting states that "The clay acts as the medium through which water rises from the water table by capillarity until it reaches the frost line where it freezes * * *." As a matter of fact, from the point of view of frost heaves, clays are less dangerous than silts since the latter possess both sufficiently great height of capillary rise and fair permeability. Clays, as a rule, lack permeability (66).

Balancing Cuts and Fills.—A field in which geologists could learn something from the engineering profession is in the approach to determining the degree of compaction of the earth mantle. In glacial zones, such as the Southern New England Zone, excavated earth (not rock) when placed in a fill shrinks —perhaps an average of 15%. This means that, in nature, glacial soils are not compacted enough although they have been compressed by huge masses of ice. Furthermore, the degree of compactness is not uniform throughout a given region.

The designing engineer must know how many cubic yards of fill can be made from 100 cu yd of excavation at a given place. Although some information on this subject can be obtained by conducting small excavating and filling experiments, a better approach is needed. In this connection, it is regrettable that (see heading, "Prediction of Character of Material to Be Excavated") Mr. Huntting did not mention anything about the influence on the excavated material, especially on its volume changes, of the following two factors: (*a*) Depth of the water table at the borrow pit; and (*b*) season of excavation. The writer recalls a case in which 100 cu yd of a material containing a certain percentage of fine particles, excavated in the neighborhood of a lake, pond, or river, furnished less than 100 cu yd of fill in summer and more than 100 cu yd of fill in early spring, due, of course, to additional water pumped from the water table during the frosts.

Conclusion.—Various specialists play a useful rôle in highway work—surveyors, designers, construction and maintenance engineers, mechanics, contractors of all kinds, chemical engineers and asphalt technologists, mathematicians and stress analysts, economists, statisticians and accountants, weather men, soil mechanicians, and geologists—and each of them has his place in the entire picture.

ROBERT F. LEGGET,[21] M. AM. SOC. C. E.—There will be little quarrel with most of the general statements formulated by Mr. Huntting. Many of them present, with renewed emphasis, well-known facts which may often be overlooked by engineers in practice. The examples presented in the paper are all interesting and useful to supplement the general propositions.

In this paper Mr. Huntting has covered an extremely wide field. It must be admitted that highway engineering itself covers many phases of engineering activity. At the same time, it must also be observed that the term "highway engineering" is used generally to denote engineering work specifically related to the construction of highways. Mr. Huntting goes far beyond this special field and really covers much of the general practice of civil engineering. In view of this, his statement (see heading, "Introduction") that "* * * no treatment of the subject as a whole is available" might have been qualified in some way. The writer may perhaps be forgiven for mentioning a book, "Geology and Engineering (12)," in which six separate chapters are devoted to six of the main topics discussed by Mr. Huntting, most of the remaining topics being dealt with in other parts of the book, although not to the extent of entire chapters.

Again, Mr. Huntting appears to suggest that the geologist, by himself, can undertake many of the tasks discussed in this paper. Therefore, the following countersuggestions (see heading, "Investigation and Prediction of Subsurface Water Conditions and Location of Underground Water Supplies") are satisfactory: "The geologist's prediction is not infallible, * * *" and (see heading, "Competency of Materials for Bridge Foundations") "A purely geological exploration of a proposed bridge site is seldom productive of enough detailed and precise data to be sufficient in itself, * * *." It is hoped, therefore, that Mr. Huntting will be willing to apply such qualifications to most if not all the problems discussed in his paper. In such work, the cooperation of geologist and engineer is most desirable. The problems, however, are essentially engineering problems in the solution of which the engineer calls to his aid the information which he can obtain through the detailed scientific study of the geologist. Doubtless this is what Mr. Huntting intended to suggest in his paper but certain parts may cause different impressions in the minds of readers not privileged to observe such cooperation as he suggests.

A particular instance of possible overemphasis on geology is the "Bibliography" of the paper which lists a number of publications quite definitely in the field of soil mechanics (essentially an engineering study), for which geology provides only a most necessary background. It is of interest perhaps to recall what Karl Terzaghi, M. Am. Soc. C. E., called "* * * the striking contrast between what we expected when digging into the earth or loading it, and what really happened * * *." Professor Terzaghi then stated (67):

---

[21] Associate Prof., Civ. Eng., Univ. of Toronto, Toronto, Ont., Canada.

> "I * * * hoped to discover the philosopher's stone by accumulating and co-ordinating geological information * * *. It took me two years of strenuous work to discover that geological information must be supplemented by numerical data which can only be obtained by physical tests carried out in a laboratory."

These comments are intended only to emphasize Mr. Huntting's arguments as noted, to the effect that geology is but one means of assisting engineering work.

The date 1888 (see heading, "Introduction") presumably refers to the publication of a paper in the *Proceedings* of the Geologists' Association (Great Britain) (68). Quite a number of publications before this date are available which include references to geology and highway engineering, most notably the writings of John Loudon McAdam; but, despite this long history, it is indeed significant that so little has been published with regard to this application of geology.

The author makes a reference (see heading, "Location of Suitable Road-Surfacing Material Pits and Quarries") to test pits, the use of which is described as haphazard. It is suggested that a very important function of geology in relation to highway engineering is guidance in the proper selection of test pits as a more useful means of exploring subsurface conditions. Test pits are sometimes placed in a haphazard manner, but this does not seem to justify the rather critical comment on them in the paper.

With reference to the surveys of road materials by the state highway departments, the Geological Survey of Canada has made investigations of this type for a considerable period, some of these publications dating back to 1916 (69).

The writer would appreciate Mr. Huntting's explanation of the term "traprock" (see heading, "Suitability of Various Earth Materials for Surfacing, Concrete Construction, and Other Highway Uses"), since its use does not appear to be generally accepted in geological circles as a specific name. It is frequently used in engineering circles but seems to be one of those very general terms, the use of which is unfortunate and, therefore, to be avoided in all carefully prepared publications. It is interesting to note (see heading, "Subgrade Treatment and Classification") the suggestion that the fundamental geological classification of soils (with reference to their origin) should be a "supplementary" classification. Surely this classification is of prime importance and should be utilized before other classifications since so many subsidiary features depend on it.

Finally, and with respect, the writer would ask what is meant by the term "within limits" in the suggestion (see heading, "Prediction of Character of Material to be Excavated") that "Within limits, the depth and shape of such deposits are reliably predictable by competent geologists." Determination of the extent of deposits of soil is always a most difficult matter. Here indeed geology can be of assistance in guiding the necessary subsurface exploration work.

These critical comments all refer to matters of detail only. They do not question Mr. Huntting's main thesis with which the writer is in entire agreement. It is indeed encouraging to find such a paper as this in the *Proceedings* of the Society, its publication being in itself evidence of the growing appreciation of geology by the engineering profession. The paper should do much to develop this appreciation.

Irving B. Crosby,[22] Affiliate Am. Soc. C. E.—Geology in highway engineering is one phase of engineering geology, that is, the application of geology to the problems of civil engineering. It appears to have become fashionable to consider engineering geology as something new, but for more than half a century geology has been applied increasingly to a great variety of civil engineering problems on many types of projects. The use of geology in highway engineering was among the first of these applications. As early as 1889 an article was written in the United States about geology and highways (70). By 1918 considerable literature was available on the geology of road materials.

Although the geology of highway engineering had an early start more attention was given to other phases of engineering geology, particularly to the geology of dams. This was probably due to the fact that these problems are generally more critical and the need for geologic investigation more pronounced. Dam projects, however, involved many cases of the application of geology to road construction both in the relocation of highways about reservoirs and in the building of access roads.

Engineering geology has developed into a separate profession which requires competence in many of the specialized fields of geology and also experience in allied sciences and an understanding of engineering. The breadth of the field makes cooperation with other sciences and techniques essential to the successful practise of engineering geology. To meet the many demands of this profession successfully, the practitioner must give his full time and energy to its study. It cannot be practiced successfully by one whose primary interest is in some other field of geology or engineering.

The twelve problems listed by the author do not cover all the possible applications of geology in highway engineering, but they do include a wide range of problems in which geology is useful. Some of them involve other sciences or techniques, as is frequently the case in engineering geology, but all of them involve geology and experienced engineering geologists can contribute to their solution. The pertinency of geological study of frost-heave problems (Problem 5) may be challenged by some, but the basic investigations which gave the first true understanding of the cause of this phenomenon were made by a geologist (15) (38). An engineering geologist can locate areas where frost heaving is likely to occur, and if these areas cannot be avoided in laying out a road provisions can be taken by the engineers to minimize frost heaving.

---

[22] Cons. Eng. Geologist, Boston, Mass.

The foundations of bridge piers (Problem 7) present problems which may be simple and easily handled by an engineer or which may be complex and may require geologic investigation. An experienced engineer should recognize the cases where geologic cooperation is needed. Buried, former river channels, which were missed by drilling, have been found by geologic study, and the detection of buried channels may be an important problem in connection with the location of bridge piers. The physiographic interpretation of aerial photographs is often helpful in this connection.

Problem 8, the location of bridges and highways with respect to possible changes of stream channels, is most important with aggrading streams. These changes may occur, due to local conditions, in areas which are in the youthful stage of erosion and where the general tendency is downward erosion. Therefore, recognition of the true regimen of the particular part of the stream in question is important. The behavior of meandering streams is not yet thoroughly understood but progress recently has been made on this problem by the Sub-Committee on Landforms of the Committee on the Dynamics of Streams of the American Geophysical Union. This committee, composed of engineers and geologists, has published several reports (71) and one of its members has published the results of field and laboratory investigations on meanders (72). Application, by an engineering geologist trained in physiography, of the known principles of stream meandering to this problem can make possible a selection of locations which will obviate or minimize future trouble from shifting channels.

Ground-water problems are handled by both professions, but the occurrence and movement of ground water depend upon the character and structure of geologic formations, and geologic investigation is desirable except in the simpler problems. A special problem of relatively rare occurrence is to detect places where highway excavation and drainage lowers the ground-water level and injures ground-water supplies.

Engineering geology is a valuable tool which, when used by an experienced, competent man, can aid in the solution of these and many other problems of engineering. It is no panacea, however, and it has its limitations. Some problems can be solved by surface, geological observation alone, many others require subsurface exploration by drilling, test pitting, tunneling, or geophysics, and for some difficult problems it is economically not feasible to obtain an accurate solution. In this latter case, however, the engineering geologist can, and should, show the limits of the conditions that can occur and explain to the engineer the type of difficulties which he must prepare to overcome. When extensive subsurface exploration is necessary some think that a geologist is not needed. On the contrary, however, an engineering geologist, by means of his understanding of the geologic forces that have acted on the formations, can lay out the investigation to reduce greatly the amount of exploration necessary; and then he can obtain the maximum information from it by correct interpretation. This requires understanding on the part of the engineer; he should allow sufficient exploration to enable the geologist to reach an intelligent and useful conclusion. On the other hand, there have been cases in which a geologist has demanded an inordinate amount of exploration to cover up his lack of experience. There is a happy medium which, unfortunately, is not always attained.

Obtaining competent engineering geologists to solve the problems of highway engineering or the other problems of engineering geology constitutes a problem with many difficulties. Engineering geology apparently appeals to many geologists as an attractive, easy, profitable field, and many geologists without experience in engineering have attempted to conduct investigations in it to the great detriment of the profession of engineering geology. At the other extreme are those who believe that, after a few courses in geology, engineers become competent to handle problems in engineering geology. This is just as dangerous as the other practice mentioned. Some understanding of geology by the engineer is essential, however, and the better he understands it, the less the danger of his overlooking some problem in which geologic aid is necessary. The most important requirements for competence in engineering geology are a thorough training in geology and a very broad experience in its application to many types of engineering projects on all types of geologic formations. A man experienced on a few types of problems in a limited area may make disastrous mistakes when he encounters different problems or different conditions. The apparent failures of engineering geology which are sometimes charged against it are often the failures of individuals who were not competent to handle the problems.

The early work in engineering geology was done by consultants who specialized in such work. Later some of the larger governmental organizations developed geological staffs composed largely of young geologists with little or no previous experience in engineering geology who were trained on the job at the expense of the job. A few state geological surveys have engineering geologists who are used in connection with highway work as has been explained by the author.

The use of consultants on special assignments is well adapted to the problems of dams where the work is concentrated and usually of considerable size. The more widely scattered problems of a highway department may not appear to be so well suited for investigation by a consultant, but when the work is well organized and especially when a permanent geologist or staff has collected data and done much routine work the more important problems can be handled, quickly and efficiently, by an experienced consultant.

The wide variety of problems in highway engineering may appear to require a large number of specialists but such is not the case. It is true that there will be problems in engineering geology, structural geology, sedimentation, physiography, ground-water hydrology, economic geology, petrology, materials testing, soil mechanics, and geophysics, but a competent engineering geologist must be trained and experienced in all but the last three and should know something about them. When particular problems in petrology arise, for example, they can usually be handled by a specialist in a university. A state highway department may have sufficient geophysical work to justify the full-time employment of a geophysicist; then, too, it may be more economical and satisfactory to engage outside consultants for that work. A department with an experienced engineering geologist and a specialist in soil mechanics and testing with assistants in proportion to the amount of work and arrangements for geophysical investigations would be competent to meet the wide variety of problems. On problems of special importance an experienced consultant in engineering geology should be used to obtain the advantage of broader experience. Some departments may handle their work most efficiently by depending entirely upon consultants for investigations in engineering geology.

Mr. Huntting has done a service both for engineers and geologists by describing many of the problems in which geology can be useful in highway engineering. He has outlined briefly the way in which geology is related to some of the problems; he has explained its value as a tool for the engineer, and discussed some of its limitations.

HYDE FORBES,[23] M. AM. SOC. C. E.—It is a matter of satisfaction to the writer that the Society has published another paper in the interest of applied geology. The paper is specific in its application to highway engineering, but the treatment is broad enough to apply to many fields in which civil engineers are active. It is of distinct value in further calling the attention of engineers and educators to the application of geology in engineering development and construction.

The late J. C. Branner, head of the Department of Geology at Stanford University, Stanford University, Calif., until his death in 1922, was a scientist of broad vision, and his efforts and accomplishments in the practical application of geology in the fields of petroleum and mining engineering are attested through the accomplishments of his students after graduation. The curriculum he developed was very broad, in that abridged courses in civil, mechanical, chemical, and electrical engineering were required, with opportunities to the individual for specialization in mining, metallurgy, petrography, geochemistry, ore deposits, paleontology, and petroleum.

The writer was particularly fortunate in having Professor Branner select him to direct in work in a new field in which the professor was endeavoring to obtain interest, research, and study; namely, Engineering Geology. After being graduated in 1913, the writer was employed under Professor Branner and was subsequently recommended by him to other similar positions prior to World War I. During these engagements, primarily directed to the investigation of the geology and ground-water conditions of certain areas, it was found that employers had problems involving geology upon which the engineers solicited the writer's services and advice.

The first of these positions, with the Spring Valley Water Company of San Francisco, Calif., afforded opportunities to do work in connection with the watertightness and stability of the abutments for the Calaveras Hydraulic Fill Dam then under construction, and the physical and geochemical characteristics of the materials used in the fill. Similar opportunities were afforded in connection with the foundation investigation for, and the construction of, the base of the Gibralter Dam by the City of Santa Barbara, Calif., in 1915, when the writer was investigating ground-water problems. Professor Branner was consulted and, with the advice of consulting civil and hydraulic engineers contacted during those employments, the writer attempted the preparation of a curriculum aiming at collegiate specialization in engineering geology.

---

[23] Cons. Engr. and Geologist, San Francisco, Calif.

After Professor Branner died in March, 1922, the attempt to institute a curriculum at Stanford University emphasizing the practical application of geology in the field of engineering development and construction was not successful. However, the writer has continued to expand the outline for applied engineering geology which he established in association with Professor Branner and in the collection of material as his experience has broadened. His files and library are indexed and cross-indexed under the headings of that outline, in all of which he has made practical and technical application of the science of geology and under which he has found much of value in the engineering literature. The writer presents that outline here in acknowledgment of his debt to Professor Branner and in the hope that it will be of service to engineering educators:

(1) Geology of Rock Formations.
  (*a*) Character and structure—jointing and fractures.
  (*b*) Weathering—effective depth and geochemical change.
  (*c*) Interstitial binder—primary and secondary cementation, vein filling, healing of fractures.
  (*d*) Strength, specific gravity, watertightness, stability, solubility.
(2) Geology of Unconsolidated Formations.
  (*a*) Source of material and method of deposition.
  (*b*) Erosion, transportation, and silting.
  (*c*) Geochemical change and physical change in transportation and deposition, solution, oxidation, carbonization, hydration, abrasion, and wear; further changes to be expected.
  (*d*) Structure, porosity, and permeability.
  (*e*) Water content—drainage and recharge.
(3) Engineering Seismology.
  (*a*) Recognition and location of faults.
  (*b*) Determination of activity of faults and intensities of earthquakes.
  (*c*) Affect of vibrations on engineering structures.
  (*d*) Location of highways, pipe lines, and structures in reference to active faults.
  (*e*) Earthquake resistant construction.
(4) Applied Ground-Water Hydrology.
  (*a*) Occurrence, movement, and head of ground water.
  (*b*) Chemical and mechanical properties of ground-water movement and their effect upon the containing media; affect of ground-water pressure.
  (*c*) Development of water supplies—through physical works such as wells, spring development, tunnels, and galleries.
  (*d*) Safe yield and expected life of ground-water developments.
  (*e*) Spreading of water for ground-water recharge.
  (*f*) Drainage of saturated ground.
(5) Landslides and Earth Movements.
  (*a*) Occurrence, investigation, and correction.
(6) Soil Technology.
  (*a*) Occurrence, and classification of soils.
  (*b*) Development of soils and geochemical changes, from origin in rock fragments or products through stages in development.
  (*c*) Soil mechanics—the mechanical properties of soils as foundation material and for use in engineering structures.

(7) Natural Structural Materials and Methods Adapted in Construction.
    (*a*) Earth-fill construction, compaction, stability, geochemical change.
    (*b*) Hydraulic fill construction, effect of water and transportation.
    (*c*) Rock-fill construction, durability, insolubility, crushing strength.
    (*d*) Subgrade for roads, highways, and air ports.
(8) Foundations.
    (*a*) Geology of dam sites, requirements of structures.
    (*b*) Foundations for bridges.
    (*c*) Foundations for highways.
    (*d*) Foundations for buildings and other structures.
(9) Tunnels and Tunneling.
    (*a*) Investigation, location, design of support required.

If the engineering student is given an opportunity to obtain a basic knowledge in the foregoing subjects, he will enter his professional career well equipped to understand natural conditions and the use of natural materials, and, what is more important, with sufficient knowledge to be aware of his own limitations and to know wherein the services of a specialist are required. This lack is responsible for a large number of failures of structures. The geology student, on the other hand, will have his eyes opened to the possibilities of a specialization that will bring much satisfaction and opportunities for service. In the past, the engineer has made the mistake of assuming that a man who has acquired a college degree in geology "knows all the answers." A geologist cannot see underground any better than the next man, but he can recognize certain conditions from surface indications and, with adequate experience, will learn how to gain subsurface knowledge and apply his basic knowledge correctly.

Under the head of "Problems," the author lists twelve items in which the geologist's services might be profitably engaged. He then discusses these from the standpoint of an experienced engineering geologist. The writer agrees with the first premise, but the testing of material goes beyond the province of the geologist in the opinion of the highway engineer, and it is true that the geologist requires additional specialized training and knowledge in applying his basic training and knowledge to problems (1), (2), and (3). The geologist must have more than a basic training and knowledge of hydrography and ground-water hydrology, too often lacking in the collegiate training, in order to be of value in connection with problems (4), (6), (8), and (10).

Training and experience can be acquired just as well, and in as short a time, on engineering development work and construction as in the field of applied geology, which has been most often associated with geologists by the engineering profession—namely, mining engineering and petroleum engineering. It has always appeared to the writer that the failure to apply geological training and knowledge properly in highway engineering was the cause of considerable economic waste.

Beginning in 1928 and continuing well into the depression years, the oil companies of the West found that the surface geological structures were practically all determined, overproduction was causing difficulties in the industry, and geological staffs were drastically cut. The older geologists were absorbed in administrative and executive positions, but the younger men were dismissed. Many of the latter came to the writer to discuss opportunities for employment and the broadening of their activities. The advice given was that they should take the examination for junior engineer in the State Highway Department and then make a job for themselves as an opportunity arose to show that the application of their special knowledge was of value. Several men took the examination, got on the lists, but were not called after long periods of waiting.

It was felt that some preference in the matter of hiring should be given men having such qualifications, and a letter was written to the Chief Engineer of the State Highway Department setting forth this matter and submitting an outline covering the application of this special knowledge in highway engineering. A conference was arranged at the State Capitol at which the subject was received with enthusiasm by the division engineers in attendance but with a lack of enthusiasm by the executive head. The writer was given to understand that such a setup would require a centralized control, which highway engineers were trying to avoid, or the retention of a consultant for the direction of the field men, which was against their general policy. As far as is now known, no benefits were derived from this effort.

In 1928 the writer was appointed to a committee of the San Francisco (Calif.) Section of the Society to study the foundation and subsidence question over the built-up area of San Francisco. The writer presented the viewpoint of the geologist, and these discussions, resulting in a report published subsequently by the Section, opened up to the writer a field of application of geology and study—namely, foundations for buildings on unconsolidated materials.

The author discusses the problem of acting as a witness in litigation (see problem (12) under the heading "Problems"). Litigation affords the time and money for extensive and exhaustive research such as is never available in engineering development and construction. Court presentation of the engineer's findings is subjected to the keenest, critical analysis in cross-examination. The writer has sometimes observed expert witnesses attempt to solve mathematically the problems of the underground. When purely mathematical solutions are attempted and broken down under cross-examination, or matched by one factually determined, it soon becomes apparent that nature does not act in an empiric manner and that empirical formulas do not apply. One is greatly impressed with the degree of confusion and the ridiculous results achieved when values of reasonable variance from those selected by the proponent, as assumption or small-scale test result, are substituted in a formula. A mathematical computation, involving factors evaluated through assumption, or determined by small-size sample test, is no better than the value of that assumption or test. Its result might have been better stated as the proponents' unsupported opinion in the first place.

A study of geology reveals that geochemical change breaks down grain size with comparative rapidity. Under one set of conditions geochemical change occurs in natural material to produce a certain product and under similar, but slightly varying conditions, the change undergone by the same material yields a different product. Moisture contents of materials, determined as percentages of their oven-dried weights, do not take into consideration any of the water adsorbed or water that remains in fixed chemical combination. There is no constant law as to the quantity of water that may be taken up in chemical combination by the natural materials. For the foregoing reasons it is difficult to accept mathematical calculations based on sample tests.

There is no such thing as an undisturbed sample. The act of sampling implies disturbance from its position of confinement and support, and a new relationship to air—its oxygen, carbon dioxide, and moisture. The degree of disturbance can be ascertained only through knowledge of the geologic history, the physical condition and ground-water condition of the wider area sampled. That does not mean that sampling and testing should be abandoned. Boring and sampling, and more exploration boring, are needed to give as complete knowledge of the subsurface conditions as possible; but the limitations of the results obtained must be realized and used, within those limitations, to denote action, reaction, trends, and ranges, as tools to work with in the exercise of judgment. The writer uses shear tests, compression tests, physical, chemical, mechanical, and moisture analyses in his work for that purpose; but, in bearing-capacity determinations in foundation investigations, he depends upon positive vertical cyclic loading of the undisturbed foundation material; and for settlement he depends upon the experience recorded upon the same or similar foundation conditions determined through complete boring exploration.

To summarize, engineering education has not provided comprehensive curriculums in applied geology but has gone "overboard" on "soil mechanics." Former students and graduates of the Stanford Geology Department have told the writer, during the past several years, that only two fields of activity appear to be open to them—teaching and the United States Geological Survey. More than fifty graduates have joined the Survey, and, after World War II, with the restriction of appropriations such as occurred after World War I, many will be seeking new employment. If they are forced into commercial lines, as geologists were during the early 1930's, much training, knowledge, experience, and ability will be lost to the profession.

The profession as a whole does not recognize and appreciate the importance of applied geology in connection with engineering development and construction and it has overemphasized soil mechanics far more than its importance warrants.

A. A. Eremin,[24] Assoc. M. Am. Soc. C. E.—By illustrative examples, Mr. Huntting has shown the importance of geological investigations in highway construction. In the past few decades considerable interest has been expressed in the value of geology. In various universities the introduction of courses in soil mechanics and geology has increased the curriculum requirements for engineering students.

Economic considerations fully justify geological study for highway structures. Various devices have been developed to insure safety in structures. Streams are regulated and protected by various types of embankments. Bridge seats are designed to follow pier displacement resulting from the movements of various geological formations. In tunnel construction a temporary lining is used to study the characteristic features of the soil penetrated by the tunnel.

---

[24] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

Without these engineering devices, geological science is still unable to yield reliable results. Further progress in soil mechanics and geology may be obtained through the cooperative effort of engineers and geologists by interpreting construction failures. A tendency still prevails to overshadow or to hide the real causes of some important structural failures. It is true that learning through failures is an expensive method; but an investigation of the failure of a structure designed according to standard assumptions is still the most reliable and effective method of improving design and construction. Many types of accidents are repeated constantly because no one studies the causes sufficiently. The final design of many large tunnels is the result of careful investigation of partial failures that occurred during construction.

Marshall T. Huntting,[25] Esq.—Every thinker or writer must inevitably be biased by his own particular training and experience. Hence, the writer may have overemphasized the place of geology in highway engineering, or he may have placed relatively too much emphasis on certain subjects. The discussions charging overemphasis or improperly placed emphasis are subject to the same analysis, of course. One man charges that soil mechanics or soil science has been neglected; others object to including the subject of soils in a geological discussion. As was pointed out by Professor Terzaghi, soil mechanics is not a substitute for engineering geology. The opposite is also true. The two should be complementary, with soil tests and geological investigations combined, to obtain best results.

The experience of at least five discussers shows that clay is not a major constituent of the soils where frost heaving is worst. The formation of ice layers causes heaving. Wherever the water table is higher than the frost line, heaving will almost certainly occur, and the more permeable the soil the more water can be furnished to freeze into ice layers. Therefore, even gravels may be heaving soils. In fact, the sand and silt soils where the water table is high will be the worst offenders for that reason, and clay is preferable because of its nearly impervious "insulating" effect. On the other hand, in areas where the water table is well below frost level and heaving is less common the water must rise by capillarity to reach the trouble zone. In this case, the writer contends that clay, mixed with other soil constituents, adds to the capillarity of the soil and makes a given soil a frost-heaving offender, whereas, under identical drainage and water-table conditions, the same soil without its clay content would not cause the water to rise high enough to allow heaving to occur. To prevent frost heaving, the examiner first must make sure the water table is below frost line. Then he must balance two costs against each other:

(1) The cost of further lowering the water table to below the depth from which water may rise by capillarity to the frost level; and

(2) The cost of breaking the capillary rise from the water table to frost level by filling with gravel or by some other means.

---

[25] Private, U. S. Army, Student Company G, Student and Service Regiment, Ft. Belvoir, Va.; formerly Geologist, State Div. of Geology, Dept. of Conservation and Development, Pullman, Wash.

Where sands, silty sands, and silts without clay are soils that heave, the writer suggests that this fact in itself may be sufficient evidence of a high water table and thus may simplify preventive studies by indicating directly the need for better drainage—no other preventive measure being applicable. Such reasoning would not necessarily apply in the case of silts, which have considerable capillarity even when clay is present in very small percentages.

Admittedly, the writer's statement (see heading, "Frost-Heave Problems") —"It has been shown that in many, if not most, instances of frost-heave disturbances clay is a major constituent of the subgrade material"—is in error. It should be amended by the addition of the clause "where the water table is well below the frost line." Also "major constituent" is much too vague a term for use when not accompanied by statistical data. Possibly, a fruitful line of research would be a study of the relation between soil particle size and capillarity, using samples taken from heaving soils. A comparison of the effects of the several individual classes of clay minerals would be important in such a study. A soil with a certain percentage of clay of one mineral composition might be expected to give results different from those given by soils with the same percentage of clays composed of other minerals.

How the soundness of a bridge superstructure can be independent of foundation materials, as stated by Mr. Feld, is difficult to conceive. A number of bridges have failed because piers and superstructure were not properly designed for the existing foundation conditions. In the discussion of bridge foundations, the writer did not wish to "indicate that taking and testing soil samples is entirely the work of geologists." His statement (see heading, "Competency of Materials for Bridge Foundations") was,

> "The geologist's sphere of usefulness in mechanical sampling lies in examining samples; in helping to interpret the samples in terms of dimensions, structures, water-bearing characteristics, and load-bearing capacities of subsurface formations; and in combining his interpretation of subsurface conditions with features of general and local geology to form the basis for recommendations for further sampling and testing."

The actual work—taking samples, testing physical properties, and most of the interpretation of physical tests—should be done by soil mechanicians and other qualified men.

It is interesting to paraphrase Mr. Feld's instance of the contractor who found himself in the class of an ex-contractor because he relied on a geological prediction that a certain hill was composed of glacial till, when excavation found solid rock instead: A patient died as the result of using drugs prescribed by a doctor who made an incorrect diagnosis of the patient's ailment. Perhaps the doctor was not very competent to diagnose that type of case, or perhaps his examination was not complete enough. In any event, such an example is scarcely a basis for condemning all doctors or the medical profession as a whole; nor does it indicate that it would have been preferable for either the patient himself or the druggist to diagnose the case and prescribe the medicine to be used.

Mr. Feld's experience undoubtedly has been shared by others. The cost of excavating solid rock would be less than that of excavating the type of earth encountered, but evidently solid rock was not preferred in the case Mr. Feld himself cited in the preceding paragraph of his discussion. In most instances, excavation of unconsolidated materials would be preferable; but the question is not what is more desirable but what will be found and in what quantities in a given excavation. The geologic history of the area will contain the answer, and the better the investigator knows that history the better equipped he is to find a solution.

In reply to Professor Legget's question as to the use of the term "traprock," admittedly the term should be avoided, and the writer's only excuse is that, in an earlier, unpublished, more detailed version of the paper, a table was included from a governmental publication giving the average results of physical tests on thousands of samples of various rock types. One of the rock types listed was "traprock." In the published version of the paper this table was not included, but inadvertently the term was retained in the text. For the purpose of this paper, "extrusive igneous rocks" should be substituted.

The "within limits" which Professor Legget questions should refer to the limits of the examining geologist's ability and the limits of geology in general, not to the limits of the depth and shape of the deposits.

Mr. Moneymaker partly answers his own question: "How should a state highway department provide for its geologic work?" Mr. Crosby offers further clarification. The answer depends upon the amount of geological investigation needed, the organization of the highway department, and the geological personnel and facilities available and economically practicable. These conditions vary widely from one state to another; each state has its own special problem.

The geologist who is to work with engineers when needed should certainly be an engineering geologist who devotes his full time and interest to that specialty. He cannot be primarily a petrologist or primarily a physiographer, for example, since geology like engineering is a highly diversified subject. Many geologists have specialized to such an extent that they have little knowledge of, and less interest in, the geological fields not included in their own lines of specialization. The engineering geologist must be competent in most of the special fields and should have a wide range of interests and a broad outlook. His willingness to recognize his own limitations is extremely important. He must not overstep the bounds of his competency and should know when to call for the assistance of other specialists.

There are many geologists who think of their science as an end in itself. Obviously, such an attitude is unsuited to the practical field of engineering, where science is but a means to an end.

SURGES IN PANAMA CANAL REPRODUCED IN MODEL

By F. W. Edwards,[1] M. Am. Soc. C. E., and Edward Soucek,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Harold A. Weggel, Harry Leypoldt, C. J. Posey, and F. W. Edwards and Edward Soucek.

Synopsis

A 1 : 60 scale model of Gaillard (formerly Culebra) Cut was built in the Panama Canal Hydraulics Laboratory for the study of surges caused by lock operations. The verification tests described in this paper consist of water-surface observations of model and prototype at corresponding locations and times, during and after corresponding lock operations. The success of these tests was made possible by the cooperation of various divisions of the Panama Canal.

The Problem

Gaillard Cut is an 8¾-mile reach of the summit level of the Panama Canal, extending from the Pedro Miguel Lock to Gatun Lake at Gamboa. Fig. 1 shows cross sections at the observation stations. The operation of filling Pedro Miguel Lock creates surges which increase the difficulty of handling ships in the Cut. Although the condition is not particularly serious at present (1942), it will be aggravated by the operation of a proposed larger lock. The navigation conditions at the junction of the proposed by-pass channel for the proposed third lock and the existing channel are of special importance. No further consideration will be given to the navigation problems involved. This paper is confined to a presentation of the results of verification tests.

Prototype Tests

The prototype observations were made in December, 1939, prior to the construction of the model. All tests were conducted at night after traffic in the Cut had ceased and the water surface had become quiescent.

Note.—Published in January, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Asst. Prof. of Civ. Eng., Pennsylvania State College, State College, Pa.

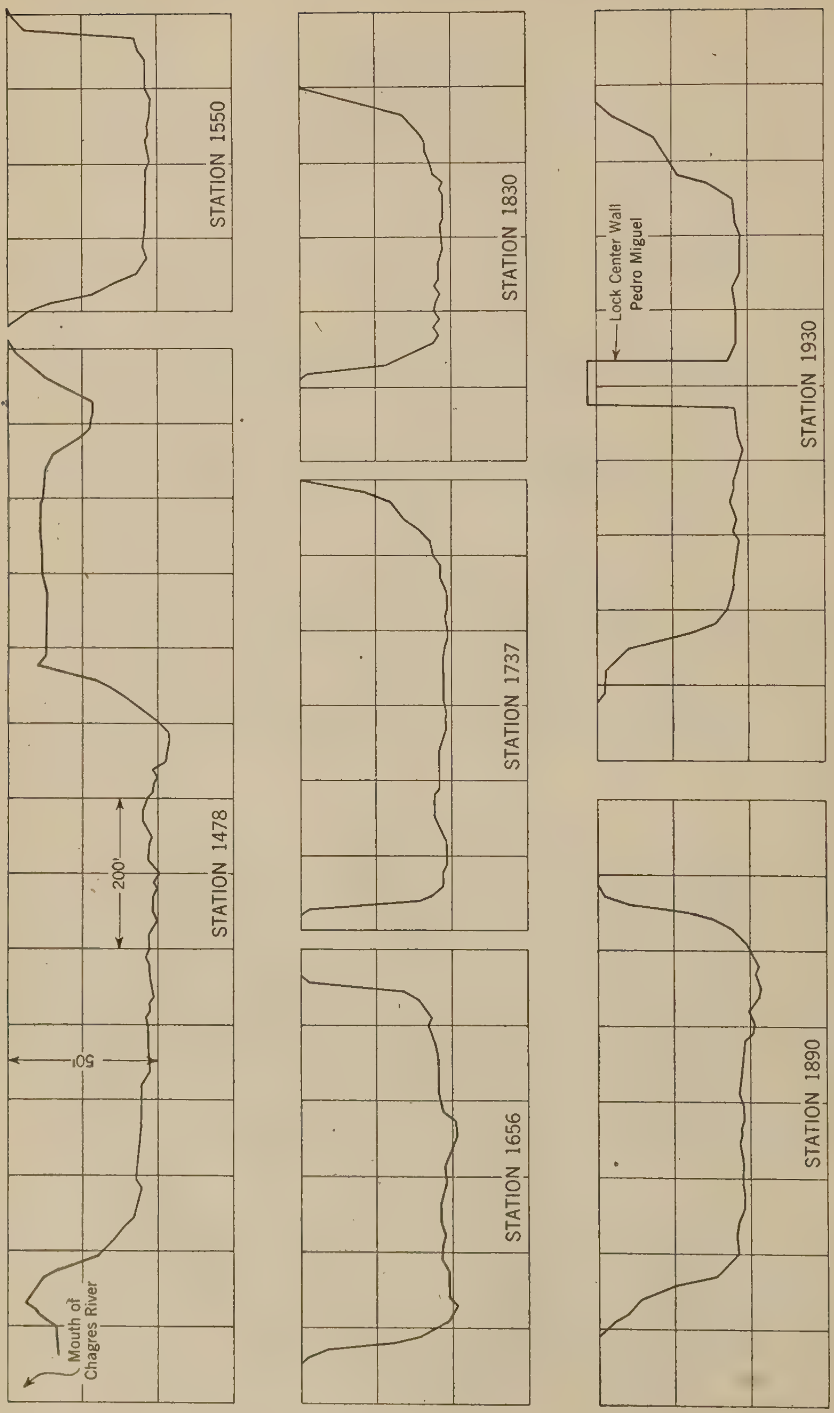

Fig. 1.—Channel Cross Sections, Viewed Toward Pedro Miguel Lock

Pedro Miguel Lock consists of twin chambers separated by a center wall. There are three filling culverts, one in each side wall and one in the center wall. The center-wall culvert is valved in such a manner that it can be opened to either chamber or to both simultaneously. The schedule of lock operations used in the tests was as follows:

Test No.	Description
I	A two-culvert fill of the East Chamber
II	A three-culvert fill of both chambers
III	Two three-culvert fills of both chambers; interval between fills 88 min
IV	Repetition of Test No. III
V	Two three-culvert fills of both chambers; interval between fills 44 min

It was necessary to plan the tests carefully because there was no means of communication with the observers. Observers met at Pedro Miguel Lock at 11:30 p. m. each night, received special instructions regarding the test scheduled for that night, were issued equipment and supplies, and were transported to their stations by launch. Synchronized stop-watches, previously checked for accuracy, were used for timing all readings and operations. All watches were started simultaneously, wound every hour, and stopped simultaneously for checking after the observers had reassembled. No adjustment of observations for errors in timing was found necessary. All equipment, such as watches, data sheets, flashlights, etc., was furnished in duplicate to each party. A party, consisting of two observers, was located at each station and at the lock control house.

Prior to the tests, a series of water-level observations was made at 10-sec intervals at one of the stations. This series was made in the daytime, under normal traffic conditions, to find the interval for test readings which would define the surges adequately. A 1-min interval was found satisfactory and this was adopted for the tests. The duration of observations each night averaged more than 5 hr.

With the exception of permanent gages at Pedro Miguel and Gamboa, temporary staff gages were installed for the verification tests. The gages were graduated in tenths of feet but readings were estimated to hundredths. The gages were leveled, prior to the tests, on a quiescent water surface during early morning hours before traffic started through the Cut. A check upon the accuracy of gage settings was obtained each night by taking readings for several minutes prior to lock operation. Small adjustments were made on the basis of these observations. Various methods of cross-checking the gage elevations were used and all indicated that the adjusted elevations were correct to the nearest one-hundredth of a foot.

THE MODEL

The model size was selected on the basis of economy, sensitivity, and relative freedom from surface tension. A distorted model was considered but rejected. Although friction was relatively unimportant, the concrete surfaces in contact with water were finished so as to give proportional friction losses in model and prototype. Lock hydraulic systems were not simulated, but filling curves—obtained during prototype tests—were approximated in the model by the use of manually operated gates. The feature most difficult to simulate was the junction of the Cut with Gatun Lake. An uncontrolled forebay large enough to simulate the lake was impracticable. A relatively small forebay (684 sq ft), with overflow troughs to maintain a constant level, was adopted. The overflow length and rate of inflow to the forebay required for similitude were determined by trial. Any constant inflow within a considerable range could be used without disturbing the similitude. This characteristic of the model supports the confidence which the writers have in the ability of the model to indicate surge conditions for which no prototype comparison is possible.

Water-surface observations in the model were made on inclined staff gages which were designed so as to minimize local disturbances. The gages were graduated at vertical intervals of one-sixtieth of a foot, representing one foot on the prototype. Readings were estimated to the nearest tenth of a foot, prototype dimension. This method of observation may be considered crude, but has been entirely justified by the results obtained. Other proposed methods had important disadvantages.

Model observations were timed by the use of a single electric timer, located at a control station. A buzzer system was used to signal the observers when readings were desired.

Nature of the Surges

Test No. II will be used to illustrate the surge phenomenon. Fig. 2 shows water-surface profiles at 5-min intervals following the beginning of lock filling. Although these profiles are based on actual prototype observations, the small number of stations permits considerable latitude in interpretation. For this reason, the profiles should be considered pictorial rather than exact.

Considerable variation in section and in average depth exists in the Cut as is apparent from Fig. 1. From consideration of approximately twenty cross sections, the average depth, y, was estimated as 41.0 ft. The corresponding wave velocity computed by the formula

$$V = \sqrt{g\,y} \qquad (1)$$

is 36.4 ft per sec. Velocities of flow are so low that wave velocities may be considered to be absolute. The point of the arrow shown with each profile of Fig. 2 indicates the position which the front of the wave would occupy if it traveled along the Cut at a uniform velocity of 36.4 ft per sec. Fair agreement between calculated and observed positions exists even after 100 min. Friction, variation in channel characteristics, and uncertainty regarding the exact stations from which reflection should be considered to occur, especially at the lake end of the Cut, would be expected to produce some discrepancy.

The surface width near the lock is about 750 ft. The rate of inflow to the locks varies, but the maximum rate in the test under consideration was approximately 22,500 cu ft per sec. From discharge, wave velocity, and surface width, the drawdown calculated by continuity is about 0.8 ft, substantially the depth which occurred. Some sections of the Cut are much narrower, the average top width being only about 480 ft. However, no increase in surge height occurred in the narrower portions of the channel. The surge height is not to be confused with velocity head.

In the 5-min profile (Fig. 2), the water at the initial level is still at rest, while flow occurs toward the lock in the depressed reach. Five minutes later, inflow to the lock has ceased and water is beginning to pile up against the lock.

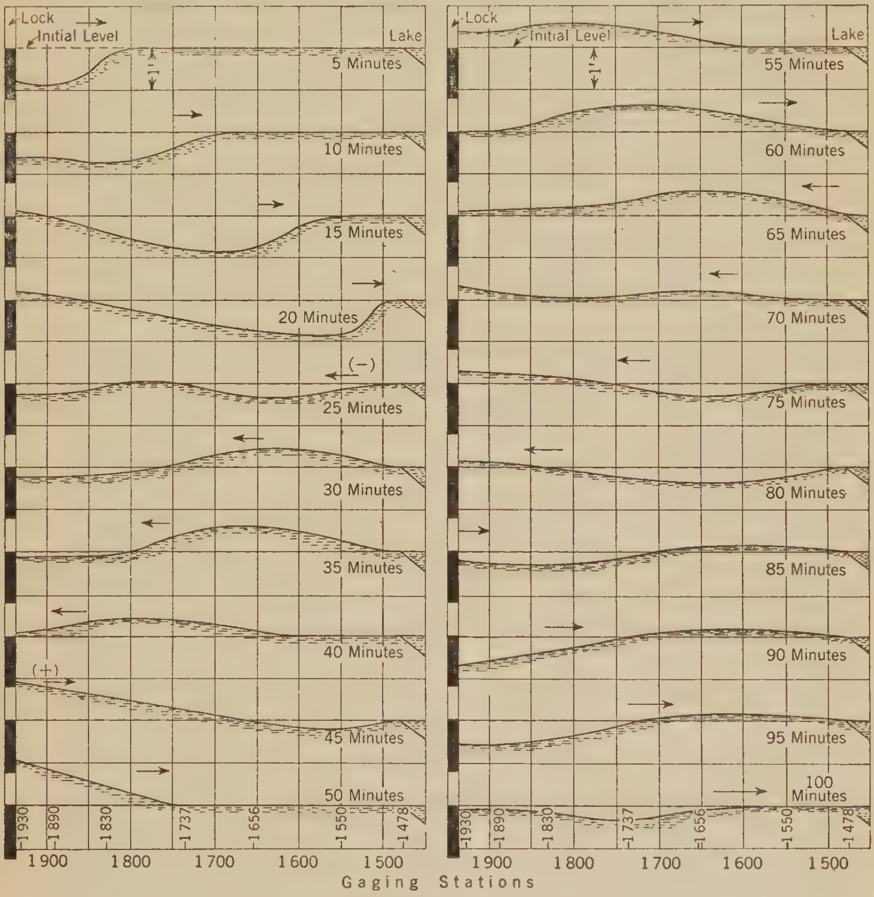

FIG. 2.—WATER-SURFACE PROFILES AT 5-MIN INTERVALS

In the 15-min profile, the surface at the lock has returned to its initial level. The "sag" in the water level at this time is a measure of the volume drawn into the locks—about 8,000,000 cu ft. Water is at rest both ahead of and behind the "sag," but it is in motion toward the lock under the "sag." Water is being transferred past the moving "sag" at a rate approximately equal to the maximum rate of inflow to the locks which occurred nearly 15 min earlier. The difference in slopes at the front and back of the "sag" is indicative of the

variation in rate of flow during the lock filling period. The length of the "sag" is a measure of the duration of inflow to the lock. The 20-min profile is a further development of the condition which has been explained.

A rigorous treatment would require that the front and back faces of the "sag" be treated separately. However, no harm to the description, and considerable simplification, result if the disturbance is considered from now on as a single wave. For discussions of the mechanics of wave reflection, reference is made to selected literature by Horace W. King,[3] Earl I. Brown,[4] and H. Rouse,[5] Members, Am. Soc. C. E. For the purposes of this paper, it may be stated simply that waves are reflected without change in sign from closed ends and negatively from junctions with large bodies of water, or those in which a constant level is artificially maintained.

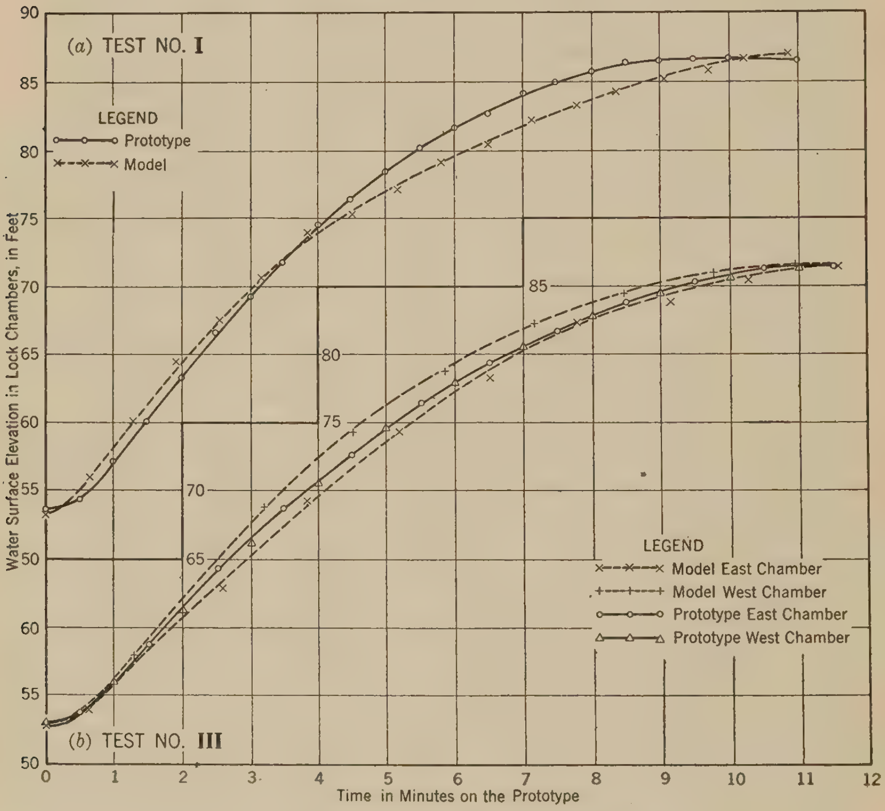

Fig. 5.—Comparison of Lock Filling Curves

[5] "Fluid Mechanics for Hydraulic Engineers," by H. Rouse, *Engineering Societies Monograph*, 1938, pp. 353–402.

The 25-min profile (Fig. 2) is a stage of the reflection in the negative sense and the 30-min, 35-min, and 40-min profiles show the return of a somewhat attenuated "hump" from the lake toward the lock. The 45-min and 50-min profiles show the positive reflection at the lock. The 55-min, 60-min, and 65-min profiles show the travel of the reflected "hump" from the lock toward the lake. The 70-min profile is the second occurrence of negative reflection and the 75-min, 80-min, and 85-min profiles show the passage of a now considerably attenuated "sag" toward the lock. The 90-min profile is the second occurrence of positive reflection. The 95-min and 100-min profiles, comparable approximately to the 5-min and 10-min profiles, show the beginning of another cycle.

The effect of successive lock fillings during either of the positive reflection phases, exemplified by Tests Nos. III and V, is predictable, at least qualitatively.

Comparison of Model and Prototype

The conformity of model observations with prototype Tests Nos. I, II, III, and V is shown in Figs. 3 and 4. Test No. IV, which was a repetition of Test No. III, is not reproduced here as the results were identical. The agreement is considered to be very satisfactory. It is evident that conclusions based upon the model observations would be the same as those based upon the prototype tests. Refinements could have been adopted which would have produced better results, but they were not warranted for the studies undertaken. It is believed that more accurate reproduction of the lock filling curves would have eliminated almost entirely the relatively small discrepancies which are indicated. Comparisons of typical filling curves are shown in Fig. 5.

A comparison of Figs. 4(*a*) and 4(*b*) is of special interest because it illustrates the result of synchronization and of anti-synchronization of the effects of consecutive lock operations.

Acknowledgments

The success of these tests was made possible by the cooperation of various divisions of the Panama Canal. Maj.-Gen. Glen E. Edgerton, M. Am. Soc. C. E., is Governor of the Canal Zone. At the time these tests were conducted Maj.-Gen. T. B. Larkin, M. Am. Soc. C. E., was supervising engineer on the Third Locks project and E. S. Randolph, M. Am. Soc. C. E., was designing engineer.

DISCUSSION

Harold A. Weggel,[6] Jun. Am. Soc. C. E.—It is very interesting to note the close conformity of model observations with prototype Tests Nos. I, II, III, and V as shown in Figs. 3 and 4. However, close conformity in five observations does not necessarily mean that all conclusions based on the model would hold true in the prototype. Test No. III and Test No. V are of special interest because they illustrate the results of consecutive lock operations; but deductions are incomplete unless the data are available for the periods of synchronization and anti-synchronization.

Observations made by the U. S. Geological Survey on the Ohio River near Huntington, W. Va., in 1938 between lock 27 and lock 28 indicate the difficulties of predicting the heights of translatory waves. At times of low discharge on the Ohio River, the slightest change of discharge, caused by operation of lock chambers and controls on the dams both upstream and downstream, was enough to create a surge. Occasionally, anti-synchronization of lock operations resulted in negative slope readings, and at other times similar operations would be the cause of superelevated translatory waves. Not always is it the amount of change of discharge that determines the height of wave or depth of trough. The rate of change of discharge may be the prime factor, especially on closing operations in conjunction with reflected waves.

The time of travel of translatory waves for the 4.65 miles between the gages at lock 28 and at 24th Street is between 17 min and 21 min; and the time of travel for the 10.6 miles between lock 27 and lock 28 (and return) is between 88 min and 100 min. Theoretical calculations give the following results for $V = \sqrt{g\,y}$ (Eq. 1): For the upper reach with $y = 10.0$ ft, $V = 17.95$ ft per sec; and, for the lower reach with $y = 13.9$ ft, $V = 21.2$ ft per sec. The time of travel is 19.3 min for the lower reach and 29.1 min for the upper reach or 48.4 min for the entire distance. At times of low flow no difference was noticed between the time of wave travel downstream and upstream.

If the canal surges in the Panama Canal are comparable to those on the Ohio River, it is doubtful whether any model could be accurate enough to reproduce the surges that would be encountered in the operation of the proposed larger lock. The only possible method is the study of the prototype itself with sufficient gages installed to plot the passage of translatory waves and to correlate the effects with the causes. When the causes of the disturbing waves are determined, it should be easy to eliminate the waves through control of the causes.

Harry Leypoldt,[7] Esq.—The data shown in Figs. 3 and 4 lend themselves to an interpretation far different from the one advanced by the authors, because the water-surface profiles show that a seiche with a period of about 29 min is present in the waterway. Let $y = 41.0$ ft; $V = \sqrt{g\,y} = 36.4$ ft per sec; and

$$t = \frac{2\,L}{\sqrt{g\,y}} \qquad \text{(2)}$$

---

[6] Associate Structural Engr., Diamond Magnesium Co., Painesville, Ohio.

[7] Los Angeles Harbor Dept., San Pedro, Calif.

in which t is the time in seconds (29 × 60). Computing the uni-nodal length of basin that will accommodate a seiche with a 29-min period, these values in Eq. 1 give $L = 31{,}668$ ft. This brings the end of the basin at about station 1614, which is obviously not a place where wave reflection can occur. From this consideration, at least a bi-nodal seiche is necessary to provide the oscillations shown. Assuming the same depth in the dredged cuts leading to the lower reaches of Gatun Lake, the loop end for a bi-nodal seiche would be at the head of the bend in the channel.

That this is the correct interpretation can be established. The gaging stations between the node at station 1772 and the loop at the locks, station 1930, should show high water when all the other gaging stations show low water. This is the condition shown in the profiles. The location of a gaging station at station 1478, very close to the node at station 1456, should result in water-surface profiles with the amplitude of the seiche nearly zero. This is certainly the case in every profile for station 1478. Also, the profiles at station 1550 and station 1656, lying on either side of the center loop, should be nearly similar, which they are. Furthermore (see the profiles from Test No. III) where a fresh impulse is given at an 88-min interval, the amplitudes should be greatest since 88 is 3 × 29 +; that is, the seiches from the two impulses would augment, whereas those in Test No. V (Fig. 4(*b*)), at the 44-min interval, should be least, since the seiches would interfere to the maximum extent possible. This is likewise the case on the given profiles. No reason was advanced for this choice of intervals.

Without further data, it is conceded that the system may have additional nodes. This can be verified easily on the prototype by gaging stations in the southern part of Gatun Lake. However, treating the problem as a bi-nodal seiche is valid for this discussion. There are minor seiches riding the major one of the prototype, which were probably produced in the canal by reflecting surfaces at places where the width or direction of the canal changes. They do not affect the problem.

The water-surface profiles of Fig. 2 do not show the actual conditions. They are seriously influenced by the findings of Professor King, who states definitely that[3] the water is moving in an open canal when water is added or removed. In the prototype, as in all other seiches, the wave form is nearly sinusoidal, instead of the odd assortment shown in Fig. 2. It is also irrelevant to cite the work of Colonel Brown[4] since his paper treats of tidal canals.

The position of Gatun Lake proper does not influence the part of the canal under consideration in the same manner that lakes do in Colonel Brown's studies. About 6 miles of narrow, shallow waterway, except for the dredged cut, intervenes.

The nomenclature adopted by students of seiche phenomena limits the term "surge" to the "to and fro" motion of the water (current), whereas the rise and fall is called "seiche," and corresponds to tides in tidal waters.

Seiches in nature are produced chiefly by differences in barometric pressure on water surfaces in the same oscillating area, or by tidal effects. In canals, as in the case under discussion, the change in pressure is effected by release of water into the locks.

Since the model was built to scale, and the seiche period is a function only of length and depth of the oscillating system, the model should be a good replica of the prototype. It would be astonishing if it were not; so no conclusions regarding model operations are valid from these experiments. Width of channel does not enter the problem, and therefore added breadth in the model will not change the period, provided depth is held constant. This may be of value in future experiments.

Roughness variations between model and prototype would only cause a difference in the number of oscillations before friction consumed the energy.

The primary object of the investigation was to study the effect on ship operation. In Los Angeles Harbor, numerous continuous seiches occur. Those with relatively long periods have little or no effect on ship maneuvering, whereas the short period seiches are a serious problem, especially in the naval base area where caisson gates for graving docks must be fitted into rather small keyways during the closing operation. The surges accompanying the seiches, with their rapid direction reversal, make the locking operation difficult. In the Panama Canal case, additional locks, with shorter filling times or greater water removal, would induce the same period seiches, but with greater amplitude, and therefore with increased surge. This is shown by the small amplitudes in Test No. 1 where slow removal occurs. However, two sets of locks, with filling operations regulated to time periods that would produce interfering seiches, should answer the problem. Another solution would be to have the filling water removed from the main canal into a paralleling conduit of such length (to be determined by model experiments) and at such places as to produce the least seiches due to interference phenomena, the water having sufficient capacity to fill the locks. The locks would be filled from the auxiliary conduit, the seiches would be reduced through interference, and little or no surge would be experienced when the lock gates were opened.

From the nature of the factors governing the period of the seiches (depth and length of oscillating basin), it is apparent that changing the depth or the length would change the period. The depth enters to the one-half power, requiring greater change to produce the same effect that a change in length would produce. Such change in length of oscillating basin could be attained by introducing a gate in the waterway at a suitable place, the gate to remain closed during lock filling.

However, in view of the fact that the surges (currents) are theoretically zero at the loop ends and greatest at the nodes, the existence of a loop at or near the locks would signify that very little current occurs here and therefore that no cause for anxiety is apparent.

C. J. Posey,[8] Assoc. M. Am. Soc. C. E.—Prototype-model comparisons of this type are all too infrequent in engineering literature. When the underlying theory is generally accepted, there is a tendency to adjust the design to fit the results of the model tests and to omit subsequent tests on the prototype. Only when the model theory is the subject of controversy is the laborious and difficult job of securing prototype data for comparisons likely to be undertaken. Many hydraulic engineers would consider satisfactory model-prototype correspondence, in this particular problem, to be almost a foregone conclusion and prototype tests unnecessary. The writer disagrees with this viewpoint, and believes that such comparisons should be undertaken whenever practicable.

---

[8] Associate Prof., Hydraulics and Structural Eng., Research Engr., Iowa Inst. of Hydr. Research, State Univ. of Iowa, Iowa City, Iowa.

Although substantial agreement with respect to wave velocities is evident from inspection of Figs. 3 and 4, a statistical study of comparative water-surface elevations might give a more definite basis for the authors' conclusion (see heading, "Comparison of Model and Prototype") that "The agreement is considered to be very satisfactory." Plotting of the model and prototype test data in the form shown in Fig. 2 should make it easier to judge the degree of correspondence.

The authors' comparison of the results of synchronization and of anti-synchronization, shown in Fig. 4, certainly is of special interest. It seems safe to assume that these are the extreme cases and that surges resulting from operation at intermediate periods will not exceed the values obtained for synchronized operation.

F. W. Edwards,[9] M. Am. Soc. C. E., and Edward Soucek,[10] Assoc. M. Soc. C. E.—It is interesting to note that one discussion expresses doubt regarding the ability of the model to reproduce surges that would be caused by operation of the proposed larger lock, whereas another expresses astonishment that it was considered necessary to conduct verification tests.

Mr. Weggel states, "Test No. III and Test No. V are of special interest because they illustrate the results of consecutive lock operations; but deductions are incomplete unless the data are available for the periods of synchronization and anti-synchronization." The data are available for these periods and were presented in Fig. 4.

In order to explain more fully, reference is made to Fig. 4(*a*). The initial lock operation depressed the water-surface elevation immediately. The second lock operation was performed 88 min later when the water surface was again approaching the low elevation. Withdrawing more water from the canal at this time lowered the water surface and increased the magnitude of the surge. It should be noted that 88 min after the second lock operation the water surface was low again but was not below the elevation caused by the initial withdrawal. The surge as augmented by the second operation, therefore, represents the worst condition likely to be produced by operation of the existing locks.

Reference is made next to Fig. 4(*b*). By performing the second lock operation 44 min after the first, when the water-surface elevation was approaching a maximum, the surface was prevented from rising to the elevation attained in Test No. III and the surge was neutralized. The choice of intervals between lock operations was not accidental, as implied by Mr. Leypoldt, but was based on calculation and on study of the water-surface profiles of Tests Nos. I and II.

Tests Nos. III and V substantiate Mr. Weggel's belief that, "Not always is it the amount of change of discharge that determines the height of wave or depth of trough." The data regarding waves on the Ohio River are interesting but do not support the opinion that a model could not reproduce, accurately, results identical to those observed in the prototype.

---

[9] Associate Prof. of Civ. Eng., Pennsylvania State College, State College, Pa.

[10] Hydr. Engr., Office, Chf. of Engrs., Washington, D. C.

The writers agree fully with Professor Posey's viewpoint that comparisons of models and prototypes should be undertaken whenever practicable. Although it was expected that the model would represent the prototype correctly, it was considered good engineering practice to check results by every reasonable method available.

The entire discussion by Mr. Leypoldt is at variance with the beliefs of the writers. He states,

> "The water-surface profiles of Fig. 2 do not show the actual conditions. They are seriously influenced by the findings of Professor King, who states definitely that[3] the water is moving in an open canal when water is added or removed. In the prototype, as in all other seiches, the wave form is nearly sinusoidal, instead of the odd assortment shown in Fig. 2."

In spite of Mr. Leypoldt's belief that the wave form should be sinusoidal, actual data, as represented in Fig. 2, show this to be untrue in the present case.

The writers stated that the profiles should be considered pictorial rather than exact, but this qualification was made because a profile representing nine miles of canal is not precise when based on relatively few observation points. The statement was not made in order to justify a fictitious representation of the data. The wave forms represented in Fig. 2 were influenced only by the observed data; not by any literature, theory, or preconceived notion on the subject. The agreement between the water-surface profiles and the field observations for Test No. II can be seen in Fig. 6. In this figure the observed water-surface elevations from Fig. 3 and the profiles originally shown in Fig. 2 are plotted.

Fig. 6 shows clearly that the writings of Professor King did not influence the drawing of the profiles. However, the theories which Professor King has described are undoubtedly applicable to the generation of the initial wave. The relationships pertaining to the height of surges formed in an open channel by sudden changes in discharge are based only on the conservation of matter (implicit in the law of continuity) and Newton's Laws of Motion. The application of the equations is affected but not invalidated by the initial zero velocity of flow. It is well known that the initial shape of a wave in a channel is a function of the manner in which it is generated; whether the wave approaches regularity in form or tends to break up as it travels along the channel depends upon conditions beyond the scope of the paper. Whether or not the wave form is an "odd assortment" probably depends on the point of view. To the writers, any apparent oddity can be due only to an attempt to classify the wave forms in accordance with a preconceived notion—an error which Mr. Leypoldt attributes to the writers.

The writers disagree with Mr. Leypoldt's contention that the data indicate a seiche of two or more nodes, one at station 1772 and another at station 1456. Since no significant oscillation occurs beyond station 1478, it is clear that none occurs at station 1456, but here the agreement ends. If a node were located at station 1772, the following conditions would exist: (*a*) The water surface at the node would oscillate less than at stations on either side, (*b*) the amplitude would increase progressively from the node to adjacent loops, and (*c*) the concurrent oscillations on the two sides of the node would differ in sign. The water-surface profiles of Fig. 2 show that none of these necessary conditions prevail for a node claimed to exist at station 1772.

Mr. Leypoldt believes the reference to Colonel Brown's work[4] to be irrelevant. He states that "Gatun Lake proper" does not influence the part of the canal under discussion in the same manner that lakes do in Colonel Brown's studies. It is clear that Mr. Leypoldt means the main body of water approximately six miles from station 1478. However, Gatun Lake is considered generally and properly to extend from Gamboa, the point where the Chagres River flows into the canal at station 1478. The second paragraph of the paper and the notation of Fig. 2 testify that this designation was used by the writers. It is Gatun Lake at station 1478 to which the work of Colonel Brown is relevant and which does act in a manner identical to that of the lakes in his studies. It is Gatun Lake at station 1478 which was represented in the model by a forebay in which the water surface was maintained at a constant level. If the waves had not been reflected from station 1478 in the manner described by Colonel Brown, the model could have agreed with the prototype only by chance, the chance being the existence of a node at that station.

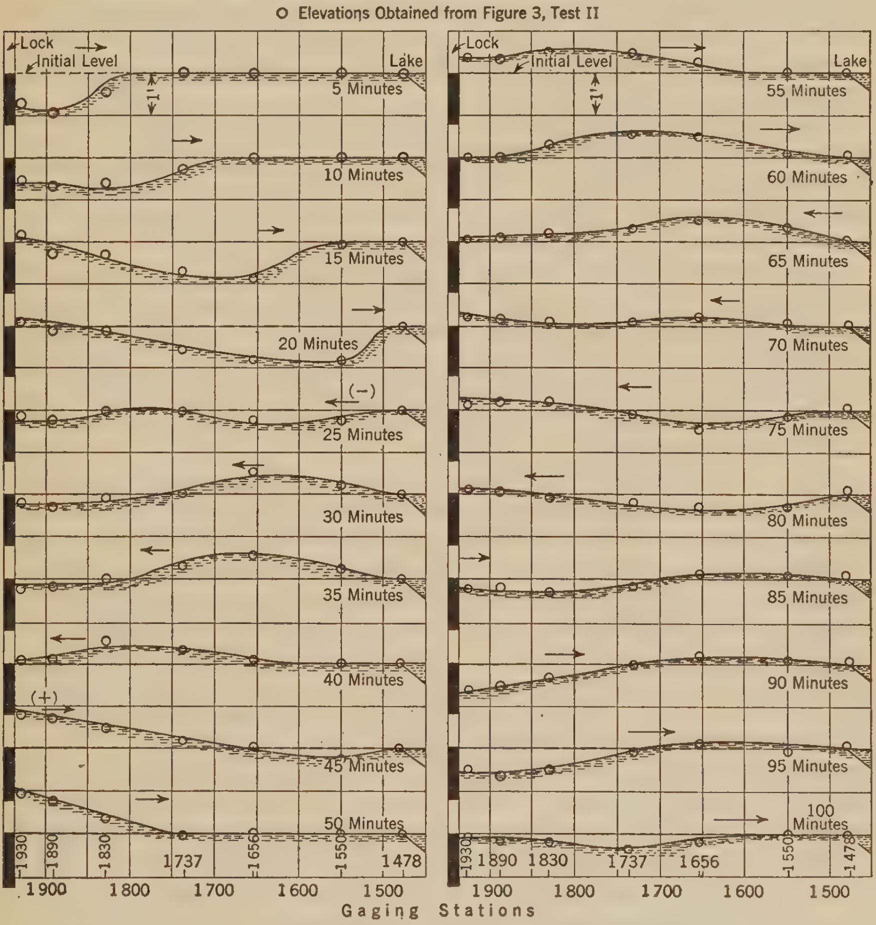

Fig. 6.—Water-Surface Profiles at 5-Min Intervals

Since Mr. Leypoldt's seiche theory does include a node near station 1478, it is necessary to go one step further to show that Colonel Brown's theory of negative reflections does apply. This step is proof that significant oscillations do not occur beyond station 1478. Mr. Leypoldt suggests that the existence of additional nodes could be verified easily on the prototype by additional gages in the southern part of Gatun Lake. Preliminary reconnaissance prior to the tests showed that significant oscillations did not occur beyond station 1478, but to remove all possible doubt, a gage at station 1367+50 was established and operated during the first two tests.

The following quotation from the official report on the prototype tests[11] explains the abandonment of this station: "As had been expected, the surges beyond Gamboa were small so this station was discontinued after the second test." This gage was located near the point where Mr. Leypoldt's analysis indicates a loop.

The "narrow, shallow waterway except for the dredged cuts," and the Chagres River each have a mean width of more than one-half mile. The quiescence of these bodies of water during the surge tests shows conclusively that the bodies are large enough to reflect waves negatively in the manner described by Colonel Brown. The creation of significant oscillations in these waters by means of impulses no greater than those caused by filling the locks is physically impossible.

From Mr. Leypoldt's comments concerning Gatun Lake proper, from his opinion that no conclusions regarding model operations are valid from these experiments, from his statements that the width does not enter the problem and that roughness is unimportant, it is not evident that he understands that the model extended only to station 1478. The model did not encompass the length of the oscillating system which he believes to exist in the prototype. Accordingly the remark that it would be astonishing if the model were not a good replica of the prototype is especially inappropriate. Although it is true that all parts of the model could have been reduced proportionately in width on the basis of gravitational and inertial considerations alone, it is by no means evident that the rate at which the surges dissipate their energy would be unaffected. If roughness affects the number of oscillations, which Mr. Leypoldt concedes, it must also have a progressive effect on their magnitude. Therefore, neither the width nor the roughness may be altered without careful consideration of the results. Since, in a model of the type described, many problems in addition to the period of oscillation are investigated—for example, the flow pattern at the junction of the by-pass for the proposed new lock—Mr. Leypoldt's suggestions regarding future experiments have no value. It does not appear desirable to adopt the restricted meaning of the term "surge," as advocated by Mr. Leypoldt, in a paper written for engineers.

Except to state that the specific suggestions offered by Mr. Leypoldt for solving the surge problems in the Panama Canal are considered impracticable, no comment on this question can be made at this time. The paper was specifically confined to an explanation of the surges and to verification of the model.

ORIGINAL AND READJUSTED REPAYMENT CONTRACTS, BOULDER CANYON PROJECT

By Clay C. Elder,[1] M. Am. Soc. C. E.

With Discussion by Messrs. W. L. Chadwick, A. R. Arledge, and Clay C. Elder.

Synopsis

The Boulder Canyon Project, after a generation of investigation, planning, and political debates, progressed to actual construction in 1930. First commercial power production occurred in October, 1936, with additional generating units still being installed as of 1944. Since June, 1943, the power output has exceeded 1,000,000 kw, the first time in history for a single power plant; so the project's record of breaking records is continued. The ultimate capacity of the plant is announced as 1,332,300 kw.

The great dam, 726 ft high, controls the flow of the Lower Colorado River on the Arizona-Nevada boundary and creates a storage reservoir of 32,000,000 acre-ft capacity, called Lake Mead. It was built and is owned and operated by the United States because of the complexity of its interstate and international problems, which were the more involved due to its being the pioneer in the field of large multiple-purpose hydro-power projects. In addition to improving navigation (for judicial purposes, at least), controlling floods, and regulating the river flow for irrigation, domestic, and municipal uses, the power production is sufficient to amortize the project's construction cost and guarantee payments to Arizona and Nevada in lieu of taxes, plus contributions to a basin development fund. Silt control and regulation of water quality are important incidental results.

The power rates were adjusted in 1941, on an amortization instead of the previous competitive market rate basis. The reasons for this change are explained in this paper, with detailed comparison of the two plans as regards allocation of construction costs.

Note.—Published in December, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Hydr. Engr., Met. Water Dist. of Southern California, Los Angeles, Calif.

The Boulder Canyon Project has now gone to war in a big way, of course; but, even before the war boom and the earlier defensive rush period, its success was assured, with power output and cost repayments running far ahead of advance estimates. As of 1944, however, one near-by metallurgical (magnesium) plant requires 200,000 kw and every available kilowatt-hour is devoted to the war industries of Southern California. Stored water is also pumped for these industries and the municipalities around them through the Colorado River Aqueduct.

BOULDER CANYON PROJECT ACT

The Congress of the United States, by the terms of the "Boulder Canyon Project Act," approved on December 21, 1928, authorized the Secretary of the Interior

> "* * * to construct, operate and maintain a dam and incidental works in the main stream of the Colorado River at Black Canyon or Boulder Canyon * * * for the purpose of controlling the floods, improving navigation and regulating the flow of the Colorado River, providing for storage and for the delivery of the stored water thereof for reclamation of public lands and other beneficial uses exclusively within the United States, and for the generation of electrical energy as a means of making the project herein authorized a self-supporting and financially solvent undertaking; * * * also to construct and equip, operate and maintain at or near said dam, or cause to be constructed, a complete plant and incidental structures suitable for the fullest economic development of electrical energy from the water discharged by said reservoir; * * *."

As indicated by this preamble to the Act, the solution of the Colorado River problems, as plans were gradually formulated after investigations over a period of many years, necessarily required a multiple-purpose project. This was perceived long before such a conveniently descriptive term became so widely used and accepted in discussions of engineering economics. Largely to this diversity of objectives, and the serious international as well as interstate complications that were involved, was due the final authorization for the construction by the Bureau of Reclamation, U. S. Department of the Interior, with federal appropriations. Indeed, the Boulder Canyon Project is generally recognized as having been the pioneer in the field of major multiple-purpose hydro-power developments.

In addition to the numerous general purposes as listed, the removal of Colorado River silt (long infamous as often "too thick to flow even though too thin to plow") has proved of vital importance, for, without such silt control, neither power installations nor water diversions could be considered as economically and permanently feasible. (The reservoir has an estimated 300-yr life, as a minimum, which will be indefinitely prolonged by the construction of numerous planned upstream dams.) Likewise, the improvement of the quality of Colorado River water by decrease of its low-flow salinity and hardness, due to storage and mixture of the previously wasted and relatively pure flood flows, was immediately of real value. Such quality improvement has become even more evident as the first filling of Lake Mead (Arizona-Nevada) and two years (1941 and 1942) of large discharges (fortunately chiefly through the gates rather than from the purer surface stratum over the spillways) have continued the leaching of the gypsum-mixed sands included in the desert reservoir's flooded area. This improvement is only temporarily retarded by the 1943 low inflow of but 70% of normal. Even the improvement of navigation, generally dismissed as merely a legal fiction, has permitted the barging of ores, previously inaccessible, on a commercial scale, as well as a recreational patronage for fishing, bathing, sailing, and motor boating, to a most unexpected extent. Visitors to the power plant until it was closed to the public on December 8, 1941, averaged more than 1,000 per day for a total of nearly two million (Fig. 1), besides still larger numbers who merely admired the dam and scenic vicinity.

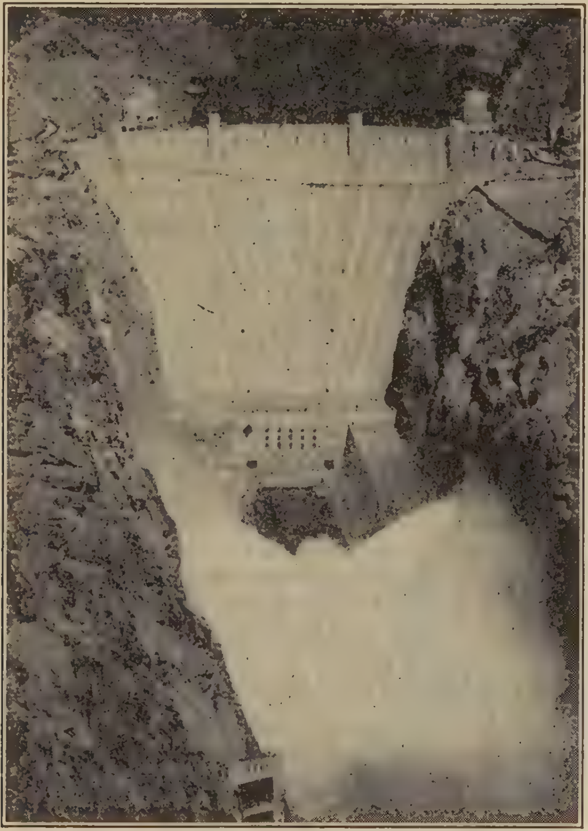

FIG. 1.—VISITORS TO THE POWER PLANT, UNTIL IT WAS CLOSED TO THE PUBLIC ON DECEMBER 8, 1941, AVERAGED MORE THAN 1,000 PER DAY

Evidently the Boulder Canyon Project has really accomplished a multiplicity of purposes.

A draft of the Swing-Johnson bill, as the project Act was generally known, was introduced in Congress as early as 1923, but enactment was delayed during five years of nearly continuous and heated debate over the basic policy of governmental ownership and construction of power dams. The question of a single-purpose versus multiple-purpose project also played a part in the controversy, as some opponents of government control of the high power dam favored instead a separate, relatively low dam at another site to be built by the United States solely for flood control, the immediate need for which seemed unquestioned. This would have left the canyon section of the Colorado River for private power development, probably taking the form of a series of several relatively low dams. The apparent economy of a multiple-purpose dam was a deciding factor in finally securing favorable Congressional action, as advocates of government ownership asserted (correctly, as is now proved) that power and other revenues would be amply sufficient to repay the cost of the project with interest. That the approval of the Boulder Canyon Project Act established a notable and important precedent is now very evident. Although the Bureau of Reclamation had previously constructed about fifteen power plants, incidental to its irrigation projects, their combined cost was less than 1% of the authorized investment for the Boulder Canyon Project. Few of these small installations had encountered serious opposition from public utilities, as they had offered little or no competition and were mostly in remote and undeveloped localities, at the time unprofitable for private power installations. On the other hand, the Lower Colorado River was considered a choice prize, for the control of which the competition was energetic and prolonged. Congressional and public sentiment finally swung definitely in favor of governmental construction of such hydro-power projects, as the decade following the passage of the Boulder Canyon Project Act has confirmed, with its series of great federal dams.

In line with the arguments that the project would be self-liquidating in fact, a definite plan of cost repayment was written into the Act (section 4-b)—

> "Before any money is appropriated for the construction of said dam or power plant, or any construction work done or contracted for, the Secretary of the Interior shall make provision for revenues by contract, in accordance with the provisions of this act, adequate in his judgment to insure payment of all expenses of operation and maintenance of said works incurred by the United States, and the repayment, within fifty years from the date of the completion of said works, of all amounts advanced to the fund under sect. 2(b) for such works, together with interest thereon * * * (at 4%)."

This requirement for bona-fide, enforceable repayment contracts, covering the estimated project cost, was followed strictly by the then Secretary of the Interior, Ray Lyman Wilbur, M.D., before President Herbert Hoover, Hon. M. Am. Soc. C. E., approved the first appropriation for initiating construction work on July 3, 1930.

Such an advance guarantee of cost repayment with interest made the Boulder Canyon Project unique among national developments, a record unshared as yet but only emphasized as to its rarity by the cases of numerous subsequent and comparable power dams constructed under federal auspices. The record is more notable in view of the rigid interpretation and enforcement given the repayment clauses of the Act, quite at variance with the long-established repayment practices on irrigation and other government projects (leniency having been often allowed, generally for good and sufficient reasons). The several contracts negotiated with the Los Angeles (Calif.) City Power Bureau, the Southern California Edison Company, and The Metropolitan Water District of Southern California, which were later supplemented by contracts with various other power distributors, represented probably the largest power transaction to date. They called for then-estimated payments over a fifty-year period of about one-half billion dollars for merely the primary project, not including costs of long transmission lines and complex distribution facilities. The enormity of such repayment promises and the seriousness and importance to all concerned of these contracts are now difficult to realize under subsequent changed conditions of more easily promoted projects as items of progressively greater relief, defense, and war budgets. The support of the Southern California Edison Company, in underwriting a large portion of the cost of this governmental and municipally-favored development, is especially notable, as inaugurating a period of enlightened public relationship and ending, regionally at least, a protracted and "totalitarian" war of uneconomic competition.

COLORADO RIVER DAM FUND

Early drafts of the Swing-Johnson bill provided for financing by a project bond issue but the Act as finally passed relied instead on normal Congressional appropriations. Patterned to some extent after the regular Reclamation fund, a special fund was established, designated as the Colorado River Dam Fund, to be available only for carrying out the provisions of the Act. Greatly simplifying the accounting procedure, and cost or repayment auditing reports, it has somewhat the relation to the U. S. Treasury of a subsidiary to a parent corporation. It appears to have served as a "small-scale" precedent for the subsequent depression era's Reconstruction Finance Corporation (as a means of financing public construction) and other government corporations and funds, which have become such a favorite and accepted method of federal administrative and accounting practice.

All advances to the Colorado River Dam Fund from the U. S. Treasury were required to be repaid with 4% interest, but a definite allocation of $25,000,000 was made to flood control to be repaid out of 62.5% of excess revenues, if and when available. If this repayment were not completed within the general fifty-year amortization period, ending May 31, 1987, repayment was to be continued out of the same proportion of the project's net revenues. Thus deferment was permissible for the repayment of the flood-control allocation, if this became necessary, but provision was made for full repayment finally, with 4% compound interest. The amount of this flood-control allocation appears to have been fixed arbitrarily, so far as is now evident, but is approximately the sum that might have been needed for a program of flood control by means of a low dam for this purpose solely, and a system of raised and strengthened levees. This solution would have given immediate, but evidently only temporary, relief from flood damages, due to relatively rapid filling with silt of a small reservoir. The federal obligation to furnish some degree of flood control on the Lower Colorado River was recognized, however, and this is probably the only case to date in which repayment (even though possibly on a deferred basis) of a government flood-control structure, or its allocated share of the construction cost, has ever been required or promised.

In addition to the flood-control allocation, other excess revenues of the Colorado River Dam Fund were allotted as follows:

> "If during the period of amortization the Secretary of the Interior shall receive revenues in excess of the amount necessary to meet the periodical payments to the United States as provided in the contracts executed under this act, then, immediately after the settlement of such periodical payments, he shall pay to the State of Arizona 18¾% of such excess revenues and to the State of Nevada 18¾% of such excess revenues.
>
> "After the repayments to the United States of all money advanced with interest, charges shall be on such basis and the revenues derived therefrom shall be kept in a separate fund to be expended within the Colorado River Basin as may hereafter be prescribed by the Congress."

Records of Congressional Committee hearings indicate that the intent of Congress was that Arizona and Nevada should receive some payments in lieu of taxes which would have been levied if the project had been privately developed. The amount is stated as having been determined on the basis of a fairly parallel case, the leasing of public oil lands, where the rule had become established that the state involved should receive 37% of the net revenue in lieu of taxes. The disposition of the balance of excess revenues, after completion of repayment of U. S. Treasury advances to the fund, was such a remote problem as not to excite immediate interest, so that it was merely left to future action of Congress, although allotted for Colorado River Basin developments if and when available.

Original Repayment Contracts

As repayment contracts were required by the Act in advance of even the beginning of construction, their terms were necessarily based on estimated project costs. Power production had also to be estimated from stream-flow records and reservoir operation studies, at first being called 4,240,000,000 kw-hr annually of firm power initially, subject to some gradual depletion. This amount was taken as 100% in the allocations of power, although a later decision to add 25 ft to the proposed height of the dam (550 ft) yielded a further block of 90,000,000 kw-hr of firm power annually. Applications for the power originally totaled more than three times the estimated production, with the City of Los Angeles and the Southern California Edison Company each asking for all of the available power. Final power allotments were made only after prolonged hearings and many protests and compromises, with eight contracts resulting from twenty-seven applications, some of which were conditional or indefinite, however. The repayment guarantees involved three main contracts:

City of Los Angeles	37%
Metropolitan Water District	36%
Southern California Edison	27%
Available power	100%

The City of Los Angeles underwrote 6% for other municipalities (which finally amounted to 4.0946%), the Southern California Edison Company similarly underwrote 0.9% for each of two other power companies, and the city and the company each were subject to a drawback of 18% by the states of Arizona and Nevada. As the Metropolitan Water District had not at the time held its aqueduct bond election, legal questions were anticipated as to the strict enforceability of its contract. The guaranteed portion of the project cost was therefore finally covered by the City of Los Angeles and Southern California Edison Company contracts for but 64% of the estimated power production.

These contracts were required to provide revenues sufficient in the judgment of the Secretary of the Interior to amortize the project cost, except for the flood-control allocation; but in addition the Act required that the contracts "shall be made with a view to obtaining reasonable returns" as found to be "justified by competitive conditions at distributing points or competitive centers." The latter condition would necessarily have been a determining factor in fixing the power rate even in the absence of such a statutory direction. In this case, the only significant power market was in Southern California, located over large oil deposits, so that the cost of energy provided by oil and gas necessarily fixed the comparative value of Colorado River hydro power, with proper allowance for transmission costs. Studies made for the Secretary of the Interior on this basis indicated a value at the switchboard for the use of the available falling water of about 1.63 mills per kw-hr. Therefore, power allocations were made on the basis of this rate, with the corresponding secondary power rate fixed rather arbitrarily at 0.5 mill per kw-hr.

ORIGINAL COST ALLOCATIONS

With firm contracts executed on April 26, 1930, for the entire power production, and the power rate fixed and agreed to as described, it was widely assumed that an allocation had been arrived at not only for the project cost but also for a dependable surplus, payable to Arizona, Nevada, and the Colorado River Basin Development Fund. Technically, to be strictly accurate, no such definite allocation of costs really had been made, because the Act prescribed that upon the demand of either party to the power contracts, at the end of fifteen years (in 1945) and every ten years thereafter, the power rate should be readjusted as found by the Secretary of the Interior to be justified by changed competitive conditions. In 1930 this factor seemed to mean little, as the first adjustment date was so far into the future, and elaborate, detailed computations and studies were prepared on the assumption of a uniform rate of 1.63 mills per kw-hr. Misleading conclusions resulted and the expenditure of anticipated surplus revenues was budgeted by those interested as if the fund accumulation were certain and automatic. As the national economic depression became more severe and protracted, affecting seriously both power markets and the all-important price of oil, or equivalent cost of gas, it became apparent that under prevailing competitive conditions the power rate had been set higher than was warranted or than could be maintained, in all probability, after the 1945 readjustment. Various alternate studies of anticipated revenues, with corresponding allocations of cost, were prepared as a basis for discussions of the resulting problems among representatives of the government, the power contractors, and the states interested in excess revenues. Several of these studies that were officially issued by the Bureau of Reclamation and are still of interest, for purposes of comparison, have been tabulated in summary form herein, following a listing of the project costs that serve as a base for the amortization computations.

Cost estimates used in negotiating the original power contracts for the Boulder Canyon Project are derived from a statement[2] by Secretary Wilbur:

Estimated cost (including interest during construction but excluding flood control)	$ 82,674,907
Interest at 4% during 50-yr period, excluding flood control	108,107,007
Interest charges on accumulated deficit	63,973
Estimated operation and maintenance (O & M)	7,262,557
Estimated depreciation	8,875,553
Total requiring "guaranteed" repayment	$206,983,997
Anticipated power revenues at 1.63 miles per kw-hr	
City of Los Angeles	$121,310,549
Southern California Edison Company	88,523,915
Subtotal	$209,834,464
Metropolitan Water District of Southern California	118,031,886
Total estimated falling water revenues	$327,866,350

The distribution of surplus revenue, if and when realized, according to the terms (as then interpreted) of the Boulder Canyon Project Act is:

Repayment of flood-control allocation	$ 25,000,000
Interest at 4% on flood-control allocation	20,981,303
18¾% of surplus to Arizona	22,665,441
18¾% of surplus to Nevada	22,665,441
Balance for Colorado River Basin Development Fund	29,570,168
Total estimated surplus at 1.63-mill rate for fifty years	$120,882,353

In addition to the foregoing totals, power machinery costs were estimated at $17,717,000. It was originally contemplated that this investment would be financed by the power-plant lessees, so that its repayment was not covered in the original power contracts. Therefore, although finally financed with federal funds, along with the remainder of the project, power equipment costs are being repaid over a 50-yr period with interest by means of separate contracts with the generating agents, the City of Los Angeles, and the Southern California Edison Company. Actual project construction costs, as of September, 1940[3]

---

[2] House Hearing, 71st Cong., 2d Session, Second Deficiency Appropriation Bill, 1930, p. 950.

[3] *Bulletin No. 1*, Boulder Canyon Project Final Reports, Pt. IV, 1941, pp. 26–28; also Exhibit 33, September 14, 1940.

(presented at the Rate Adjustment hearings at Los Angeles) can be summarized in abbreviated form as follows:

Feature	Costs
Dam and Reservoir	
Right of way and mining claims	$ 782,219
Surveys, tests, and examinations (field)	766,335
Stripping canyon walls	627,499
River diversion, cofferdam, dredging	2,348,984
Diversion works (four tunnels)	26,996,604
Main dam and miscellaneous	23,578,724
Spillways	5,868,792
Outlet works	16,337,587
Permanent cableway and landings	607,913
Subtotal	$ 77,914,657
Power Production	
Power-house substructure	$ 5,094,098
Power-house building, water, oil, and air systems	3,726,170
Penstocks	3,330,950
Electrical equipment	13,624,964
Hydraulic, mechanical, and general station equipment	6,620,512
Switchyards	3,265,609
Subtotal	$ 35,662,303
General Plant	
Roads, railroad, construction and concrete plant	$ 2,491,967
Boulder City, Nev., government buildings, telephone system, etc.	2,182,565
Materials and supplies (field)	305,511
Subtotal	4,980,043
Total investment (field)	$118,557,003
Overhead and Undistributed	
Engineering and inspection (Denver, Colo., office)	$ 2,875,341
Concrete and other research	624,431
Colorado River Board and consultants	83,887
Legal, general, printing, furniture, etc. (Denver)	406,602
General and overhead (Washington, D. C., office)	282,076
Secondary investigations, Colorado River Basin	314,416
Subtotal	4,586,753
Total project cost to September, 1940	$123,143,756

Installations of additional power-plant equipment, continuing into 1944, and other permanent work of a minor nature, raised the project cost to approximately $130,000,000, with the completed cost to be somewhat greater. The most recent available studies, dated February 19, 1941, indicate a final reimbursable cost of $82,878,131 for the new power (falling water) rate determinations, not including generating machinery and the deferred flood-control allocation. This is not exactly comparable with the 1930 estimate of $82,674,907, as the latter includes interest during construction at 4% and also interest during construction at the same rate on the deferred flood-control allocation of $25,000,000. Under the present revised Act and regulations, the latter is considered to be the sum of the first project expenditures instead of being an amount deducted from the construction cost on May 31, 1937, as previously, so that interest during construction on this amount is now omitted, and on the remainder of the cost is computed at a 3% rate. This adjustment for revised interest during construction is estimated as amounting to about $5,000,000 which may be considered the approximate overrun on the cost of the dam and power-plant building, as compared with the 1930 estimates. Most of this increase appears to have resulted from the inclusion of exceptionally thorough and costly research, basin surveys not directly related to project construction, very considerable overhead, and unanticipated expenditures for Boulder City and for guide, scenic, and protection facilities, etc. The actual field construction cost of the dam and power-plant building evidently has exceeded the 1930 estimates but slightly, if at all.

Early rapid progress on the dam was aided by the lowest runoff year (1934) on record, and, with the favorable depression prices of the same period, financial studies made in 1936 (Denver Drawing No. 45-D-10,327 dated September 18, 1936) were allowed to become optimistic to the extent of estimating the reimbursable cost as of May 31, 1937, at $75,927,921. Due apparently to cost accountants being overworked, a considerable lag occurred before the effect of large overhead and indirect costs became fully evident. Annual O & M costs were estimated at but $102,000, compared with $145,000 in 1930 (present studies include O & M costs at $554,000 annually) and, on the other hand, allowances for secondary power and water storage revenues were somewhat more liberal than in either 1930 or at present (1944). The combined effect of these various factors, in addition to the previously mentioned faulty assumption of a 1.63-mill rate for fifty years, was to increase the estimated payments to Arizona and Nevada by 30% and to the Colorado River Basin Development Fund by about 90%, as compared with the quoted 1930 anticipations. Naturally, these larger amounts became fixed in the minds of those interested as being so certainly available within the near future that subsequent smaller but more accurate versions of probable surplus revenues were correspondingly unpopular and dismissed as propaganda.

Beginning in 1937, however, such financial studies were revised to conform to the quoted requirement of the Act (section 5) that payments into the separate Colorado River Basin Development Fund should not be made until completion of all repayments to the United States. Earlier interpretations had assumed that amortization of the dam's cost would cover the permitted 50-yr period, whether such a long time was necessary or not, with surplus funds first amortizing the flood-control allocation and then being paid to the separate fund.

On the corrected basis, however, the federal government share of the surplus was devoted to accelerated project cost amortization, with initial payments into the separate fund being postponed from about 1960 to the very end of the amortization period, 1985 or later, as well as being greatly decreased in amount. The last such study, prepared by the Bureau of Reclamation as of May, 1940, conforming to the original Act but with then-current assumptions for the reimbursable total and estimated O & M costs, and involving varying future power rates, both firm and secondary, after 1945, is available in print.[4] Detailed tabulations are shown for firm power rates of 1.30 and 1.08 mills after 1945, with the secondary rates proportionately decreased. Using identical assumptions and computation methods, similar tabulations have been prepared for 1.63 mills and other future firm rates. These several studies were then brought a step further up to date by corrections for the 1941 estimate of future O & M costs of $554,000 annually (instead of $270,000 annually). They are summarized in Table 1 on a present-value basis, to show the varying allocations of revenues and costs that might have occurred under the terms of the original Act, according as future competitive power conditions more or less severely affected the contracted revenues. Conforming to the May, 1940, O & M estimate, the fixed charges have a present value, computed at 4% as of May 31, 1937, of 100.3 million dollars, including past and deferred investment of 91.2

TABLE 1.—ESTIMATED SURPLUS REVENUES AND VARYING ALLOCATIONS[a] IN PERCENTAGE OF ACTUAL-PLUS-DEFERRED INVESTMENT[b]

Firm power rate after 1945 (mills per kw-hr)	SURPLUS		ARIZONA AND NEVADA		DEVELOPMENT FUND[c]		REPAYMENT[d]	
	Millions of dollars	Percentage of investment	Millions of dollars	Percentage of investment	Millions of dollars	Percentage of investment	Millions of dollars	Percentage of allocation
(a) ANNUAL COST OF OPERATION AND MAINTENANCE AS ESTIMATED IN MAY, 1940 ($270,000)								
1.63	45.0	49	17.3	19.0	2.7	3.0	25.0	100

1.163	9.0	10	3.4	3.7	0.0	0.0	5.6	22
1.08[e]	9.0	10	3.4	3.7	0.0	0.0	5.6	22

[a] Expressed as present values, at 4% interest rate, as of May 31, 1937. [b] Taken as 91.2 million dollars on a present-value basis as of May 1, 1937. [c] Colorado River Basin Development Fund. [d] Flood-control allocation. [e] With a firm power rate of 1.08 mills, $5,000,000 (present value) of project investment would have been unpaid in a 50-yr period.

---

[4] Hearings on H. R. Doc. No. 9093, Committee on Irrigation and Reclamation, 76th Cong., 3d Session, p. 177.

million dollars in dam and power-plant building (but not hydraulic machinery), plus operation and maintenance, depreciation, and replacements. All of these costs would have been repaid with any firm power rate, after 1945, of 1.08 mills per kw-hr or greater. Correcting the O & M estimate to the 1941 basis, the present value of all such fixed charges is increased to 105.3 million dollars. A firm power rate of at least 1.163 mills per kw-hr is required to amortize this amount within fifty years at 4% interest. The lower rate of 1.08 mills, if applied after 1945, would have repaid only 95% of the reimbursable project cost, in addition to O & M and depreciation charges. The varying amounts of surplus, and its allocation for the several specified purposes for different firm power rates after 1945, are given in Table 1 for comparison.

This tabulation is an extremely condensed summary of voluminous, detailed cost and revenue studies, referred to previously but not included herein because they are now obsolete and of interest only in reviewing the evolution of the present power contracts and rates. A full explanation of their engineering, legal, and accounting complexities would also be most voluminous, and likewise obsolete. In further explanation of Table 1, however, it may be noted that in all cases included, except the first (1.63 mills power rate for fifty years and preliminary estimate of O & M cost), the present value of the hypothetical payments to Arizona and Nevada is 37.5% of the corresponding present value of the surplus, as is specified in the Boulder Canyon Project Act. With the assumptions of the first case, however, the flood-control allocation of $25,000,000 would have been amortized in about thirty-eight years, as a result of the larger revenues. Then for the next nine years the government's 62.5% share of the surplus would have been applied to accelerating the amortization of the project construction cost. During the last three years of the life of the contracts, Arizona and Nevada would not have shared in the surplus (the Act limited their payments to the amortization period), but instead the entire surplus would have been paid into the Colorado River Basin Development Fund, for subsequent appropriation by Congress. The actual disposition of the surplus revenues would thus have been as follows, on a present-value basis:

	Million dollars
Net surplus (1.63 mills rate for fifty years)	45.0
"Surplus" applied to project cost amortization	+3.8
Surplus of last three years for Colorado River Basin Development Fund	−2.7
Portion of surplus shared by Arizona and Nevada	46.1
37.5% to be divided between Arizona and Nevada	17.3
(or 38.5% of net surplus and 35.5% of full 50-yr surplus)	

As some estimates of the probable firm power rate after 1945, revised on the basis of changed competitive conditions, ranged as low as 1.0 mill per kw-hr, and as this rate would have repaid (within fifty years and at 4% interest rate) only 88% of the investment in the dam and power-plant building, considerable concern arose as to the solvency of the project finances. By the terms of the original Act. the readjustment of the power rate in 1945, and at 10-yr intervals thereafter, was to be the responsibility of the Secretary of the Interior, as might be justified by competitive conditions. The opinion was frequently expressed that a rate lower than required to amortize the reimbursable portion of the project investment within fifty years was not permitted by the Act; but the legality of this idea was in disagreement and was indeterminate. This result was not improbable, however, as the manner of such a rate redetermination was left vaguely undefined by the Act and would be complex and difficult as well as seriously controversial. Even if the rate could be maintained high enough to insure repayments to the U. S. Treasury, however, the payments to the states and the basin fund were obviously in jeopardy. General recognition of this fact was the cause and basis of the negotiations for a revision of the original Act.

Revenues from Water Storage

Project cost allocations and amortization have been analyzed without special reference to anticipated water revenues because estimates of the latter, as included in the various official financial studies of the Boulder Canyon Project, have amounted to only 2.5% to 3% of the total expected revenues. Furthermore, no adjustment was required or has been made with respect to water charges, all recent discussions having involved power questions only. Water storage revenues are incidental and relatively minor in importance, in the case of this multiple-purpose project, partly because conditions were so favorable for power development. The high head and large generating units, rated at 82,500 kva, made possible a low power cost; and the large power demand, even with competitive marketing conditions of the depression period, has kept the project self-liquidating. More direct and fundamental factors control the water revenue that can be secured for the project.

The Boulder Canyon Project Act specifically exempted lands in Imperial and Coachella valleys, California, from any water storage charge. The first area is now, and the latter will soon be, supplied by the All-American Canal, also constructed by the Bureau of Reclamation under the authorization of the same Act. The justification for this exemption is that large appropriative water rights of very early priority had been established by such Lower Colorado River projects as Palos Verdes, Imperial, and Yuma valleys. Upstream developments gradually encroached on these prior water rights, causing more and more frequent shortages of irrigation water. These were climaxed by the most severe drought on record in 1934, just a few months before storage began in Lake Mead on February 1, 1935. Such water shortages were largely limited to the Imperial Valley because its diversion point was then below all others on the river, and litigation against junior upstream diversions had seemed unavoidable until the Colorado River Compact was negotiated. Due to these circumstances, the California ratification of the Compact was conditional on the construction by the federal government of a reservoir of at least 20,000,000 acre-ft capacity, at or below Boulder Canyon on the Colorado River.

A considerable portion of the investment in the Boulder Canyon Project may therefore be conceived as a contribution to prevent threatened litigation, and to stabilize past as well as future water rights and diversions in the Upper as truly as in the Lower Colorado River Basin. Except for the effect of such upstream diversions, now legalized by the Compact and the storage operations of Lake Mead, the natural, unregulated flow of the Colorado River would have been practically sufficient for Imperial Valley irrigation. Present exemption from reservoir storage charges is merely a recognition of this fact.

Other diversions from the Lower Colorado River are not definitely exempt from Boulder Canyon Project storage charges, and the reasonableness of such a charge (fixed at $0.25 per acre-ft) as a contribution toward the repayment of the cost of the project was recognized, for example, in the water contracts for the Colorado River aqueduct of The Metropolitan Water District of Southern California and for the City of San Diego, Calif. Even with the later priority of the water-right appropriation for the aqueduct, however, diversions might have been made during half or more of the time in most years from the river's natural flow, without dependence on storage. The present (1944) charge of $0.25 per acre-ft for all water diverted by the aqueduct, therefore, is in effect, about a $0.50 charge for water really derived from Lake Mead storage. Incidental benefits are obtained as regards desilting and improvement of water quality during non-flood periods, so that the charge on all water diverted was agreed to, it being realized that no accurate or practical separation or determination of natural flow could now be made. A rate of $2.00 per acre-ft was demanded at various times by Arizona representatives, but this was considered to be inequitable and impossibly exorbitant, amounting to a 22% increase in the $8.00 per acre-ft base price of water furnished by the $200,000,000 aqueduct. The rate of $0.25 per acre-ft as determined by the Secretary of the Interior was found justified on a showing that, if the portion of the Colorado River runoff made utilizable for the first time by Lake Mead regulation (about 10,000,000 acre-ft annually) was charged approximately this storage fee, the actual reservoir cost, omitting power production features and the flood-control allocation, could be amortized within fifty years from this revenue source alone, disregarding power revenues. Power revenues are available, of course, amounting (at the average reservoir power head) to $0.73 per acre-ft with the original rate of 1.63 mills per kw-hr, and to $0.52 per acre-ft with the 1941 adjusted rate of 1.163 mills per kw-hr.

On this comparative basis, the water charge does not seem disproportionate to the relative services rendered. It must be emphasized, of course, that the charge is not for the sale of water but rather for storage service only. Prior to 1943, the only contracts for water deliveries other than to the exempt irrigation projects were with The Metropolitan Water District of Southern California and the City of San Diego. Whether a water charge would be made for other projects, proposed or under construction, that will involve diversions from the Lower Colorado River, was not previously evident, as no delivery contracts had been issued for such projects. To be conservative, therefore, all previous financial studies for the Boulder Canyon Project have neglected the possibility of such additional water revenues. In May, 1943, a water contract was announced with the State of Nevada for diversions from Lake Mead, above Boulder Dam, with a charge of $0.50 per acre-ft, including about $0.15 per acre-ft for storage service and $0.35 per acre-ft as compensation for kilowatt-hours lost at Boulder Dam. In present drafts of a proposed water contract with the State of Arizona (not as yet approved by the Secretary of the Interior) the same charge is fixed for diversions from Lake Mead, and a maximum of $0.25 per acre-ft for downstream diversions. An actual storage charge of $0.15 per acre-ft for such agricultural diversions now seems probable. In view of these recent developments, the project's total water revenues by 1987 may considerably exceed the $7,500,000 previously estimated.

BOULDER CANYON PROJECT ADJUSTMENT ACT

The 50-yr amortization period of the project began on June 1, 1937, with the announcement of the Secretary of the Interior that storage and installed generators were sufficient for the production of 1,250,000,000 kw-hr annually for the first power contractor, the City of Los Angeles. Power had already been sold at the secondary rate, however, amounting to $247,000 under interim contracts. During the construction period of seven years after the execution of the contracts, various events had occurred which forced the conclusion that the 1930 power rates were inequitable and excessive, and could not long be sustained. The competitive value of the hydro power had fallen, as a result of decreases in the cost of fuel and in the capital costs of steam plants, as well as improvements in the art of steam power generation. The record indicated that advances to the construction fund by the U. S. Treasury had been secured at an interest rate averaging about 2.75% and that to charge the project a rate in excess of 3% would involve an unintended and undue profit. The United States had constructed or initiated numerous large multiple-purpose projects in other sections of the nation on a rate basis which abandoned the competitive plan previously applied, in favor of a power rate fixed by the amount needed to amortize such part of the investment as was determined to be allocable to power, plus costs of operation, maintenance, replacements, etc. This policy was later generalized by statute as to all reclamation projects. Several early determinations of allocations, particularly for navigation and flood control, appeared to be on a relatively liberal basis, resulting in power rates very unfavorable for the Southwest, as regards regional competition for heavy industry and electro-metallurgical plants. Consequently, the Boulder Canyon Project power contractors found themselves obligated to pay, until 1945, a rate considered excessive whether measured by the requirements of the Act or externally, by comparison with the newer projects.

Accordingly, a request for a review of the rates was filed in 1937 with the Secretary of the Interior, in line with a right granted when the initial allocation of the project energy was made. Preliminary conferences showed that a change from the competitive to the amortization basis, however, involved unavoidable differences of interest among the seven states of the Colorado Basin. Two years of almost continuous discussion and negotiation followed, with frequent formal conferences, before all such interests were brought into agreement. As the surplus revenues of the original Act would be entirely eliminated on an amortization basis, determination by compromise and agreement was necessary as regards payments to be made in lieu of taxes to Arizona and Nevada, and additional payments to the Colorado River Basin Development Fund, for the benefit of all seven of the states involved.

Numerous water problems had required previous conferences, in efforts to avoid litigation among the states, so that the power problems came naturally before the same conference groups under the auspices of the several governors and most frequently under the chairmanship of the late Hon. Henry H. Blood, then governor of Utah. As the governors were generally unable to give the time personally for the more frequent conferences, and the difficulty of changing personnel and lack of continuity of program between sessions became apparent, the now well-known "Committee of 14 and 16" began to function. It consists of two representatives of each of the seven basin states, appointed by each governor or by state boards appointed by him, as its only authority is derived from the various governors, being without legislative authorization. To this Committee of 14 are added, for consideration of power problems, two representatives of the California power contractors (Los Angeles and the Metropolitan Water District) which has the further effect of equalizing the basin representation. The committee has operated under the very able chairmanship of Clifford H. Stone of Colorado, to whom in a large measure is due the credit for reaching an harmonious agreement among the states in 1939 on the question of allocation of Boulder Canyon Project power revenues. The committee recommendation that Arizona and Nevada should each receive $300,000 annually, with $500,000 annually going to the Colorado River Basin Development Fund, was adopted by Congress in the Boulder Canyon Project Adjustment Act, approved July 19, 1940.

In view of the immediate benefits to be derived by the three Lower Basin states, a further agreement was made that expenditures from the Development Fund should be limited to the Upper Basin states until 1955. The first three annual payments were applied to the completion of surveys and studies for a "Comprehensive Plan of Basin Development," long under way by the Bureau of Reclamation. Division of the fund among the Upper Basin states was required to be on an "equitable" basis (whatever that might mean), and not until October, 1941, was agreement finally reached to interpret this as meaning "equally." This is an example of the committee's help in avoidance of litigation over the allocation of the project revenues, although protracted discussions were required at times. Without such a forum to give an opportunity for thorough debate of the controversial problems, and final agreement by compromise before the questions could become political issues at Washington, it seems that passage of the Adjustment Act would have been impossible. Even then, however, difficulties were not ended, as this Act required definite repayment contracts to be entered into by June 1, 1941, covering 90% of the firm power or otherwise the Act would be void. Not until May 29, 1941, were the contracts finally signed, making the Adjustment Act effective.

Hearings on these contracts had been convened at Los Angeles on August 12, 1940, continuing until December 6, before a special board of three representing the Secretary of the Interior. The resulting record includes about 2,000 pages of transcript of oral evidence and argument, besides 91 exhibits, many of these being lengthy reports. Chief questions at issue involved details of the agency (generating) contracts; generating charges; time and method for future readjustments of rates, to insure full repayment to the government; O & M cost estimates; allowances for replacement and depreciation; estimates of firm and secondary energy, available and also marketable; and of greatest interest, the new energy rate. Only the latter point appears to be of importance to the purpose of this paper, as its determination finally achieved the definite cost and revenue allocation that had been lacking under the terms of the original Act. Slight readjustments are still provided for, as of June 1, 1947, and at 5-yr intervals, to correct for excesses or deficiencies in estimated revenues; and annually, to allow for the effect of variations in actual cost of operation, maintenance, and replacements. The latter adjustments increased the firm power base rate (fixed at 1.163 mills per kw-hr for 1937 to 1942) to 1.172 for 1943 and 1.190 for 1944. A proportionate decrease to 0.34 mill per kw-hr for secondary power in the years 1937 to 1942 was changed to 0.346 for 1943 and 0.357 for 1944. The annual secondary rate is to be computed from future adjusted firm rates as the average of (1) a rate which bears the same ratio to the firm rate as 0.3 to 1.1, and (2) a rate which is 0.8 mill less than the firm rate; or otherwise expressed, as the firm rate times 0.6363636, less 0.4; but not less than 0.2 mill per kw-hr.

With similar infinitely detailed and legalistic exactitude, every possible or imaginable contingency of the future as affecting the power rate structure has been provided for at painful length in the several contracts and general regulations, now in force and effect. Revising the original power allocations to allow for the increased power production with the 25-ft higher (575 ft) dam, which change had caused the first allocations to total in excess of 100%, the present power contracts result in the following firm energy allocation:

Allocation	Percentages
Metropolitan Water District of Southern California (for aqueduct pumping only)	35.2517
State of Nevada (for use in Nevada only)	17.6259
State of Arizona (for use in Arizona only; no contract as yet)	17.6259
City of Los Angeles, Calif.	17.5554
Southern California Edison Company	7.0503
City of Glendale, Calif.	1.8475
City of Pasadena, Calif.	1.5847
California Electric Power Company	0.8813
City of Burbank, Calif.	0.5773
Total	100.0000

The power blocks for the two states are equally underwritten by the City of Los Angeles and Southern California Edison Company, with drawback privileges as formerly. Not to exceed 20,000-kw peak demand is reserved for the United States, to be charged equally against the Los Angeles and Edison Company allocations for distribution in Boulder City or for other government camps and uses. This is in addition to power for dam operation, which is to be furnished without charge and included with station losses.

Conforming to the exact terms of the Adjustment Act, the general regulations and the foregoing contracts, a detailed financial operations study now indicates estimated project revenues over the 50-yr period to May 31, 1987, of $256,303,360, which are sufficient to repay the reimbursable investment in the dam and power-plant building (estimated for rate determinations at $82,878,131 as of June 1, 1941, including 3% interest during construction, or about 82.5 million dollars present value as of June 1, 1937, including some allowance for deferred construction), within fifty years amortized at a 3% interest rate. In addition, all estimated operation, maintenance, and replacement costs are covered, and Arizona and Nevada will each receive $15,000,000 during the fifty years, with $25,000,000 going to the Colorado River Basin Development Fund.

These allocations are compared in Table 2, on a present-value basis, as in Table 1, with the results under the original Act for various firm power rates after 1945, and with the various payments capitalized at 3%. Table 2 shows that, under the terms of the Adjustment Act, Arizona and Nevada will each receive 4.2 times as much revenue in lieu of taxes from the Boulder Canyon Project as they were assured of receiving by the original Act, and that only in case the average revised firm power rate after 1945 had exceeded 1.52 mills per kw-hr would the states have received as much revenue as they are now assured of getting. This is equivalent, on a present-value basis, to 18% of the investment in the dam and power-plant building. Likewise, the Colorado River Basin Development Fund will receive annual payments with a present value of 15% of the project investment, instead of the probability (almost certainty) of obtaining nothing under the original Act. A general understanding of these comparisons, at least on an approximate qualitative basis, explains the high degree of agreement that was finally attained in compromising the interests of the various states of the Colorado River Basin.

TABLE 2.—ALLOCATION OF ESTIMATED REVENUES AND COSTS, AS PRESENT VALUES, AT 3%, AS OF MAY 31, 1937

Firm power rate (mills per kw-hr)	DAM AND POWER-PLANT BUILDING[a]		REPAYMENT[b]		ARIZONA AND NEVADA		COLORADO FUND[c]	
	Million dollars	Percentage of investment	Million dollars	Percentage of allocation	Million dollars	Percentage of investment	Million dollars	Percentage of investment

1.40	110.3	134	18.6	74	11.3	14	0.0	0
1.555	110.3	134	26.3	105	15.8	19	0.0	0
1.63	110.3	134	30.2	121	18.1	22	0.0	0

[a] Repaid within fifty years. [b] Flood-control allocation repayment. [c] Colorado River Basin Development Fund. [d] Deferred beyond the 50-yr amortization period. [e] Present values of costs and payments required by the original Act but capitalized at 3% interest rate (as allowed by the Adjustment Act).

By the Adjustment Act, the government obtained certainty as to the amortization of its investment, less the flood-control allocation, within a 50-yr period, at a 3% interest rate, pronounced reasonable under the circumstances. Repayment of the flood-control allocation is definitely deferred beyond the 50-yr period; but the 1945 revision of power rates, under the original Act, would almost certainly have accomplished the same effect, at least as to 77% of the allocation.

On the other hand, assuming for purposes of illustration that the new firm power rate of 1.163 mills per kw-hr is fair and reasonable on a competitive market basis (as seems indicated by its acceptance by all of the power contractors), it may be considered that, on a 3% present-value basis, the government surrendered the possibility of a profit of about $27,800,000 (the difference between 4% and 3% interest charges) besides deferring for fifty years the dependable repayment of $5,700,000 toward the flood-control allocation. The recipients of this relinquished profit vary for different assumptions of future competitive rates, but, on the basis of the present rate as stated, the "split-up" would appear to be as follows:

Arizona (additional revenue)	$ 5,700,000
Nevada (additional revenue)	5,700,000
Colorado River Basin Development Fund (additional revenue)	12,400,000
Power contractors (reduced payments, 1937 to 1945)	9,700,000
Total	$33,500,000

The savings to the power contractors will be divided among power consumers in Arizona, Nevada, Utah (slightly), and Southern California, the chief beneficiary; but this is considerably less than the 100-million-dollar gain which the power contractors were often asserted to be obtaining, during the years of consideration of the Adjustment Act. With the Colorado River Basin Development Fund probably to be divided about equally among the four Upper Basin states until 1955, the indicated advantage of the Adjustment Act to each Upper Basin state is computed at $2,600,000, and to each of the states of Arizona and Nevada, $6,700,000 in addition to $1,750,000 apiece to the latter two under the terms of the original Act (all amounts as of June 1, 1937, discounted at 3%). After 1955 it may benefit Nevada and Arizona projects also. California is most unlikely to share in the fund then, because of the earlier completion of all projects having an available water supply. It is not implied that the 1945 revised firm power rate, by the original Act on the basis of competitive market conditions, would have been exactly 1.163 mills per kw-hr or even approximately this amount; but a similar comparison of individual benefits can be derived from Table 2 for any other revised rate that may be assumed. The illustration given, however, shows at least that the division of the benefits allocated by the Adjustment Act was not merely or solely in proportion to the Congressional voting strength of the various states, for example. Other factors also received consideration, such as anticipated receipts under the terms of the original Act and competitive power market conditions, regional as well as local.

The government, of course, ends by owning the entire project including replacement and depreciation funds for items subject to loss with use, and also retains final discretion as to the expenditure of the Colorado River Basin Development Fund. The foregoing "split-up" of this fund within the Upper and Lower basins, prior to and after 1955, is simply in accordance with the recommendation of local interested officials, which Congress may or may not follow exactly.

In refreshing contrast, from an engineering point of view, to the foregoing allocations, which are so largely dependent on legal and accounting, as well as political, considerations, is a novel rate item in the November, 1941, issue of *Intake* (Los Angeles Water and Power Department publication). New concepts in physics establish a definite relationship between energy and matter, making it possible to assign a weight to electrical energy and compare it with other commodities on the basis of cost per pound. At present Los Angeles retail prices, electricity costs about $20,000,000 per lb or two thirds the price of radium. As the power production from the Boulder Canyon Project in 1943 was about six "pounds" of electrical energy, on this futuristic basis, the adjusted falling water charge is equivalent to $900,000 per lb, or about the market valuation for fine, large cut diamonds. Although this fact certainly was not given much, if any, consideration in the project's cost allocation and power rate determination, to an engineer fully appreciative of the Boulder Canyon Project, it does not seem too far-fetched to value the output of the project as highly as precious jewels.

SUMMARY

Revised power contracts for the Boulder Canyon Project (Arizona-Nevada), dated May 29, 1941, provided for the amortization of the cost, at 3% interest rate, by terms of the Adjustment Act of July 19, 1940. A power (falling water) charge of 1.163 mills per kw-hr was reduced from the 1930 rate of 1.63 mills per kw-hr, as the original Act's competitive basis for power rate determination was abandoned. Depression conditions had affected adversely the competitive rate factors (price of oil and natural gas, cost of steam plants, etc.) so that the rate revision required by the original Act, in 1945, would probably have resulted in approximately the same or perhaps a greater rate reduction.

This loss of revenues would have decreased or even eliminated the project payments to Arizona and Nevada, which are considered to be in lieu of taxes, and also would have ended the chance of payments to the Colorado River Basin Development Fund which were not available in any case until about 1985. Even the repayment of the government's investment in the dam and power-plant building might not have been completed within fifty years as planned. Therefore, by agreement among the United States, the power contractors, and the seven Colorado River Basin states, as represented by their "Committee of 14 and 16," the interest rate was reduced from 4% to 3%, repayment of $25,000,000 flood-control allocation was deferred beyond the 50-yr period, but amortization of balance of investment was made certain within this period, and definite annual payments to states were provided. These include $300,000 apiece to Arizona and Nevada, and $500,000 to the Colorado River Basin Development Fund, limited to use in the Upper Basin only, until 1955.

In this paper, project revenues made available by the present revised contracts and the Adjustment Act, derived from power sales and also water storage service charges, are tabulated by allocations to repayment of investment, payments in lieu of taxes, contributions to the Colorado River Basin Development Fund, and flood-control allocation repayments. For comparison, similar allocations under the terms of the original Act and contracts are presented in Table 3, assuming varied power rates after the 1945 adjustment date, and computing present values at both the adjusted 3% interest rate and at the 4% rate of the original Act. The change in interest rate was made on a showing that the interest cost to the U. S. Treasury for long-term loans during the project construction period did not exceed 2.75%.

DISCUSSION

W. L. Chadwick,[5] M. Am. Soc. C. E.—A full and interesting description of the power contracts for the Boulder Canyon Project is presented in this paper, which contains valuable information on the reasons for many of the paragraphs and clauses. As the author states, the problem of allocating the cost of the multiple-purpose Boulder Canyon Project to the several beneficiaries was encountered in only an unimportant way because the Boulder Canyon Project Act required, before money for construction could be appropriated, that provision be made by contract for revenues sufficient to insure payment of all expenses of operation and maintenance and repayment of construction advances by the United States, with interest at 4%. Since the rate for firm energy was determined by the competitive costs of steam generated energy at load centers in Southern California, there was no problem of allocating costs for rate-fixing purposes. Furthermore, the flood control allocation of $25,000,000 was statutory. Although a price was set for water storage service, this rate was not based on capital investment allocated to the purpose. Allocation complexities, however, did enter importantly into the drafting of the numerous contracts under the Boulder Canyon Project Adjustment Act.

Under the original contracts the "power privilege" was leased to the City of Los Angeles and Southern California Edison Company. Under this lease the city undertook to generate the energy requirements of the Metropolitan Water District of Southern California; the municipalities of Pasadena, Burbank, and Glendale; the states; and itself. The company undertook to generate the energy required by the two other companies and itself. The United States agreed to pay the lessees "in the form of credits upon the account of such lessee * * * the cost incurred by it in generating energy for other allottees * * *" and agreed to "require such other allottees to repay such cost to the United States."

The lease contract included the obligations of the lessees to take and pay (pay, in any case) for the energy allotted to each. Separate contracts were then executed by the other allottees requiring, similarly, that each take or pay for the energy allotted.

As the author states, conditions during 1936 and 1937 indicated that the price of 1.63 mills per kw-hr established for falling water would considerably more than liquidate the project costs. The late F. E. Weymouth, M. Am. Soc. C. E., then general manager and chief engineer of the Metropolitan Water District, realizing that the taxpayers and ratepayers of the district would be required to contribute 36% of all revenues collected in excess of actual costs, began negotiations for a downward adjustment of rates. The district was particularly interested, because the economic depression had made large inroads into anticipated water sales and it was apparent that foresight in contracting in advance for a pumping power supply that would be adequate for many years would require payment over a long period for large quantities of energy which could not be used and for which there then seemed little probability of making effective temporary releases for salvage sales.

---

[5] Chf. Civ. Engr., Southern California Edison Co., Los Angeles, Calif.

The first efforts were directed toward obtaining a revision of rates under the lease and energy contracts then in effect. Meeting opposition from those interested in excess revenues under the original contracts, Mr. Weymouth proposed revised contracts based on the repayment of all costs only, rather than on the requirement that charges be fixed by competitive conditions. Although long and tedious negotiations were required before this principle was enacted in legislation, it is the basis for rates under the Adjustment Act.

For reasons not known to the writer, during preliminary conferences and negotiations on the adjustment legislation, it was proposed that the lease of power privilege be canceled and that the United States operate the generating plant, as well as the dam, penstock, outlets, town site, utilities, etc. Alternatively, it was proposed that generation be by means of agency agreements between the United States and the lessees. Legal difficulties involving security of tenure and loss of the valuable leasehold rights of both lessees were resolved by a form of agency contract with about the same tenure to the lessees as previously enjoyed under the lease. Under the agency agreements, the agents agree to generate energy under substantially the same bases for the same allottees as formerly.

Under the original agreements, the rate of 1.63 mills per kw-hr covered the use of falling water delivered to the butterfly valve on the upstream side of the turbines. Accordingly, associated with this rate were costs for construction, operation, and maintenance of the dam; penstocks; outlet structures; power plant building; common station facilities, such as cranes, elevators, and offices; and Boulder City, with its utilities, parks, streets, and administration; etc. However, the rate did not include costs for investment in, or operation, maintenance, and replacement of, turbines, generators, switchgear, switch racks, power conductors, and related equipment. The latter were costs repaid by the lessees and collected, in turn, from the allottees by the United States.

Under the Adjustment Act it was required that:

> "The Secretary of the Interior is authorized and directed to, and he shall, promulgate charges, or the basis of computation thereof, for electric energy generated at Boulder Dam during the period beginning June 1, 1937, and ending May 31, 1987, computed to be sufficient, together with other net revenues from the project, to accomplish the following purposes:
>
> "(a) To meet the cost of operation and maintenance and to provide for replacements * * *.
>
> "(b) To repay to the Treasury, with interest at 3 per cent, the advances to the Colorado River Dam Fund, made prior to June 1, 1937, within fifty years from that date.
>
> "(c) To provide $600,000 for each of the years [payable $300,000 each to States of Arizona and Nevada] * * *.
>
> "(d) To provide $500,000 for each of the years * * *." (To the Colorado River Development Fund for additional development in the Colorado River Basin.)

The Adjustment Act required no adherence to the original principle of dividing the rate into a falling water charge and charges for generation. Accordingly, the entire subject of rates and "rate architecture," as referred to by W. F. Durand, was opened during the hearings held in Los Angeles during 1940 with R. V. L. Wright presiding as special representative of the Secretary of the Interior. Mr. Durand and Leland Olds served as special advisers. An early principle agreed to, however, was that the revisions in cost allocations or in rate design should not change the obligations of any allottee at the expense of another.

Allocations of cost for rate purposes were complicated by the size of generating units, the design of the generating plant, the number of allottees, and differences in standards of service on the several power systems involved.

Boulder Canyon power plant (January, 1944) contains six generators on the Nevada side and six on the Arizona side, all of 82,500-kva capacity except for one of 40,000 kva on the Arizona side (unit A-8). The distribution of these machines between generating agents and the allottees for whose benefit the machine is operated is as follows:

Generating units	Allottee for whose benefit the machine is operated
Nevada Side—	
N-1	City of Los Angeles, Burbank, Glendale, Pasadena, Boulder City, California Pacific Utility Company, and Citizens Utility Company (contractors for the Metropolitan Water District), and the State of Nevada for the Southern Nevada Power Company and the Lincoln County Power District No. 1
N-2	
N-3	
N-4	
N-5	Metropolitan Water District and Basic Magnesium, Inc.
N-6	Metropolitan Water District and Basic Magnesium, Inc.
Arizona Side—	
A-1	City of Los Angeles et al. (see N-1 to N-4)
A-2	City of Los Angeles et al. (see N-1 to N-4)
A-5	Southern California Edison Company
A-6	Southern California Edison Company
A-7	Southern California Edison Company
A-8	California Electric Power Company

The Southern California Edison Company is the agent operating units A-5, A-6, A-7, and A-8. All the remainder are operated by the City of Los Angeles.

Including three contractors for energy allotted to but not used by the Metropolitan Water District, there are thirteen agencies receiving energy directly from the Boulder plant. Transmission to City of Los Angeles is at 287,000 v; to Edison Company at 220,000 v; to Metropolitan Water District and Basic Magnesium, Inc., at 220,000 v; to California Electric Power Company and Lincoln County Power District at 138,000 v; to Burbank, Glendale, and Pasadena via City of Los Angeles lines at 287,000 v; to Southern Nevada Power Company at 33,000 and 69,000 v; to Citizens Utilities at 69,000 v; to California Pacific Utilities Company at 69,000 v; and to the United States at 33,000 v. Further complicating the situation are the different frequencies. At the time construction of the plant was undertaken, all Southern California utilities, except California Electric Power Company (then Southern Sierras Power Company) and Los Angeles Gas and Electric Company (later part of the City of Los Angeles system) were operated at 50 cycles. In 1936 and 1937, the City of Los Angeles converted its system to 60 cycles, which, because of joint transmission obligations, required similar conversion by Burbank, Glendale, and Pasadena. Accordingly, the Southern California Edison generators are operated at 50 cycles and all others at 60 cycles. Hence, parallel operation of all units is not possible. Such parallel operation is further undesirable because of the tremendous energy concentrations to be interrupted during short circuits.

Accordingly, after determining the costs to be met (that is, for investment, interest, payments to states, Colorado River Development Fund, operation, maintenance, and replacement) equitable allocation of shares in these costs between allottees and contractors was necessary. At the request of the special board, most of the allottees submitted suggestions for rate design. These varied from complicated bases involving consideration of all differences between allottees to others which would have allocated all on a straight kilowatt-hour allocation. The complications were decidedly undesirable, and the straight kilowatt-hour charge was inequitable because of differences in load factor, cost of generating equipment, differences in operating costs, etc.

An equivalent of the original falling water charge was determined by estimating all costs and charges for the 50-yr contract period, estimating the generation of both firm and secondary energy during the same period, and determining the quotient of the two.

The energy component was finally resolved by dividing the generation and transforming and switching facilities into sections according to uses, determining the investment costs for each, estimating the operation, maintenance, and replacement costs for a year in advance, and billing monthly for the total of such costs per section. Adjustments are made at the end of each operating year.

Costs for facilities used for joint service, such as generators N-1, N-2, N-3, and N-4, were finally allocated on the basis of kilowatt-hour use, although much testimony was taken favoring a kilowatt basis for this purpose.

Essentially, with two minor exceptions, it may be said that

(1) Allocation of all common costs for the dam and appurtenances, general plant, and other facilities necessary to all generation is entirely on a delivered kilowatt-hour basis;
(2) Allocation of costs for generation is on a direct recorded cost basis; and
(3) Allocation for jointly used generating facilities is on a kilowatt-hour basis.

The exceptions are that the cost of common station facilities operated by agents is allocated on the basis of generator months and that operation costs of Southern California Edison Company for operating its own generators and those of the California Electric Power Company are allocated on the basis of generator units operated.

Because billings must be made from month to month, they are based on estimates made a year in advance, adjusted at the end of each year.

Realizing the impossibility of estimating costs and energy output accurately, fifty years in advance, the Adjustment Act contract and regulations provide for adjustments in energy rates at specified times.

The Adjustment Act contracts have now (1944) been in effect for nearly three years. Although, like all negotiated contracts, those under the Adjustment Act involve numerous compromises (based on neither pure economics nor engineering), no fault has yet developed in the allocation bases to indicate their impracticability.

A. R. ARLEDGE,[6] M. AM. SOC. C. E.—A record of the history of the Boulder Canyon development and the not generally known facts regarding the background of the pioneer in multiple-purpose projects are presented in this excellent paper. Although the author has mentioned the varied interests involved and the need for negotiating the contracts, further emphasis should be placed on the long negotiations for the Adjustment Act and the readjusted repayment contracts. The question may be asked: "Are not these contracts reasonably simple legal documents in which the engineering factors are either known or lend themselves readily to fairly close engineering estimates, although these factors involve long periods of time and economic factors of great magnitude?"

From the data submitted, the answer to this question does not seem so simple. The participants in the negotiations at no time considered the task an easy one; but they became more aware of the involved nature of the problems confronting them as time passed, and the pattern of the varied sectional economic and engineering difficulties assumed shape. The engineers, attorneys, and others called upon to solve these problems, of necessity, had to be men, not only informed on the subject matter, but endowed with both prophetic acumen and diplomatic dexterity of first magnitude, in order to cope with the situations as they arose.

In recognition of these difficulties, the Hearings before the Committee on Irrigation and Reclamation, United States Senate,[7] state in part, with reference to the Boulder Canyon Project Act:

> "As is hereinafter more fully pointed out, the text of the act contains many uncertainties, ambiguities, and inconsistencies."

And further[8] in regard to controversies which arose:

> "The chief causes for controversy have been, first, the method of determining charges for electric energy at the dam; second, the extent of, and method of determination of, the rights of the States of Arizona and Nevada in the revenues from the project; and third, the extent of the interest of the several States of the Basin of the Colorado River, in the revenues from the dam."

The original Project Act involved the interests of the seven states of the Colorado River Basin, the United States of Mexico, and the United States of America. Although the Adjustment Act, as its name implies, is primarily an act of Congress amending the Project Act, it required the close cooperation of the seven basin states and the power contractors as represented by the Committee of 16, and the other power allottees and irrigation interests. To complete this complex picture, it is necessary to add the satellite interests which revolve around and affect each of the foregoing major groups.

[7] Boulder Canyon Project Adjustment Act, Hearings Before the Committee on Irrigation and Reclamation on S. 4039, United States Senate, 76 Cong., 3d Session, May 28, 1940, p. 6.

[8] *Ibid.*, p. 7.

In 1937, when the request for a review of the rates was filed, it was thought that the Secretary of the Interior with his broad discretionary powers could correct the difficulties in the energy rate structure as well as those encountered in administering the Project Act, but competent legal authority ruled otherwise. This ruling started, in earnest, the long and tedious negotiations which culminated in the approval of the Adjustment Act on July 19, 1940. This Act carried a provision, in substance as follows: It shall cease to be operative and shall be of no further force or effect, if contracts (the readjusted contracts of the City of Los Angeles, the Metropolitan Water District of Southern California, and the Southern California Edison Company) in accordance with the requirements of Section 10 of the Act shall not have been entered into prior to June 1, 1941. The principal function of the Adjustment Act seemed to be to provide requirements, rules, regulations, and a time limit under which the readjusted repayment contracts could be perfected. The time limit was beaten by a day.

In spite of the seemingly insurmountable difficulties and the duration of the negotiations for both the Adjustment Act, setting up requirements and limitations for the new contracts, and the new contracts, there were leveling elements which provided the incentive for a mutual agreement. First, the contractors for energy at Boulder Dam were paying a rate about 50% greater than actually was required under the conditions as stated in the Project Act. Second, there was grave doubt that the states of Arizona and Nevada would receive payments in lieu of taxes commensurate with the intent of the Project Act, or that the seven states of the Colorado River Basin would receive any payments that might be used as a development fund, because of uncertainties and ambiguities of the Act. Third, as the author has stated, there was some uncertainty, under the original Act, as to whether the federal government would be fully reimbursed in fifty years because of the requirement to readjust rates periodically in accordance with rates prevailing at competitive centers.

The leveling elements, which provided each main group with trading points, under certain conditions may have given the contractors of energy some slight advantage. The "Contract for Lease of Power Privilege," under date of April 26, 1930, in Article 16, has the following provision:

> "At the end of fifteen (15) years from the date of execution of this contract and every ten (10) years thereafter. the above rates of payment for firm and secondary energy shall be readjusted upon demand of any party hereto, either upward or downward as to price, as the Secretary may find to be justified by competitive conditions at distributing points or competitive centers."

Under this provision, a readjustment of rates would have taken place automatically in 1945. Unless the prices of fuel oil and gas had increased materially, the rates for firm and secondary energy, probably, would have been too low to guarantee the repayment of the federal government's advances in fifty years, and also to make payments to the states of Arizona and Nevada, and to the Colorado River Development Fund to be used in the interest of developing a comprehensive plan for the Colorado River Basin as a whole. If the contractors had chosen this alternate, they would have been penalized by the payment of many millions of dollars in excess revenues before 1945. It seems that the best long-term plan has been accepted, measured in terms of benefits to the entire basin.

Engineers may not be in agreement on the merits of one project subsidizing other projects, but, perhaps, all will agree that, to develop a contract extending fifty years into the future, under the present conditions of social and economic flux, it required men of vision and resourcefulness in each major group, working earnestly and diligently for a comprehensive plan of development of the Colorado River Basin.

Clay C. Elder,[9] M. Am. Soc. C. E.—The discussions by Messrs. Chadwick and Arledge are helpful in presenting the viewpoints of the two generating agencies at Boulder Dam. Their clarifying statements are greatly appreciated. To one who recalls the controversies that raged around articles on Boulder Dam a decade or two ago, when the project was being planned, authorized, and constructed, the absence of similar present discussions is at first surprising. This lack of controversy indicates at least that the Adjustment Act of 1941 has been a practical success, in spite of its numerous compromises, and that the compromises have left no serious ill feeling among the seven states and numerous interests involved. The Adjustment Act relates chiefly to rate revisions and revenue allocations, however. On more fundamental questions, the lack of present criticism seems to indicate a successful accomplishment of the project's multiple purposes—flood control, water conservation, power development, silt control, water quality improvement, recreational uses, and even the improvement of navigation.

With the closing of the Boulder Dam magnesium plant, as recently announced, the project is leading the way into the period of reconversion, even as it was previously in the forefront of total war production. The Boulder Dam power output and demand are not decreased by the change but regionally an important saving of essential oil and gas fuel results from the decreased operation of steam standby plants.

The only remaining serious controversies involving the Boulder Canyon Project relate to the allocation of permanent water rights to its conserved flood waters. Recent ratification by Arizona of the Colorado River Compact seemed a major step toward real peace, although current proposals for large irrigation diversions in Arizona above Boulder Dam may finally cancel many of the benefits of the Adjustment Act and may make the project insolvent as to cost repayment to the federal government. Of more immediate importance is the pending treaty with Mexico relating to the utilization of the waters of the Rio Grande and the Colorado River. Hearings on this proposed treaty are scheduled for early in 1945 before the Senate Foreign Relations Committee and, judging from the preliminary rounds of the battle, will be as hotly contested as any similar arguments of the "good old days." So at Boulder Dam, and along the Colorado River, as elsewhere in the world, it appears that "peace in our times" has yet to be achieved.

SHEAR EFFECT ON THE STRENGTH OF STRUTS

BY S. SERGEV,[1] ESQ.

WITH DISCUSSION BY MESSRS. LEON BESKIN, MARSHALL HOLT, DAVID B. HALL, AND S. SERGEV.

SYNOPSIS

In studying the strength of initially straight struts, pin-supported at one end and laterally restrained at the other, loaded by a concentrated axial load at some intermediate point between the supports, it is desirable to know the effect of shearing forces on the critical load on the struts. This paper treats that problem. A general expression for buckling criteria is derived for struts of different but constant cross sections. A special case and an example is solved in detail comparing the strength of a latticed strut, considering shear effect, with a strut the strength of which is determined by bending considerations only.

INTRODUCTION

General.—Ordinarily, a strut is an initially straight slender member, principally subjected to axial loads. Struts may have different means of support with the loads applied anywhere along the length of the member. Slender struts fail by buckling caused by a critical load or loads on the strut. The usual method of determining critical loads on initially straight struts is to assume, at every normal cross section, the curvature to be proportional to the bending moment only. This is satisfactory for solid struts, but not for latticed struts in which shearing forces may substantially reduce the critical load. Formulas have been derived for initially straight latticed struts subjected to end loads.[2]

In practice, some struts are pin-supported at one end and laterally restrained at the other, and loaded by a single concentrated axial load applied at some intermediate point between the supports. The effect of shearing forces on the critical load has not yet been established for this case. It is desirable, therefore, to derive formulas that yield this information.

NOTE.—Published in November, 1943, *Proceedings.* Positions and titles given are those in effect when the paper or discussion was received for publication.

Notation.—The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials,[3] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = cross-sectional area of a strut; also, where specially defined, A, B, C, and D are integration constants:
  A_a = area of top strut section;
  A_b = area of bottom strut section (see Fig. 1);
  A_d = area of two diagonals;
  A_p = area of two batten plates;
a = length of top strut segment (b = length of bottom segment); as a subscript, a refers to the upper strut segment;
B = integration constant (see A);
b = length of bottom strut segment (see a); as a subscript, b refers to the bottom strut segment;
C = integration constant (see A);
c = spacing of batten plates (see Fig. 2);
D = integration constant (see A);
E = Young's modulus of elasticity;
e = deflection of strut at point of load P;
G = shear modulus of elasticity;
h = length of batten plates and spacing of channels (see Fig. 2);
I_a = moment of inertia of the strut cross-sectional area about the z-axis, in the top segment equal to $u\, I_b$;
I_b = moment of inertia of the strut cross-sectional area about the z-axis, in the bottom segment;
I'_b = inertia moment of two batten plates;
I_c = moment of inertia of the cross section of a vertical channel about its own gravity axis parallel to the web;
K = beam constant for determining shear deflections;
k = a span ratio equal to $\frac{b}{L}$;
L = total length of strut equal to $a + b$;
M = bending moment about the z-axis;
m = a substitution constant (Eq. 5*b*); $m^2 = \frac{P}{E\, I_b}$;
n = a substitution constant; $n^2 = \frac{P}{E\, I_a} = \frac{m^2}{u}$;
P = critical load on the strut:
  P' = buckling or critical load on solid struts;
q = a substitution constant (Eq. 10*e*);
r = least radius of gyration with respect to the z-axis (Eq. 34*a*);
t = a parameter dependent on the dimensions of the column and the material (Eq. 30);
u = ratio of inertia moments $= \frac{I_a}{I_b} = \frac{m^2}{n^2}$;

---

[3] ASA—Z10a—1932.

V = total transverse shearing force;
x = rectangular coordinate measured along the axis of the strut:
  x_a = values of x measured from the top down;
  x_b = values of x measured from the bottom upward;
y = deflection of the strut at any point x:
  y_m = deflection at x due to bending moment;
  y_v = deflection at x due to shearing force;
z = rectangular coördinate measured along the z-axis;
α = a substitution constant (see Eq. 30);
β = a parameter dependent on the dimensions of the column and the material (see Eq. 32);
γ = a substitution constant for solid struts (Eq. 25);
ϕ = (see Fig. 2) angle between batten plates and diagonals;
ρ = radius of curvature; and
ψ = a substitution constant for latticed struts.

Assumptions.—All equations and formulas derived in this paper are based on the following assumptions:

1. The strut is initially straight;
2. The material composing the strut is homogeneous;
3. The weight of the strut is neglected;
4. All stresses and strains are within the limits of proportionality; that is, they conform to Hooke's law; and
5. The deflection, and hence the curvature, of the strut is small.

Except No. 5, these assumptions need no comment. To avoid repetition, and because the implications in Assumption 5 are significant, this assumption will be discussed at some length.

The deflection of a strut at the incipient buckling state is small, but for all practical purposes the strut is considered to have failed at the first indication of buckling. After buckling begins, with slight increase in the loading, the deflection increases greatly, but its relationship to the effects producing it is no longer of practical interest. Since the deflection is small within the range considered, it can be shown easily that the curvature ρ of the strut axis is approximately equal to

$$\frac{1}{\rho} = \frac{d^2y}{dx^2} \quad \text{.........................(1)}$$

(This is the usual assumption made in all approximate computations.) The exact relationship of curvature to the bending moment M causing it is expressed by

$$\frac{1}{\rho} = \frac{M}{E\,I} \quad \text{.........................(2)}$$

in which E = modulus of elasticity; and I = moment of inertia of the strut cross-sectional area about the z-axis. Eliminating the curvature between these two expressions:

$$\frac{d^2y}{dx^2} = \frac{M}{E\,I} \quad \text{.........................(3)}$$

Eq. 3 defines a valid relationship between the deflection and bending moment when the deflection is small relative to the span. $\Bigl($Another way of stating this is that, for flat curves, the rate of change of the slope at any point equals the curvature of the curve at that point, which in turn equals $\frac{M}{EI}$.$\Bigr)$

CRITICAL LOAD ON SOLID STRUTS

Consider a strut that is pin-supported at one end and restrained laterally at the other, and loaded by a single concentrated load at some intermediate point between the supports (see Fig. 1). The load is assumed to be symmetrically applied, thus simulating concentric load condition. The flexural rigidities of the strut in the two segments a and b are constant but unequal. Assume a solid strut for the present discussion.

FIG. 1

Under a critical load, P, due to initial crookedness or small eccentricity, the strut axis will deflect slightly so that P will be a distance e from the initial or unloaded state of the strut. The indicated reactions are determined from the laws of equilibrium.

First consider the bottom segment b, and express the curvature of the strut axis in terms of the bending moment. The bending moment at any section distance x_b from the bottom origin is

$$M = -P\,y_b + \frac{P\,e\,x_b}{L} \qquad \text{(4)}$$

in which the positive sign denotes compression on the side adjacent to the positive y-coordinate. The general relationship, for flat curves, between the bending moment and the deflection, y_{bm}, that it produces is

$$E\,I_b \frac{d^2 y_{bm}}{dx^2_b} = -P\,y_b + \frac{P\,e\,x_b}{L} \qquad \text{(5a)}$$

Dividing Eq. 5a by $E\,I_b$ and using the notation $\frac{P}{E\,I_b} = m^2$:

$$\frac{d^2 y_{bm}}{dx^2_b} = -m^2\,y_b + \frac{m^2\,e\,x_b}{L} \qquad \text{(5b)}$$

Considering the effect of shearing forces on the deflection of the strut, the total transverse shearing force is:

$$V_b = \frac{dM}{dx_b} = \frac{d}{dx_b}\left(-P\,y_b + \frac{P\,e\,x_b}{L}\right) = -P\left(\frac{dy}{dx}\right)_b + \frac{P\,e}{L} \qquad \text{(6)}$$

from which

$$\left(\frac{dV}{dx}\right)_b = -P\left(\frac{d^2y}{dx^2}\right)_b \qquad \text{(7)}$$

The slope of the strut axis due to shear strain, from fundamental concepts, is equal to

$$\frac{dy_{bv}}{dx_b} = -\frac{K\,V_b}{A_b\,G} \qquad \text{(8)}$$

in which the negative sign follows from Fig. 1(c) where V_b is positive and acting alone would give a negative slope. The factor K is a constant depending on the cross section of the strut. (This factor is 1.2 and 1.11 for rectangular and circular cross sections, respectively.)[4] Taking the first derivative with respect to x_b in Eq. 8, an expression is obtained for the shear curvature as a function of the total transverse shearing force:

$$\frac{d^2 y_{bv}}{dx^2_b} = -\frac{K}{A_b\,G}\left(\frac{dV}{dx}\right)_b \qquad \text{(9)}$$

---

[4] "The Theory and Practice of Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, 10th Ed., John Wiley & Sons, 1910, Vol. 2, p. 27; also "Theory of Statically Indeterminate Structures," by W. M. Fife and J. B. Wilbur, McGraw-Hill Book Co., Inc., 1st Ed., p. 27.

In Eq. 9, the expression found in Eq. 7 is substituted for $\left(\frac{dV}{dx}\right)_b$:

$$\frac{d^2 y_{bv}}{dx^2_b} = \frac{K\,P}{A_b\,G}\left(\frac{d^2y}{dx^2}\right)_b \quad\text{(10a)}$$

This relationship gives the curvature of the elastic line of the strut due to shearing force. The total curvature resulting from bending moment and shearing force is the sum of the two curvatures; that is,

$$\left(\frac{d^2y}{dx^2}\right)_b = \frac{d^2y_{bm}}{dx^2_b} + \frac{d^2y_{bv}}{dx^2_b} \quad\text{(10b)}$$

If the expressions for the curvatures found in Eqs. 5*b* and 10*a* are substituted into Eq. 10*b*—

$$\left(\frac{d^2y}{dx^2}\right)_b = -\,m^2\,y_b + \frac{m^2\,e\,x_b}{L} + \frac{K\,P}{A_b\,G}\left(\frac{d^2y}{dx^2}\right)_b \quad\text{(10c)}$$

or rewriting

$$\left(\frac{d^2y}{dx^2}\right)_b\left(1 - \frac{K\,P}{A_b\,G}\right) = -\,m^2\,y_b + \frac{m^2\,e\,x_b}{L} \quad\text{(10d)}$$

Dividing each term in Eq. 10*d* by $1 - \frac{K\,P}{A_b\,G}$ and using the notation $q^2 = \frac{m^2}{1 - \frac{K\,P}{A_b\,G}}$, Eq. 10*d* may be written in the form:

$$\left(\frac{d^2y}{dx^2}\right)_b + q^2\,y_b = q^2\,\frac{e\,x_b}{L} \quad\text{(10e)}$$

The general solution of Eq. 10*e* is

$$y_b = A\sin q\,x_b + B\cos q\,x_b + \frac{e\,x_b}{L} \quad\text{(11a)}$$

The constants A and B may be determined from the boundary conditions $y_{x_b=0} = 0$ and $y_{x_b=b} = e$. The constants are found to be $B = 0$, and $A = \frac{a\,e}{L}\sin q\,b$. Substituting these into Eq. 11*a*,

$$y_b = \frac{a\,e\sin q\,x_b}{L\sin q\,b} + \frac{e\,x_b}{L} \quad\text{(11b)}$$

The slope of the elastic line of the strut, corresponding to the deflection y_b, is found by taking the first derivative with respect to x_b in Eq. 11*b*. The slope is

$$\left(\frac{dy}{dx}\right)_b = \frac{a\,e\,q\cos(q\,x_b)}{L\sin q\,b} + \frac{e}{L} \quad\text{(12)}$$

Consider next the deflection of the top segment. The bending moment of any distance x_a from the top origin is

$$M = -\,\frac{P\,e\,x_a}{L} \quad\text{(13)}$$

The curvature produced by this moment, using the argument discussed before, is

$$E\,I_a \frac{d^2 y_{am}}{dx^2_a} = -\frac{P\,e\,x_a}{L} \quad \text{(14)}$$

Dividing both sides by $E\,I_a$ and using the notation $\frac{P}{E\,I_a} = n^2 = \frac{m^2}{u}$,

$$\frac{d^2 y_{am}}{dx^2_a} = -\frac{m^2\,e\,x_a}{u\,L} \quad \text{(15)}$$

Now, considering the effect of the shearing force,

$$\frac{dM}{dx_a} = V_a = -\frac{P\,e}{L} \quad \text{(16)}$$

From the study of shear strain, as discussed before,

$$\frac{dy_{av}}{dx_a} = -\frac{K\,V_a}{A_a\,G} = \frac{K}{A_a\,G} \times \frac{P\,e}{L} \quad \text{(17)}$$

The curvature of the elastic line due to shearing force is equal to

$$\frac{d^2 y_{av}}{dx^2_a} = \frac{d}{dx_a}\left(\frac{K}{A_a\,G} \times \frac{P\,e}{L}\right) \quad \text{(18)}$$

Since the term in the parentheses will be a constant at the instant buckling begins, it is seen that the curvature due to shearing forces in the top segment is zero. Consequently, the total curvature of the elastic line is that due to bending only. Hence, $\frac{d^2 y_{am}}{dx^2_a} = \frac{d^2 y_a}{dx^2_a}$, and from Eq. 15, integrating once—

$$\left(\frac{dy}{dx}\right)_a = -\frac{m^2\,e\,x^2_a}{2\,u\,L} + C \quad \text{(19)}$$

Integrating again,

$$y_a = -\frac{m^2\,e\,x^3_a}{6\,u\,L} + C\,x_a + D \quad \text{(20)}$$

The constants C and D may be evaluated from the following conditions:[4a]

$$(y_a)_{x_a=0} = 0; \qquad \left(\frac{dy_a}{dx_a}\right)_{x_a=a} = -\left(\frac{dy_b}{dx_b}\right)_{x_b=b} \quad \text{(21)}$$

from which $D = 0$, and

$$C = \frac{m^2\,e\,a^2}{2\,u\,L} - \frac{a\,e\,q}{L}\cot q\,b - \frac{e}{L} \quad \text{(22)}$$

Finally, substituting these values[4b] into Eq. 20:

$$y_a = -\frac{m^2\,e\,x^3_a}{6\,u\,L} - \left(\frac{m^2\,e\,a^2}{2\,u\,L} - \frac{a\,e\,q}{L}\cot q\,b - \frac{e}{L}\right)x_a \quad \text{(23)}$$

[4a] The second condition in Eq. 21 has been found incorrect; see discussions and Eq. 65.

[4b] See Eq. 64.

The deflection e may be eliminated from Eq. 23, using the condition that $y_a = e$ at $x_a = a$. Performing this operation and simplifying:[4c]

$$\tan q\, b = \frac{a^2\, q}{\dfrac{m^2\, a^3}{3\, u} - a - L} \quad \text{. . . . .} (24a)$$

If $b = k\, L$, then $a = L\,(1 - k)$, and Eq. 24a may be rewritten as follows:[4d]

$$\frac{\tan k\, q\, L}{q\, L} = \frac{1}{\dfrac{m^2\, L^2}{3\, u}\,(1 - k) - \dfrac{2 - k}{(1 - k)^2}} \quad \text{. . . . .} (24b)$$

The smallest useful roots satisfying Eq. 24b, using predetermined values of k and u, give the desired solution of the buckling problem under consideration. Before making specific applications of Eq. 24b, which, it will be remembered, was derived for solid struts, it will first be interesting to show that, with minor changes, it will apply to latticed struts.

Latticed Struts.—Eq. 24b applies to latticed and solid struts alike, provided the appropriate constants are used for each case. In straight solid struts loaded as shown in Fig. 1, the slope at any distance x_b from the bottom origin due to shearing force, from Eqs. 6 and 8, is

$$\left(\frac{dy}{dx}\right)_b = -\frac{K\, V_b}{A_b\, G} = -\frac{K}{A_b\, G}\left[-P\left(\frac{dy}{dx}\right)_b + \frac{P\, e}{L}\right]$$

$$= -\gamma\, P\left[\frac{e}{L} - \left(\frac{dy}{dx}\right)_b\right] \quad \text{. . . . .} (25)$$

and the resulting curvature (see Eq. 10a) is

$$\frac{d^2 y_{bv}}{dx^2_b} = \frac{K}{A_b\, G} \times P\left(\frac{d^2 y}{dx^2}\right)_b = \gamma\, P\left(\frac{d^2 y}{dx^2}\right)_b \quad \text{. . . . .} (26a)$$

in which $\gamma = \dfrac{K}{A_b\, G}$. For built-up or latticed struts similarly loaded, the corresponding slope due to shearing force is

$$\frac{dy_{bv}}{dx_b} = -\psi\, V_b = -\psi\, P\left[\frac{e}{L} - \left(\frac{dy}{dx}\right)_b\right] \quad \text{. . . . .} (26b)$$

and, for the curvature,

$$\frac{d^2 y_{bv}}{dx^2_b} = \psi\, P\left(\frac{d^2 y}{dx^2}\right)_b \quad \text{. . . . .} (26c)$$

The constants γ and ψ may be thought of as the slope of the strut axis caused by a shearing force of unity in the solid and latticed struts, respectively. Similar logic may be applied to the top segment.

The curvature due to bending of a built-up strut is independent of the type of lattice used, the lattice bars merely serving the purpose of keeping apart the principal longitudinal component parts of the strut. (It is implied that there is a large number of lattice bars.) Consequently, no change in fundamental approach to curvature caused by bending need be made for latticed struts from that used for solid struts.

[4c] See Eq. 69a.

[4d] See Eq. 69b.

The foregoing demonstrates that the only difference in analysis and design of solid and latticed struts lies in the constants γ and ψ. Thus, Eq. 24*b* is valid for solid and latticed struts with the following differences: For solid struts

$$q = \frac{m}{\sqrt{1 - \frac{KP}{A_b G}}} = \frac{m}{\sqrt{1 - \gamma P}} \qquad (27a)$$

and, for latticed struts,

$$q = \frac{m}{\sqrt{1 - \psi P}} \qquad (27b)$$

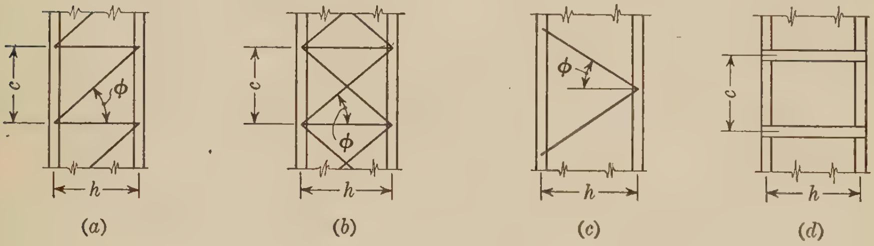

FIG. 2

The expressions for ψ for different built-up struts shown in Fig. 2 and for different types of lattice are, respectively,[5]

$$\psi_a = \frac{1}{E}\left(\frac{1}{A_d \sin\phi \cos^2\phi} + \frac{h}{c\,A_p}\right) \qquad (28a)$$

$$\psi_b = \frac{1}{E}\left(\frac{1}{2\,A_d \sin\phi \cos^2\phi}\right) \qquad (28b)$$

$$\psi_c = \frac{1}{E}\left(\frac{1}{A_d \sin\phi \cos^2\phi}\right) \qquad (28c)$$

and

$$\psi_d = \frac{1}{E}\left(\frac{c\,h}{12\,I_p} + \frac{c^2}{24\,I_c}\right) \qquad (28d)$$

in which c is the spacing of battens; h, the length of the battens between the hinges; A_p, the cross-sectional area of the two battens; A_d, the cross-sectional area of two diagonals; ϕ, the angle between batten plates and the diagonals; I_p, the moment of inertia of two batten plates about axes through the center of gravity and parallel to the z-axis; and I_c, the moment of inertia of the cross section of a vertical channel about its own gravity axis parallel to the web.

[5] "Theory of Elastic Stability," by S. Timoshenko, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1936, pp. 141–145.

SPECIAL APPLICATION

A special application of the formulas derived will be made now for the case when $k = 0.5$, and $\frac{I_a}{I_b} = u = 1.0$. Substituting these factors into Eq. 24*b* and rearranging slightly,

$$\frac{\tan \frac{1}{2} q L}{q L} = \frac{6}{m^2 L^2 - 36} \qquad (29)$$

The relationship between m and q, for solid struts, is

$$q L = \frac{m L}{\left(1 - \frac{K P}{A_b G}\right)^{0.5}} = \frac{m L}{\left(1 - \frac{K E I_b m^2 L^2}{A_b G L^2}\right)^{0.5}} = \frac{t}{(1 - \alpha t^2)^{0.5}} \qquad (30)$$

in which $m^2 = \frac{P}{E I_b}$, $t = m L$; $\alpha = \frac{K E I_b}{A_b G L^2} = \frac{K E}{G \left(\frac{L}{r}\right)^2}$. Eq. 29 is now rewritten:

$$\frac{\tan \left[\frac{\frac{1}{2} t}{(1 - \alpha t^2)^{0.5}}\right]}{\frac{t}{(1 - \alpha t^2)^{0.5}}} = \frac{6}{t^2 - 36} \qquad (31a)$$

The constant α in Eq. 31*a* is small, being in the order of 0.001 for $\frac{L}{r} = 50$ and $\frac{E}{G} = 2.5$. The corresponding smallest useful root satisfying Eq. 31*a* is $t = 4.3$, whereas for $\alpha = 0$, $t = 4.32$ in the writer's paper on this subject.[6] (The root is inadvertently shown as 2.2 instead of the correct root 2.16 for slenderness $\frac{b}{r}$. For slenderness $\frac{L}{r}$, the root is 2 (2.16) = 4.32.) It is thus seen that, for solid stout struts, the shear effect on the strength is small. For more slender struts, the effect of shear on the strength will be even less. Thus, it is permissible to neglect the shear effect when measuring the strength of solid struts.

Latticed Struts.—The situation is somewhat different for built-up or latticed struts, the strength of which may be significantly reduced by shearing deflections. To write the theoretical equation depicting the buckling state, use Eq. 31*a* substituting β for α:

$$\frac{\tan \left[\frac{0.5 t}{(1 - \beta t^2)^{0.5}}\right]}{\frac{t}{(1 - \beta t^2)^{0.5}}} = \frac{6}{t^2 - 36} \qquad (31b)$$

in which

$$\beta = \frac{\psi E I}{L^2} = \frac{\psi E A}{\left(\frac{L}{r}\right)^2} \qquad (32)$$

---

[6] *Bulletin No. 101*, Eng. Experiment Station, Univ. of Washington, Seattle, p. 18.

The smallest useful roots of t satisfying Eq. 31*b*, using different values of β, determine the buckling state and the critical load, P. Values of β varying from 0.0 to 0.05 were assumed and the corresponding t roots found. The results are shown in Fig. 3. An approximate relationship between t and β may be expressed by the equation

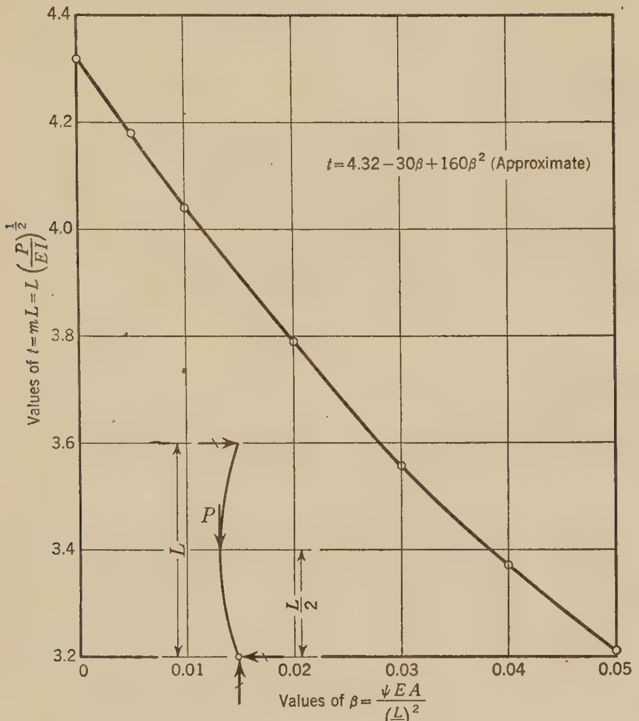

FIG. 3.—t ROOTS FOR DIFFERENT VALUES OF β

$$t = 4.32 - 30\,\beta + 160\,\beta^2 \qquad (33a)$$

Having found the root t for a given value of β, the critical load on the strut may be found from the relation

$$t^2 = m^2\,L^2 = \frac{P\,L^2}{E\,I} \qquad (33b)$$

Solving for P, the buckling or critical load is

$$P = \frac{t^2\,E\,I}{L^2} = \frac{t^2\,E\,A}{\left(\frac{L}{r}\right)^2} \qquad (34a)$$

The strength of a latticed strut may be obtained from the strength of a solid strut having the same flexural rigidity, by using a fictitious length, L_f.

This length may be determined as follows: The critical load for the solid struts is

$$P' = \frac{(4.32)^2 E A}{\left(\frac{L}{r}\right)^2} \qquad (34b)$$

and, for the latticed struts,

$$P = \frac{t^2 E A}{\left(\frac{L}{r}\right)^2} = \frac{(4.32)^2 E A}{\left(\frac{L_f}{r}\right)^2} \qquad (34c)$$

The effect of shear deflections on the critical load is neglected in Eq. 34*b*. From Eq. 34*c* the required fictitious length is found to be

$$L_f = \left(\frac{4.32}{t}\right) L \qquad (35a)$$

or, approximately,

$$L_f = \left(\frac{4.32}{4.32 - 30\,\beta + 160\,\beta^2}\right) L \qquad (35b)$$

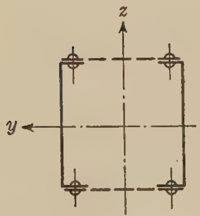

FIG. 4

Numerical Example.—Consider a straight strut (see Fig. 4) composed of two 15-in. channels weighing 35 lb per ft laced together by 2-in. by $\frac{3}{8}$-in. batten plates and lattice bars as in Fig. 2(*a*), so that $c = h = 8.5$ in., $\phi = 45°$, $A_p = A_d = 1.5$ sq in.; $A = 20.46$ sq in.; $I_y = 637$ in.^{4}, $I_z = 627$ in.^{4}, $(r_z)_{\min} = 5.5$ in., approximately, and $E = 30 \times 10^6$ lb per sq in. Then (see Eq. 32),

$$\beta = \frac{\psi E A}{\left(\frac{L}{r}\right)^2} = \frac{\psi E\,(20.46)}{\left(\frac{L}{r}\right)^2} \qquad (36)$$

and, from Eq. 28*a*,

$$\psi_a = \frac{1}{E}\left(\frac{1}{1.5 \times 0.707 \times 0.707^2} + \frac{8.5}{8.5 \times 1.5}\right) = \frac{2.550}{E} \qquad (37a)$$

Finally—

$$\beta = \frac{52.2}{\left(\frac{L}{r}\right)^2} \qquad (37b)$$

By assuming different slenderness ratios, $\frac{L}{r}$, the corresponding t roots can be obtained, and subsequently the critical loads for the latticed struts, with respect to the z-axis. The critical loads on solid struts can be calculated easily. These are listed in Table 1, Cols. 5 and 6, respectively. The ratios of the critical loads on latticed and solid struts of the same slenderness and cross-sectional areas are given[6a] in Col. 7, Table 1. The effect of shearing deflections on the critical load is thus shown to be more pronounced for the stout struts than for the more slender ones. For the latticed strut of usual slenderness, a decrease in strength occurs from 5% to 10% of the strength of a strut with a solid web and equal flexural rigidity; the higher percentage pertaining to steels with a high proportional limit.

TABLE 1.—COMPARISON OF STRENGTH OF STRUTS

CONCLUSION

The strength of latticed struts, pin-supported at one end, laterally restrained at the other, and loaded halfway between the supports, may be substantially reduced by the shearing forces, if battens and lacing bars of small cross section are used. For the lattice systems indicated in Fig. 2, using definite batten and lacing bar sizes, the percentage reduction in strength due to shear effect can be calculated for the type of strut herein considered, by the method presented in the paper.

[6a] See Table 2.

DISCUSSION

Leon Beskin,[7] Assoc. M. Am. Soc. C. E.—Extended treatment of conditions involved in Assumption 5 is superfluous, since it is accepted perforce as the conventional basis of any elementary approach to the problem of the instability of struts (see heading, "Introduction: Assumptions").

The list of assumptions is incomplete, since those leading to Eq. 2, expressing the relation of moment to curvature when the state of stress is not pure bending, and the more important assumptions leading to Eq. 9 are omitted. In that respect, it is to be noted that the values given for the constant K are approximate.[8] This constant varies somewhat with the method of applying the load. It is approximately equal to 1 for I-beams, A being the area of the web.

The introduction of Eq. 8 as the fundamental relationship between shear and slope is incorrect. The basic relationship for shear deflection is given by Eq. 9. The former equation is derived by integration of the latter, and is valid for straight beams on two supports only when (*a*) the end moments are zero, or are equal; and when (*b*) there are no applied moments in the span.

Moreover, in this form, Eq. 9 must be extended to include concentrated loads, by adding the equation—

$$\Delta\left(\frac{dy_v}{dx}\right) = \frac{-K\,\Delta V}{A\,G} \qquad \text{(38)}$$

—at each point of application of a concentrated load P, thus giving a variation of shear ΔV. Eq. 38 represents a sharp angle of the neutral line of the strut. It can be derived simply by integrating Eq. 9 along an infinitely small element dx on which a constant load is applied. It purports to express a variation ΔV of the shearing force, although the correct proof of its validity can only be established from considerations of theory of elasticity.[9] By failing to make the foregoing distinction the author has developed Eq. 21, and consequently Eqs. 25 and 26, incorrectly.

For problems in which the principle of superposition does not apply, as is the case for buckling, the distribution of the deflection y into two components, y_m due to bending and y_v due to shear, is improper. It is easily seen that, if the deflection due to bending is neglected, there is no deflection due to shear in the problem discussed. More generally, when side load exists, two conditions can be considered:

(*a*) Without longitudinal load, $y = y_m + y_v$. The deflections y_m and y_v are computed, assuming first that $\frac{1}{A} = 0$, and second that $\frac{1}{I} = 0$. In this case, the two components have definite meanings.

---

[7] Senior Stress Analyst, Consolidated Vultee Aircraft Corp., Allentown, Pa.

[8] "Theory of Elasticity," by S. Timoshenko, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1934, pp. 37, 41, 74, 104, and 150.

[9] *Ibid.*, p. 103.

(*b*) With a longitudinal compressive load, $y > y_m + y_v$, if the two components are computed as in Condition (*a*).

The only correct relationship is

$$\frac{d^2y}{dx^2} = \frac{1}{\rho} = \frac{1}{\rho_m} + \frac{1}{\rho_v} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

the two component curvatures $\frac{1}{\rho_m}$ and $\frac{1}{\rho_v}$ being defined by the right members of Eqs. 5*b* and 10*a*. Incidentally, the two quantities y_v and y_m that would result from the integration of Eqs. 5*b* and 10*a*, once y is known, have no significance, although their sum is equal to y, provided they are both equal to zero at the supports.

A concentrated transverse load deforms the neutral axis of the strut. Thus, Eq. 21 $\left[\left(\frac{dy_a}{dx_a}\right)_{x_a=a} = -\left(\frac{dy_b}{dx_b}\right)_{x_b=b}\right]$ is not correct. The shearing forces in parts a and b of the strut at the point of application of the load are, respectively,

$$V_a = -\frac{P\,e}{L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40a)$$

and

$$V_b = P\left[\frac{e}{L} + (y_b)'\right] \ldots\ldots\ldots\ldots\ldots\ldots\ldots (40b)$$

(In Eqs. 40, $(y_a)'$ and $(y_b)'$ are the slopes on both sides of P.) The variation of shearing force at P is

$$\Delta V = -(V_a + V_b) = -(y_b)'\,P \ldots\ldots\ldots\ldots\ldots (41)$$

Then

$$-(y_b)' = (y_a)' + \frac{K\,\Delta V}{A\,G} = (y_a)' - \frac{(y_b)'\,P\,K}{A\,G} \ldots\ldots\ldots (42)$$

Eq. 42 can easily be transformed into

$$(y_b)'\,m^2 = -(y_a)'\,q^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

which should be substituted for Eq. 21. If the cross-section area changed at P, the calculation would be changed since $-\frac{\Delta V}{A}$ would be replaced by $\frac{V_a}{A_a} + \frac{V_b}{A_b}$. Using Eq. 43, Eq. 24*b* is changed to

$$q\,L \cot k\,q\,L = \left(\frac{q^2\,L^2}{3\,u}\right)(1 - k) - \frac{1 - k + \frac{q^2}{m^2}}{(1 - k)^2} \ldots\ldots\ldots (44)$$

It is apparent that the final equation sought by the author is modified considerably by the foregoing correction.

The constants γ and ψ are not directly related to the slope of the axis and are equal to the slope only when definite conditions are fulfilled. They define the angle between the perpendicular to the average direction of the cross section, as distorted by the effect of shear, and the neutral axis.

It is incorrect to state in a general manner that "the curvature due to bending of a built-up strut is independent of the type of lattice used" (see paragraph following Eqs. 26). For instance, the buckled shape of the members of a strut that is latticed only by batten plates is a wavy curve, and, if there are a few battens, only an average, badly defined curve will be identified with the elastic line of a solid strut. Theoretically, it is impossible to separate, definitely, the effect of shear from that of bending, and the values of ψ are valid only when several conditions are satisfied. For instance, the buckling between diagonals or battens must be such as can be disregarded. A thorough investigation of the problem has been presented by Julius Ratzersdorfer.[10]

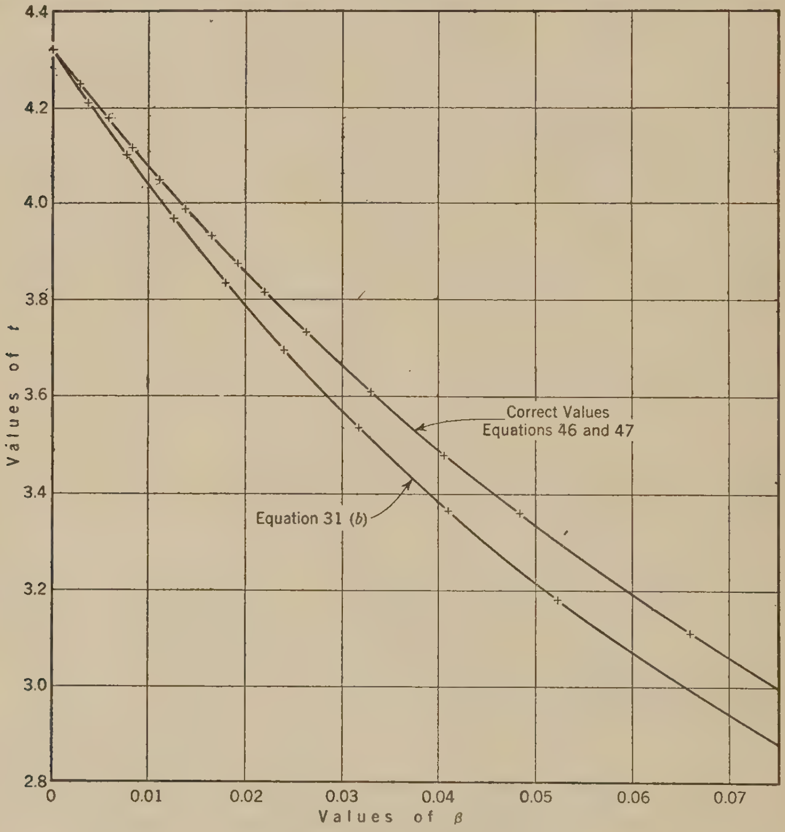

FIG. 5.—RELATIONSHIP BETWEEN t AND β

Application of Eq. 44 will change Eq. 29 as follows:

$$6\,q\,L\cot\tfrac{1}{2}\,q\,L = q^2 L^2 - 12 - \frac{24\,q^2}{m^2} \ldots\ldots\ldots\ldots (45)$$

and Eqs. 31 will be changed to:

$$6\,w\cot\tfrac{1}{2}\,w = w^2 - 12 - \frac{24\,w^2}{t^2} \ldots\ldots\ldots\ldots\ldots (46)$$

---

[10] "Die Knickfestigkeit von Stäben und Stabwerken," by Julius Ratzersdorfer, Wien, 1936, pp. 201–243.

in which

$$w = \frac{t}{(1 - \alpha\, t^2)^{0.5}} = \frac{t}{(1 - \beta\, t^2)^{0.5}} \qquad (47)$$

Fig. 3 must be corrected correspondingly. The values of β and t that satisfy Eqs. 46 and 47 are easily computed when w is entered as an independent variable:

$$t^2 = \frac{24\, w^2}{w^2 - 12 - 6\, w \cot \tfrac{1}{2}\, w} \qquad (48a)$$

and

$$\beta = \frac{1}{t^2} - \frac{1}{w^2} \qquad (48b)$$

Using the incorrect Eq. 31*b*, t becomes equal to

$$t^2 = 36 + 6\, w \cot \tfrac{1}{2}\, w \qquad (49)$$

β remaining the same as in Eq. 48*b*. The corrected and erroneous curves are both plotted in Fig. 5. The error can be estimated to vary between 10% and 15% of the variation of t due to the effect of shear—that is, of the difference $t(\beta) - t(0)$, which is always too great in the author's calculation.

The general conclusions stated by the author are well known. The method of calculation presented is an application to a special case of the general method originally derived by S. Timoshenko;[11] and Eq. 24*a* is the application of the general formula established by Professor Timoshenko[12] to the condition in which there is no end load:

$$\left(\frac{k_4}{k_1}\right)^2 (1 - k_1\, L_1 \cot k_1\, L_1) - k_1\, L \cot k_1\, L_1 = \left(\frac{k_2}{k_3}\right)^2 + \left[k_3\, L - \frac{(k_2)^2\, L_2}{k_3}\right] \cot k_3\, L_2 \qquad (50)$$

In Eq. 50, when $k_1 = 0$:

$$(k_2)^2 = (k_3)^2 = \frac{P}{E\, I_b} = m^2;\ (k_4)^2 = \frac{P}{E\, I_a} = n^2;\ L_1 = a;\ \text{and}\ L_2 = b.$$

Noting that, for infinitely small values of k_1,

$$\frac{1 - k_1\, L_1 \cot k_1\, L_1}{(k_1)^2} = \frac{(L_1)^2}{3} \qquad (51)$$

Eq. 50 becomes

$$\frac{n^2\, a^2}{3} - \frac{L}{a} = 1 + m\, a \cot m\, b \qquad (52)$$

As demonstrated by Professor Timoshenko,[13] the influence of the shearing force is equivalent to the replacement of the moment of inertia I by a decreased moment of inertia $I\left(1 - \frac{K\,P}{A\,G}\right)$, which shows that, in Eq. 52, m must be replaced by q, whereas n remains unchanged. By substitution, Eq. 24a is derived directly, obviously containing the error related to the change of slope at P, and making unnecessary all the development presented in the paper. If the correct formula, Eq. 43, is applied to Eq. 52, the latter becomes

---

[12] *Ibid.*, p. 113, Eq. 79.

[13] *Ibid.*, p. 140.

$$q^2\left(\frac{n^2\,a^2}{3} - \frac{L}{a}\right) = m^2\,(1 + q\,a \cot q\,b) \quad \text{.............} (53)$$

which is identical to Eq. 44 when the necessary changes are made in the notation.

Marshall Holt,[14] Assoc. M. Am. Soc. C. E.—In the design of latticed struts it may be desired to have the effective slenderness ratios about the two principal axes equal so that the computed column strengths for bending in the two directions will be equal. In other words, the question may be raised as to how far apart two channels, as used in the numerical example, need be placed so that the column strengths about the axes y and z will be equal.

Eq. 34a will be useful in this study. Instead of finding a fictitious length of the member, as the author does, one can find the necessary radius of gyration r_z. Thus, instead of Eq. 34c, one can write

$$P_y = \frac{(4.32)^2\,E\,A}{\left(\frac{L}{r_y}\right)^2} = P_z = \frac{t^2\,E\,A}{\left(\frac{L}{r_z}\right)^2} \quad \text{...............} (54)$$

in which r_y = the radius of gyration with respect to the y-axis; and r_z = the required radius of gyration about the z-axis. It then follows that

$$\frac{r_z}{r_y} = \frac{4.32}{t} \quad \text{........................} (55a)$$

or, approximately,

$$\frac{r_z}{r_y} = \frac{4.32}{4.32 - 30\,\beta + 160\,\beta^2} \quad \text{................} (55b)$$

Eqs. 55 are quite like Eqs. 35. A direct solution is impossible because the value of β depends on the size and arrangement of the lacing bars, and these have not yet been determined. A trial solution is possible which consists essentially in checking a trial value of r_z by means of Eq. 55b or the curve of Fig. 6.

Since β is an inverse function of slenderness ratio, Fig. 6 shows that the ratio of r_z to r_y should be relatively larger for small slenderness ratios than for large slenderness ratios. In other words, for a given system of lacing and a given size of lacing bar, the relation between the two radii of gyration should not be specified by a single value.

---

[14] Research Engr., Aluminum Research Laboratories, New Kensington, Pa.

In problems of design it might be practicable to plot curves of the type shown in Fig. 6 for the system of lacing and size of bars under consideration. For this purpose, the first scale of abscissas (scale a) is in terms of β, the second (scale b) is in terms of the slenderness ratio about the z-axis, and the third (scale c) is in terms of the slenderness ratio about the y-axis. Scale c was obtained from scale b and the indicated values of the ratio r_z/r_y since the slenderness ratios are in this inverse ratio. For a certain length of column, say 320 in., the slenderness ratio about the y-axis is 57.4, and the required ratio of r_z/r_y is 1.15. The necessary value of r_z is found to be 6.41 in., and the distance back to back of the channels (14.28 in.) follows from simple computations.

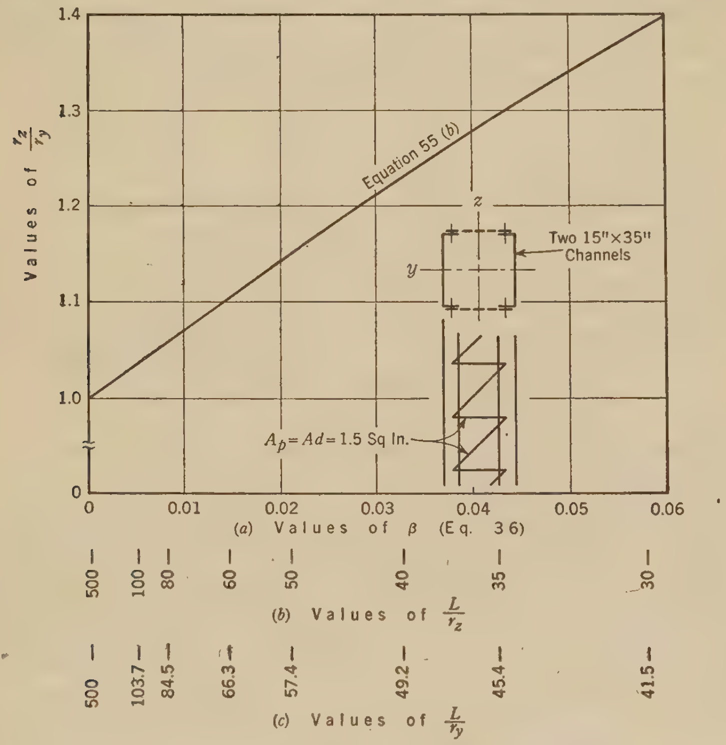

FIG. 6.—RATIO OF r_z TO r_y FOR EQUAL COLUMN STRENGTHS FOR BENDING ABOUT THE z AND y AXES

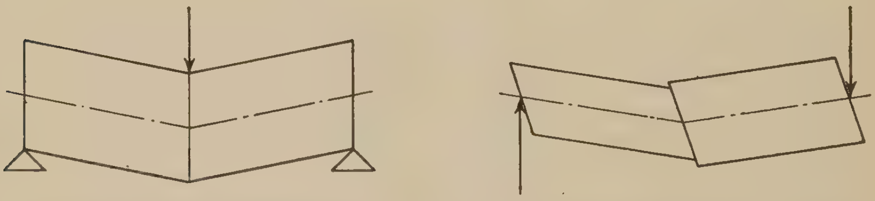
In some cases it may not be desirable to have the column strength for bending about the two axes equal because of different conditions of restraint or support in the two directions. In this case a factor of proportionality of the column strengths can be introduced into Eq. 54. The procedure is the same as that for equal column strengths.

A procedure similar to that followed by the author was applied to columns loaded on the ends by Ernst Amstutz[15] in 1941.

David B. Hall,[16] Assoc. M. Am. Soc. C. E.—This paper, together with another by the same author,[17] which it supplements, is a useful addition to the literature of column analysis. Hence, with some regret the writer notes an error in the derivation which will necessitate some revisions.

The error is in Eq. 21, which was introduced to establish continuity between the two segments of the strut shown in Fig. 1. The author has assumed that the elastic curves of both segments must have the same slope at the point of application of the concentrated load P, where they join. This assumption is incorrect. The slope of the elastic curve of shearing deflection of a beam is discontinuous at points of concentrated loading (Fig. 7(a)), and at points of abrupt change in section (Fig. 7(b)).



(a) EFFECT OF CONCENTRATED LOAD

(b) EFFECT OF CHANGE OF SECTION

Fig. 7.—Shearing Deflection Curves

The correct method of establishing compatibility at $x_a = a$ is to fit together the two faces of the section cut through that point. The expressions for the slopes of cross sections of the upper and lower segments of the strut are shown in Fig. 8. This figure is diagrammatic. In solid members, for example, plane sections under shearing loads become S-shaped. The sloping plane surfaces shown represent effective values, obtained with the aid of the shape factor K in the case of solid members, or by means of Eqs. 28 in the case of built-up members.

To make the lower face of the upper segment match the upper face of the lower segment one must write, in place of Eq. 21:

$$\left(\frac{dy_a}{dx_a} - \frac{P\,e\,K_a}{L\,A_a\,G}\right)_{x_a=a} = -\left[\frac{dy_b}{dx_b} - P\left(\frac{dy_b}{dx_b} - \frac{e}{L}\right)\frac{K_b}{A_b\,G}\right]_{x_b=b} \quad \ldots(56)$$

The substitution of Eq. 56 for Eq. 21 must have some effect on all further development in the paper. The remainder of this discussion will be confined to ascertaining whether the effect is of any actual consequence, leaving the detailed work of revising the affected equations for the author to perform, if warranted, in his closing discussion.

$\frac{dy_a}{dx_a}$

(*a*) UPPER SEGMENT (*b*) LOWER SEGMENT

Fig. 8.—Relation of Slope of Cross Section to Slope of Elastic Curve

Attention first will be directed to the simplified problem which results when the strut is of constant section throughout its length. For this condition, Eq. 56 reduces to

$$\left(\frac{dy_a}{dx_a}\right)_{x_a=a} = -\frac{dy_b}{dx_b}\left(1 - \frac{P\,K}{A\,G}\right)_{x_b=b} \qquad (57a)$$

or

$$\left(\frac{dy_a}{dx_a}\right)_{x_a=a} = -\frac{m^2}{q^2}\left(\frac{dy_b}{dx_b}\right)_{x_b=b} \qquad (57b)$$

Also, $u = 1$. The operations which immediately follow are analogous to those of the paper, and, in place of Eq. 24*b*,

$$\frac{\tan k\,q\,L}{q\,L} = \frac{1}{\frac{q^2\,L^2}{3}(1-k) - \frac{\frac{q^2}{m^2} + 1 - k}{(1-k)^2}} \qquad (58)$$

For purposes of comparison it will be convenient to convert both Eq. 24*b* and Eq. 58 into the terms introduced in Eq. 30, with some modification. In the paper t is a measure of the critical column load, and α is a measure of the relative shearing flexibility. Now designate all corresponding terms pertaining to a strut subject to bending deflection only by the subscript M. Let:

$$t = t_M + \delta t \qquad (59)$$

Then

$$m_M\,L = t_M \qquad (60a)$$

$$m\,L = t_M + \delta t \qquad (60b)$$

and

$$q\,L = \frac{t_M + \delta t}{[1 - \alpha\,(t_M + \delta t)^2]^{0.5}} \quad \text{(61}a\text{)}$$

It will be of further advantage to confine the comparison to struts for which α is a small number. As α approaches zero, δt will also approach zero, and a linear relation between them can be found by the same processes used in deriving the rules for differentiation. Eq. 61*a*, for example, may now be rewritten:

$$q\,L = t_M + \delta t + \tfrac{1}{2}\,\alpha\,t^3_M \quad \text{(61}b\text{)}$$

By (1) making the indicated substitutions, (2) carrying out the process of differentiation, and (3) subtracting from each side of the equation the terms that would appear in the equation for a strut subject to bending deflection only—one will finally arrive at the following new equations: From Eq. 24*b*—

$$(\delta t + \tfrac{1}{2}\,\alpha\,t^3_M)\left(\frac{k\sec^2 k\,t_M}{t_M} - \frac{\tan k\,t_M}{t^2_M}\right) = \frac{-\,2\,t_M\,\delta t\,(1-k)}{\left[\dfrac{t^2_M\,(1-k)}{3} - \dfrac{2-k}{(1-k)^2}\right]^2} \quad \text{(62}a\text{)}$$

and, from Eq. 58—

$$(\delta t + \tfrac{1}{2}\,\alpha\,t^3_M)\left(\frac{k\sec^2 k\,t_M}{t_M} - \frac{\tan k\,t_M}{t^2_M}\right)$$
$$= \frac{-\,2\,t_M\,\delta t\,(1-k) - \alpha\,t^2_M\left[\dfrac{t^2_M\,(1-k)}{3} - \dfrac{1}{(1-k)^2}\right]}{\left[\dfrac{t^2_M\,(1-k)}{3} - \dfrac{2-k}{(1-k)^2}\right]^2} \quad \text{(62}b\text{)}$$

Numerical values of t_M, or $k\,t_M$, as a function of k are already known,[6] and may be substituted in Eqs. 62*a* and 62*b*. Thus values of $\delta t/\alpha$ may be calculated as a function of k for each of these equations, Eq. 62*a* representing the development from Eq. 21, and Eq. 62*b* representing the development from Eq. 56. The two functions are plotted together in Fig. 9. The principal relations between these two curves can easily be interpreted: (*a*) The lateral component of P, producing the effect shown in Fig. 7(*a*), acts inward when P is applied in the upper part of the strut, and outward when P is applied in the lower part of the strut, thus increasing the stability in the former case and decreasing the stability in the latter case; and (*b*) the part of the shearing effect considered by the author—namely, the change in curvature in the loaded segment—diminishes in importance as the load approaches the lower support; hence, the relative error is greatest for small values of k.

The problem is more complicated when there is a change of section as in Fig. 7(*b*). Under ordinary conditions of design, the loaded segment of such a strut as that shown in Fig. 1 will be made stronger than the unloaded segment, and in many cases will be more resistant to shearing deflection. Under this, the normal condition, the angle at the junction of the two segments, produced by the shearing force $\frac{P\,e}{L}$, will always be in such a direction as to increase the deflection, and hence decrease the stability of the strut. In a case where the upper segment of the strut is considerably more yielding than the lower segment, and the load is applied at approximately midheight, this phenomenon may prove a substantial, or even the predominant, part of the total shear effect. Where the load is applied near either end, this effect will be less.

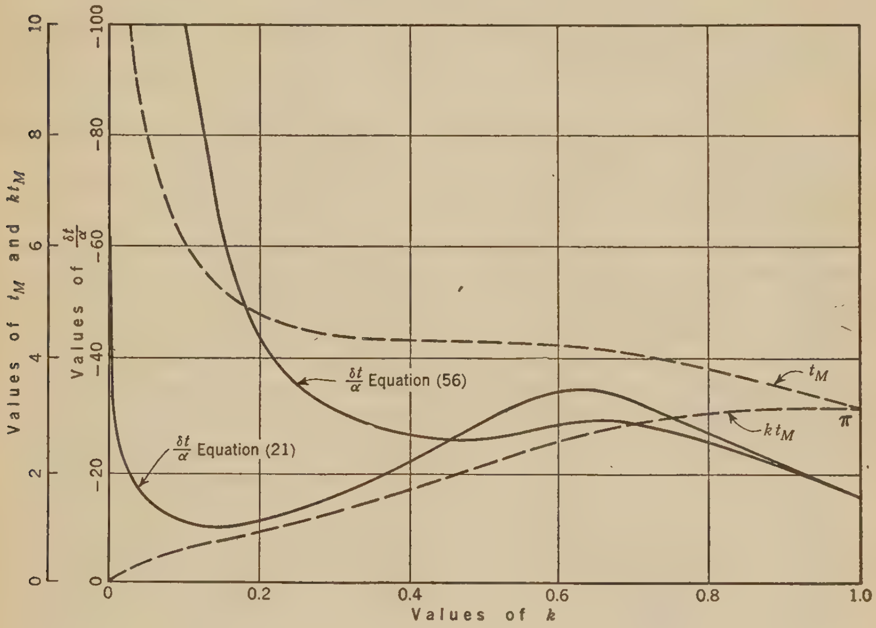

FIG. 9.—VALUES OF $\frac{\delta t}{\alpha}$ COMPUTED FROM EQS. 21 AND 56

Basing his judgment on the foregoing comparisons, the writer believes that the error in the paper is sufficiently large to warrant revision of the equations affected.

S. SERGEV,[18] ESQ.—An error in analysis was made in overlooking the discontinuity in slope of the strut axis caused by shearing forces. (The check method used was not independent as subsequent examination revealed.) Discontinuity of slope due to shearing action in members of homogeneous material may result from discontinuities of shearing forces and cross-sectional areas, separately or in combination. In the strut under discussion, both factors enter into consideration because the shearing forces and cross-sectional areas above and below the point of loading are different. For the special application, when the strut cross section is constant throughout, there is a sudden change in the shearing forces at the point of loading, and consequently a sudden change in the shearing strains is to be expected. Thus, the final slopes due to bending and shearing actions above and below the point of loading are different from each other and a kink in the elastic curve exists.

---

[18] Associate Prof., Dept. of Civ. Eng., Univ. of Washington, Seattle, Wash.

To introduce the correct concept of slope relationships at points of discontinuity into the analysis, again consider Eq. 20. The constants C and D may be evaluated from the conditions (compare Eq. 21):

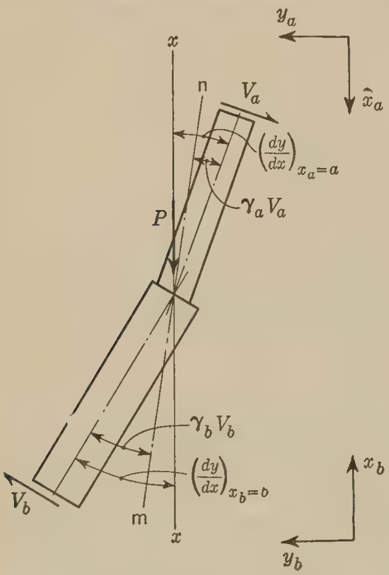
$$(y_a)_{x_a=0} = 0; \quad \text{and} \quad (y_a)_{x_a=a} = e \ldots\ldots\ldots\ldots\ldots (63)$$

from which $D = 0$, and $C = \frac{e}{a} + \frac{P\,e\,a^2}{6\,E\,I_a\,L}$. Substitution of these values into Eq. 20 gives (compare Eq. 23):

$$y_a = -\frac{m^2\,e\,x^3_a}{6\,u\,L} + \left(\frac{e}{a} + \frac{m^2\,e\,a^2}{6\,u\,L}\right) x_a \ldots\ldots\ldots\ldots\ldots (64)$$

This expression for y_a will be simpler to use in the strain energy which follows later.

The interrelationship between the slopes of the upper and lower segments can be established using the following arguments: Consider a small part of the strut in the vicinity of the loading (Fig. 10) under the action of the shearing forces as indicated. The line mn represents the tangent to the elastic curve if the shearing strains are neglected. The angles between the line mn and the vertical are numerically equal but opposite in sign, the latter fact following from the choice of the coordinate axes. This is the requirement of continuity for bending actions only. However, if it is desired to consider shear deformations, then the shearing strains in the upper and in the lower segments must be taken into account, and the following equality, with due regard to signs, should be used:



y_a
x
x_a
n
V_a
$\left(\frac{dy}{dx}\right)_{x_a=a}$
$\gamma_a V_a$
P
$\gamma_b V_b$
$\left(\frac{dy}{dx}\right)_{x_b=b}$
x_b
V_b
m
x
y_b

FIG. 10

$$\left(\frac{dy_b}{dx_b} + \gamma_b\,V_b\right)_{x_b=b} = -\left(\frac{dy_a}{dx_a} - \gamma_a\,V_a\right)_{x_a=a} \ldots (65)$$

In Eq. 65:

$$\gamma_b\,V_b = \frac{K\,V_b}{A_b\,G} = \frac{K}{A_b\,G}\left(-P\,\frac{dy}{dx} + \frac{P\,e}{L}\right)_{x_b=b} \ldots (66a)$$

and

$$\gamma_a\,V_a = \frac{K\,V_a}{A_a\,G} = \frac{K}{A_a\,G}\,\frac{P\,e}{L} \ldots (66b)$$

Substituting these equivalents into Eq. 65, keeping in mind that

$$\left(\frac{dy}{dx}\right)_{x_b=b} = \frac{e\,a\,q\cot q\,b}{L} + \frac{e}{L} \ldots\ldots\ldots\ldots\ldots (67a)$$

and

$$\left(\frac{dy}{dx}\right)_{x_a=a} = -\frac{m^2\,e\,a^2}{2\,u\,L} + \frac{e}{a} + \frac{m^2\,e\,a^2}{6\,u\,L} \ldots\ldots\ldots\ldots (67b)$$

gives

$$\frac{e\,a\,q\cot q\,b}{L} + \frac{e}{L} + \frac{K\,P}{A_b\,G}\left(-\frac{e\,a\,q\cot q\,b}{L} - \frac{e}{L} + \frac{e}{L}\right)$$
$$= -\left(-\frac{m^2\,e\,a^2}{2\,u\,L} + \frac{e}{a} + \frac{m^2\,e\,a^2}{6\,u\,L} - \frac{K\,P\,e}{A_a\,G\,L}\right) \quad \ldots\ldots\ldots\ldots(68)$$

Eliminating e and noting that $\frac{K\,P}{A_a\,G} = \frac{A_b}{A_a}\left(1 - \frac{m^2}{q^2}\right)$, Eq. 68 may be written as follows:

$$a\,q\cot q\,b = \frac{q^2\,a^2}{3\,u} - \frac{q^2}{m^2}\left(1 + \frac{L}{a} - \frac{A_b}{A_a}\right) - \frac{A_b}{A_a} \quad \ldots\ldots\ldots(69a)$$

Let $b = k\,L$, $a = L\,(1 - k)$, and, rearranging slightly, Eq. 69a becomes

$$L\,q\cot k\,q\,L = \frac{q^2\,L^2\,(1-k)}{3\,u}$$
$$- \frac{q^2}{m^2}\left[\frac{2-k}{(1-k)^2} - \frac{A_b}{A\,(1-k)}\right] - \frac{A_b}{A_a\,(1-k)} \quad \ldots\ldots\ldots(69b)$$

which should replace Eq. 24b as first derived. It can now be seen that not only does the ratio of the moments of inertia u enter into consideration but also the ratios of the cross-sectional areas $\frac{A_b}{A_a}$. Thus, it is possible to study a strut with $I_a = I_b$ and with the areas A_b and A_a unequal.

The result given in Eq. 69b completely describes the buckling criteria for struts of uniform but unequal cross sections in each segment loaded as previously described (see Fig. 1).

Check by Strain Energy.—If the equations for the elastic curve of the strut axis are established in both segments, then a solution of the problem may be obtained without resorting to the relationship expressed in Eq. 65, by using the strain energy method. If it is admitted that under a critical load P a slight deflection of the strut is possible, then a small amount of strain energy of flexure and shear will be stored in the strut in the form of potential energy ΔV. This potential energy must be equal numerically to the loss in potential energy of the force P due to loss in elevation.

The potential energy of strain can be calculated in the usual way from the following expression:

$$\Delta V = \int_0^b \left(\frac{M^2_b}{2\,E\,I_b} + \frac{K\,V^2_b}{2\,A_b\,G}\right) dx_b + \int_0^a \left(\frac{M^2_a}{2\,E\,I_a} + \frac{K\,V^2_a}{2\,A_a\,G}\right) dx_a \quad ..(70)$$

in which

$$M_b = -P_y + \frac{P\,e}{L}\,x = -\frac{P\,a\,e\sin q\,x}{L\sin q\,b} \quad \ldots\ldots\ldots\ldots(71a)$$

$$V_b = -P\frac{dy_b}{dx_b} + \frac{P\,e}{L} = -\frac{P\,a\,e\,q\cos q\,x}{L\sin q\,b} \quad \ldots\ldots\ldots\ldots(71b)$$

$$M_a = -\frac{P\,e\,x}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(71c)$$

and

$$V_a = -\frac{P\,e}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(71d)$$

Substituting these equivalents into Eq. 70, and performing the indicated operations, give

$$\Delta V = \frac{m^4\, E\, I_b\, e^2}{L^2}\left(\frac{a^2\, b}{4\sin^2 q\, b} + \frac{a^2 \cot q\, b}{4\, q} + \frac{a^3}{6\, u} + \frac{K\, a\, E\, I_b}{2\, A_a\, G}\right.$$
$$\left. + \frac{a^2\, q^2\, b\, K\, E\, I_b}{4\, A_b\, G \sin^2 q\, b} + \frac{K\, a^2\, q^2\, E\, I_b \cot q\, b}{4\, q\, A_b\, G}\right) \ldots\ldots\ldots\ldots (72)$$

The loss in potential energy of the force P is equal to the product of the force and the distance that it moves downward. This loss in potential energy will be designated by ΔU, and it can be calculated in the following manner:

$$\Delta U = \int_0^b P\,(ds_b - dx_b) = P \int_0^b \left[\sqrt{1 + \left(\frac{dy_b}{dx_b}\right)^2} - 1\right] dx_b \ldots . (73)$$

If higher powers than the first of the small quantities are neglected, the loss in potential energy becomes

$$\Delta U = P \int_0^b \frac{1}{2}\left(\frac{dy_b}{dx_b}\right)^2 = \frac{P}{2}\int_0^b \left(\frac{a\, e\, q \cos q\, x}{L \sin q\, b} + \frac{e}{L}\right)^2 dx_b \ldots\ldots (74a)$$

or

$$\Delta U = \frac{m^2\, E\, I_b\, e^2}{L^2}\left(\frac{a^2\, q^2\, b}{4\sin^2 q\, b} + \frac{a^2\, q^2 \cot q\, b}{4\, q} + a + \frac{b}{2}\right) \ldots\ldots (74b)$$

Setting Eqs. 72 and 74*b* equal to each other and simplifying, an expression identical to Eq. 69*b* is obtained.

This check method is not entirely independent, as it uses the results obtained from the geometrical properties of the elastic curve of the strut. Its merit lies in the fact that it is independent of the discontinuities of slope at the point of loading.

Approximate Solution.—A check of the results previously obtained can be made by using an approximate method based on strain energy and an assumed shape for the elastic curve. (A check of this kind may not reveal errors in analysis if the influence of the errors on the solution is small, say, less than 1%.) As a first approximation, assume that the deflection curve is a sine curve,

$$y = f_1 \sin\frac{\pi\, x}{L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

in which f_1 is a constant. The general expression for the strain energy is that expressed by Eq. 70, in which the bending moments and shearing forces will be now expressed as follows:

$$M_b = -P\, y + \frac{P\, e\, x_b}{L} = -P\, f_1 \sin\frac{\pi\, x}{L} + \frac{P\, e\, x_b}{L} \ldots\ldots . (76a)$$

$$V_b = \frac{P\, e}{L} - P\frac{dy_b}{dx_b} = \frac{P\, e}{L} - \frac{P\, f_1}{L}\cos\frac{\pi\, x_b}{L} \ldots\ldots\ldots\ldots (76b)$$

$$M_a = -\frac{P\, e\, x_a}{L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76c)$$

$$V_a = -\frac{P\, e}{L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76d)$$

and

$$e = f_1 \sin \frac{\pi b}{L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76e)$$

Substituting Eqs. 76 into Eq. 70, and performing the indicated operations, the expression for strain energy becomes

$$\Delta V = \frac{P^2}{2 E I_b} \left[\frac{b f^2_1}{2} - \frac{f^2_1 L}{4} \sin \frac{2 b \pi}{L} + \frac{e^2 b^3}{3 L^2} - \frac{2 f_1 e L}{\pi^2} \sin \frac{\pi b}{L} \right.$$
$$\left. + \frac{2 f_1 e b}{\pi} \cos \frac{\pi b}{L} + \frac{e^2 a^3}{3 u L^2} \right] + \frac{K P^2}{2 A_b G} \left[\frac{b e^2}{L^2} + \frac{f^2_1 \pi^2}{L^2} \left(\frac{b}{2} + \frac{1}{4} \sin \frac{2 b \pi}{L} \right) \right.$$
$$\left. - \frac{2 f_1 e}{L} \sin \frac{b \pi}{L} + \frac{e^2 a A_b}{L^2 A_a} \right] \ldots\ldots\ldots\ldots\ldots\ldots (77)$$

The loss in potential energy ΔU of the load P due to a lowering of its point of application can be calculated as previously described. The expression for ΔU is

$$\Delta U = P \int_0^b \frac{1}{2} \left(\frac{d y_b}{d x_b} \right)^2 d x_b = \frac{P f^2_1 \pi^2}{2 L^2} \int_0^b \cos^2 \frac{\pi x_b}{L} d x_b$$
$$= \frac{P f^2_1}{2 L} \left(\frac{\pi b}{2 L} + \sin \frac{2 \pi b}{L} \right) \ldots\ldots\ldots\ldots\ldots\ldots (78)$$

Substituting $e = f_1 \sin \left(\frac{\pi b}{L} \right)$ into Eq. 77, and equating it to Eq. 78, a general expression for P may be obtained. If in this expression $b = \frac{L}{2}$ is used, it will give, after a slight rearrangement,

$$P = \frac{\pi^2 E I_b}{L^2} \frac{1}{\left(\frac{7}{6} - \frac{8}{\pi^2} + \frac{1}{6 u} \right) + \frac{K E I_b}{A_b G L^2} \left(\pi^2 - 6 + \frac{2 A_b}{A_a} \right)} \ldots (79)$$

in which, for struts with solid webs, $\frac{K E I_b}{A_b G L^2}$ is denoted by α and for latticed struts by β.

Special Application.—As a special application of the formulas previously derived, consider the case in which $I_b = I_a = I$, $A_a = A_b = A$, and $k = \frac{1}{2}$. Substitution of the values into Eq. 69*b* gives

$$6 L q \cot \frac{1}{2} q L = q^2 L^2 - 24 \frac{q^2}{m^2} - 12 \ldots\ldots\ldots\ldots (80)$$

Let $m L = t$ and $q L = w$; then Eq. 80 may be transformed into Eq. 46, in which for the latticed struts $\beta = \frac{1}{t^2} - \frac{1}{w^2}$. The roots of Eq. 46 were determined by Mr. Beskin.

Now consider Eq. 79. Making the substitutions noted herein and simplifying gives the following relationship between P and β,

$$P = \frac{\pi^2 E I}{L^2} \frac{1.913}{1 + 11.23\,\beta} = \frac{1.012\,P'}{1 + 11.23\,\beta} \ldots\ldots\ldots\ldots (81a)$$

As a function of ψ, the critical load,

$$P = \frac{\pi^2 E I}{L^2} \frac{1.913}{1 + P'\,(0.602\,\psi)} = \frac{1.012\,P'}{1 + 0.602\,\psi\,P'} \ldots\ldots\ldots (81b)$$

in which P' is the critical load on the strut similarly loaded but neglecting shear deflections; that is,

$$P' = \frac{(4.32)^2\,E\,A}{\left(\frac{L}{r}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (82)$$

The degree of accuracy of Eq. 81*a* will be studied now by comparing the critical load P obtained from it with that obtained from Eq. 46. Using the data in the numerical example following Eq. 35*b*, and the $\frac{L}{r}$ ratios in Table 1, the critical loads determined by Eqs. 46 and 81*a* may be ascertained (see Table 2). From these calculations it can be concluded that, for practical applications, Eq. 81*a* gives sufficiently accurate results.

Source	Eq. 37*b*	Fig. 5	Eq. 34*a*	Eq. 81*a*	Eq. 34*b*	Exact	Approximate

An advantage of the approximate method is the fact that it gives explicit functions such as Eq. 81*a* or 81*b* for evaluating the critical load. The more exact method reduces to an implicit function, Eq. 46, the roots of which must be found first before it can be used practically.

In Col. 7, Table 2, ratios of the buckling load on latticed struts to that on struts with solid webs are given using the more exact analysis. Similar ratios are given in Col. 8, Table 2, where the buckling load on the latticed struts was determined by the approximate method. When the results in Cols. 7 and 8 are compared, the approximate method slightly underestimates the shear effect on the strength of the strut but is sufficiently accurate for most practical purposes. Finally, comparing the final results in Table 1, Col. 7, with the corrected values as shown in Table 2, Col. 7, the conclusion is that the solution, as first given, exaggerated the shear effect on the strength of the struts.

Comment on Discussions.—Mr. Beskin's criticism that the extended treatment of the conditions involved in Assumption 5 is superfluous is partly justified. Eqs. 1 to 3 were intended only to show the approximate relationship existing between curvature and the corresponding bending moment. It would have been logical to have included the shear effect on the final curvature. To make Eqs. 8 and 17 general a constant should be added to the right side. This constant is found from the boundary conditions, is dependent on both the shear and moment effects, and in the general case can be determined only after the final solution is obtained. It is the angle through which the member must be rotated so that the shear deflection will satisfy the end condition. Since the shearing force V is affected by this rotation, Eq. 8, as altered, may be considered fundamental but not always useful as a starting point in the solution of a given problem. In straight simple beams of constant cross section symmetrically loaded, the constant is zero. However, if the loading is symmetrical but the cross section varies, it is necessary to rotate the member about one end so that the shear deflection will vanish at the other. A simple beam of constant cross section unsymmetrically loaded by a concentrated force also requires that the constant be zero as do simple beams of constant cross section loaded by couples, the latter showing distortion in the longitudinal direction.

The separation of the deflection y into components is permissible provided those components are properly evaluated. In problems to which the principle of superposition does not apply, these components cannot be found independently and resort is made to adding together the elastic properties of the member which are free from constants not known in advance. For the problem at hand, the addition of the curvatures due to the corresponding shear and moments is such a sum.

The expression $\frac{K\,V}{A\,G}$ represents the relative sliding angle of two adjacent transverse cross sections of the member and is the average effect of the shearing stresses over the entire cross section. The constant K is found by the energy method equating the work of the shearing force to the total work of the shearing stresses, or by using the more refined methods of the theory of elasticity.[19]

The mode of restraint at the ends of a member plays a significant rôle in the solution of shear deflection problems, and can only be treated adequately by the more exact methods developed in the theory of elasticity. Experience shows, however, that comparatively simple problems in elasticity become extremely difficult or defy solution altogether except by approximate methods. For practical needs, the approximate methods often give the desired accuracy.

Mr. Beskin is correct in calling attention to the misstatement that "the curvature due to bending of a built-up strut is independent of the type of lattice used." If (as implied from the outset) there are many lattice bars in the length of the member, the average curvature may seem continuous and independent of the type of lattice. Actually it is not.

---

[19] "Theory of Elasticity," by S. Timoshenko, 1st Ed., McGraw-Hill Book Co., Inc., New York and London, 1934, pp. 42 and 150.

The author laid no claim on originality in handling the problem as the references show. The prime purpose was to ascertain quantitatively the influence of the shearing forces on the strength of the type of struts under consideration.

Mr. Holt calls attention to the important practical problem of estimating the distance between the principal parts of the built-up strut for equal strengths about the principal axes, and develops a relationship between the radii of gyration. Regretfully, because of the error already noted, Fig. 6 may need to be modified.

Mr. Hall early found the error in analysis and much later submitted his discussion with convincing evidence that a change in the affected equations is warranted. His treatment of the comparison of the corrected values with those derived by the writer is interesting and conclusive.

In conclusion, the writer feels that, although the continuity of the paper has been disturbed by the error in analysis, this defect is compensated for by again emphasizing the discontinuity of slopes in elastic bodies due to shearing forces. The writer appreciates the participation of the discussers. At this time it also seems appropriate to thank D. H. Young for his interest. Modesty prevented his sending a discussion because the writer called attention to the error in advance.

ECONOMICAL CANAL CROSS SECTIONS

By Victor L. Streeter,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. V. A. Endersby, Julian Hinds,
D. C. McConaughy, C. J. Posey, and Victor L. Streeter.

Synopsis

The use of machines for trimming the subgrade and for placing concrete lining in canals has dispensed with the need for simple cross sections composed of straight-line segments. By the use of curved canal cross sections, the hydraulic properties are improved, resulting in a substantial saving in concrete and excavation. This paper shows the method of analyzing several typical curved sections, as well as the most economical trapezoidal section for comparable paving-machine speeds. As the paving machines have cover forms for the concrete which move continuously, their speeds will depend upon the properties of the concrete and upon the steepness of the cross section. An index of steepness is derived in the paper and, assuming the mix to be constant, the speed of the machines is assumed to be constant for cross sections having the same steepness index. This provides a basis for comparing various sections all having the same steepness index.

Introduction

Most of the problems encountered in civil engineering practice require the exercise of judgment and experience. No amount of economic studies will displace this sound judgment and experience, but economic studies of certain factors of an engineering project will provide additional information for the designing engineer which will permit him to design a structure of comparable safety at less total cost.

Large paving machines were used in the construction of the open-channel portions of the Colorado River aqueduct. In 1938, W. L. Chadwick, M. Am. Soc. C. E., and G. E. Archibald, Assoc. M. Am. Soc. C. E.,[2] described this paving machine as follows:

Note.—Published in May, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[2] "Machines and Methods for Canal Construction, Colorado River Aqueduct," by W. L. Chadwick and G. E. Archibald, *Civil Engineering*, February, 1938, p. 104.

> "In this machine, the important element was a form or screed plate, shaped exactly to the cross-section of the finished canal, fastened to the under side of a trussed frame, and provided with feed hoppers and a motorized distributor car. * * * The machine, drawn by power winches, operated like a great trowel. * * * The machine was moved forward continuously, shaping both invert and sides as it passed. It was capable of placing lining as accurately as the grade of the tracks [supporting it along the berm] could be maintained. * * * One record shows a combined trimming and placing accuracy of better than 1 per cent."

As the initial cost of a paving machine is large, its use is limited to the construction of long canals of constant cross section. The two principal items of cost are concrete and excavation. The cost of lining is proportional to the wetted perimeter and the cost of excavation depends upon the area, water-surface width, and height of natural ground surface above the hydraulic grade line. The ideal cross section from the standpoint of minimum excavation and concrete would be a semicircle. In general, however, the excavation would not stand, and cover forms for the concrete would be required, making the construction very expensive. By selecting a section which permits the trimmed subgrade to stand by itself, and which permits the use of a paving machine operated at a reasonable speed, a smaller total cost of canal is obtained.

In this paper the speed of paving machine is taken to be a function of the steepness index which is derived in the next section. Several types of cross sections are computed for three values of the steepness index, and their perimeters and water-surface widths are compared.

Notation

The letter symbols used in this paper conform essentially to American Standard Letter Symbols for Hydraulics, prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942.[3]

The Steepness Index

When concrete is placed on a flat slope (say, 1 on 2) cover forms are not required. The friction developed between the subgrade and the fresh concrete, as well as the adhesion to the reinforcing steel (usually added to control temperature effects), provides stability immediately after placing. There is also some resistance to change of shape in the concrete itself before the initial set. When concrete is placed on a steep slope the effect of friction and internal resistance may not be sufficient to hold the concrete in place. An index to this stability is derived as follows:

Consider a strip of concrete of unit width placed on a sloping surface (see Fig. 1). The force tending to cause motion is the component of the weight tangent to the surface. Let the frictional force resisting motion (including effect of reinforcing bars) be designated by F per unit area of surface; and let γ_c equal the unit weight of concrete. Then for a volume element $t\,dl$ the resultant force tending to cause motion is $t\,dl\,\gamma_c \sin\theta - F\,dl$, provided the first term is greater than the second term. The accumulated force for the slope would be $\int (t\,\gamma_c \sin\theta - F)\,dl$, integrated over the portion of one side of the cross section where the integrand is positive. Taking θ_0 as the angle for which the integrand is zero,

---

[3] ASA—Z10.2—1942.

$$F = t\,\gamma_c \sin\theta_0 \qquad (1)$$

and the accumulated force may be expressed as $t\,\gamma_c \int (\sin\theta - \sin\theta_0)\,dl$, carried out from $\theta = \theta_0$ to the water surface. As $\sin\theta = \frac{dy}{dl}$ the force becomes $t\,\gamma_c\,(y_0 - l\sin\theta_0)$, in which y_0 is the vertical distance from the point on the section where $\theta = \theta_0$ to the water surface, and l is the length of section from $\theta = \theta_0$ to the water surface, as shown in Fig. 2. These calculations are for sections which are concave upward, or straight lines, which are the only practical shapes for canal cross sections. Dividing the accumulated force by $t\,\gamma_c$, a steepness index, σ, is obtained having the dimensions of a length, thus

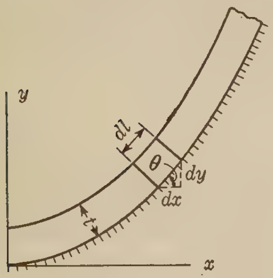

FIG. 1.—SECTION OF CANAL LINING

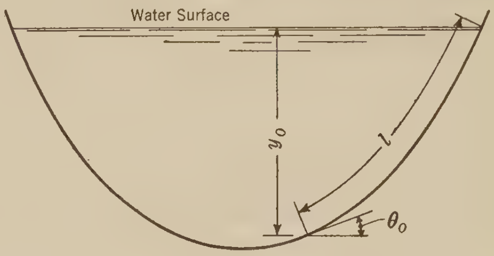

FIG. 2.—A CURVED CANAL CROSS SECTION

$$\sigma = y_0 - l\sin\theta_0 \qquad (2a)$$

If it is considered, for example, that $\tan\theta_0 = 2/3$, then the steepness index becomes

$$\sigma = y_0 - 0.555\,l \qquad (2b)$$

In this paper two canal sections having the same values of σ are presumed to be capable of construction with the same speed of paving machines.

RELATIVE COST OF LINING AND EXCAVATION

The horizontal and vertical alinement of the canal is assumed to have been determined by other studies.[4] The problem of determining the most economical cross section to convey a given discharge at a given slope of the hydraulic gradient for a given or assumed roughness of lining is approached in the following manner.

The Manning formula may be written

$$A\,R^{2/3} = \frac{Q\,n}{1.486\,S^{0.5}} = K \qquad (3)$$

in which: A is the cross-sectional area of canal below water line in square feet; R is the hydraulic radius of the cross section—that is the cross-sectional area divided by the wetted perimeter; Q is the discharge in cubic feet per second; n is the Manning roughness factor; S is the slope of water surface for uniform, steady flow; and K is a known constant for any given study, defined by Eq. 3. Writing $R = \frac{A}{P}$, in which P is the wetted perimeter in feet, Eq. 3 may be written

---

[4] "Aqueduct Size and Slope," by Julian Hinds, *Engineering News-Record*, January 28, 1937, pp. 113–120; and "Economic Sizes of Pressure Conduits," by Julian Hinds, *ibid.*, March 25, 1937, pp 443–449.

$$A = P^{0.4}\,K^{0.6} \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The cost of concrete lining for comparable cross sections (same steepness index σ and same freeboard) is proportional to the wetted perimeter, P. For minimum cost of lining, a solution of Eq. 4 is required for minimum P. The cost of excavation depends in general upon the yardage, which in turn depends upon the cross-sectional area and the water-surface width. Referring to Fig. 3, the cost of the canal in dollars per foot of length may be expressed as

$$c_l = C + b_w \frac{y_z\,c_e}{27} + \frac{A\,c_e}{27} + \frac{P\,t\,c_c}{27} \quad \ldots\ldots\ldots\ldots\ldots (5)$$

in which the constant C is independent of the cross-sectional shape; and: b_w is the water-surface width; y_z is the average depth of hydraulic gradient below the natural ground surface; t is the thickness of lining in feet; c_e is the cost of excavation per cubic yard; and c_c is the cost of concrete lining in place, per cubic yard.

In Eq. 5, A, P, and b_w are factors dependent upon the cross section. The problem resolves itself into selecting a cross section for a predetermined steepness index which makes Eq. 5 a minimum. Theoretically, the problem could be solved by methods of calculus of variations, but practically it reduces to an examination of the properties of various types of cross sections.

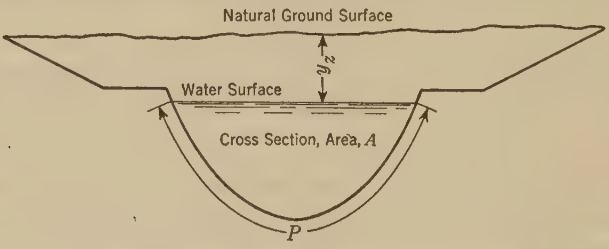

FIG. 3.—CURVED CANAL CROSS SECTION IN CUT

COMPUTATION OF PROPERTIES OF CANAL CROSS SECTIONS

Typical procedures to use in the computation of canal cross-section relationships, such as perimeter, area, water-surface width, and steepness index, are illustrated for the following sections: (1) Trapezoidal cross section, (2) straight sides, circular bottom cross section, (3) circular segment cross section, (4) parabolic cross section, (5) semicubical parabola cross section, and (6) catenary cross section.

The problem reduces to one of finding the dimensions of the cross section such that the given discharge may be conveyed at the specified slope and with a given steepness index. For the first two types of cross sections these conditions may be satisfied in many ways; hence the condition of minimum perimeter of section is also used. For the first two sections the conditions to be satisfied are

$$(a)\quad A\,R^{2/3} = \frac{Q\,n}{1.486\,S^{0.5}} = \text{a known constant} = K \ldots\ldots\ldots (6)$$

$$(b)\quad \sigma = y_0 - l \sin\theta_0 \ldots\ldots\ldots (2a)$$

and

(c) P = a minimum, subject to conditions (a) and (b) (see Eqs. 2a and 6).

For the remaining four sections, only conditions (a) and (b) (Eqs. 2a and 6) are to be satisfied.

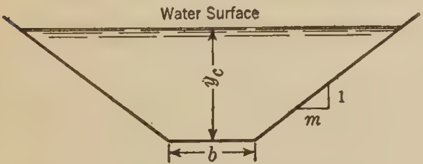

FIG. 4.—TRAPEZOIDAL CROSS SECTION

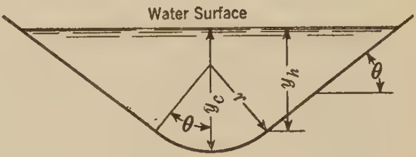

FIG. 5.—STRAIGHT SIDES AND CURVED BOTTOM, CIRCULAR

(1) *Trapezoidal Cross Section.*—Using the notation of Fig. 4,

$$A = b\,y_c + m\,y^2_c \ldots\ldots\ldots (7a)$$

$$P = b + 2\,y_c\sqrt{1+m^2} \ldots\ldots\ldots (7b)$$

$$\sigma = y_c\,(1 - \sqrt{1+m^2}\,\sin\theta_0) \ldots\ldots\ldots (7c)$$

and

$$A - K^{0.6}\,P^{0.4} = 0 \ldots\ldots\ldots (8)$$

Eliminating A, b, and y_c from Eqs. 7 and 8,

$$\frac{P\,\sigma}{1 - \sqrt{1+m^2}\,\sin\theta_0} + \frac{(m - 2\sqrt{1+m^2})\,\sigma^2}{(1 - \sqrt{1+m^2}\,\sin\theta_0)^2} - K^{0.6}\,P^{0.4} = 0 \ldots (9)$$

which expresses the perimeter, P, as a function of m for given values of σ, θ_0, and K. For minimum P, Eq. 9 is differentiated with respect to m, and $\frac{dP}{dm}$ is set equal to zero. The resulting equation is

$$\frac{P}{\sigma} = \frac{2}{\sin\theta_0} - \frac{\sqrt{1+m^2}}{m\sin\theta} + \frac{4\sqrt{1+m^2} - 2\,m}{1 - \sqrt{1+m^2}\,\sin\theta_0} \ldots\ldots\ldots (10)$$

which is independent of K. Eliminating P in Eqs. 9 and 10 leaves an equation with m the only unknown. Its value may be determined by trial for given values of σ, θ_0, and K.

(2) *Straight Sides, Circular Bottom Cross Section.*—This cross section, shown in Fig. 5, is completely specified by values of θ, r, and y_h. In terms of these quantities (notation shown in Fig. 5)

$$A = y^2_h \cot\theta + y_h\,r \times 2\sin\theta + r^2\,(\theta - \sin\theta\cos\theta) \ldots\ldots\ldots (11a)$$

$$P = y_h \times 2\csc\theta + r \times 2\,\theta \ldots\ldots\ldots (11b)$$

and

$$\sigma = y_h \left(1 - \frac{\sin \theta_0}{\sin \theta}\right) + r\,(\cos \theta_0 + \theta_0 \sin \theta_0 - \cos \theta - \theta \sin \theta_0) \ldots (11c)$$

Using the Manning formula, condition (*a*), it may be shown that the condition for minimum P is

$$y_h = r \cos \theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

which states that the center of curvature of the circular portion lies in the water surface, and that the result is independent of θ_0 or K. To obtain Eq. 12, eliminate A between Eqs. 6 and 11*a*. Considering y_h and r as functions of P, σ, and θ, differentiate with respect to σ, holding θ constant, and set $\frac{dP}{d\sigma} = 0$. Differentiating Eq. 11*b* with respect to σ and setting $\frac{dP}{d\sigma} = 0$ the terms $\frac{dy}{d\sigma}$ and $\frac{dr}{d\sigma}$ may be eliminated. Simplifying, it is found that $y_h = r \cos \theta$. Eq. 11*c* is not used. Using Eq. 12:

$$A = r^2\,(\theta + \cot \theta) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13a)$$

$$P = 2\,r\,(\theta + \cot \theta) = \frac{2\,A}{r} \ldots\ldots\ldots\ldots\ldots\ldots (13b)$$

$$\sigma = r\left[\cos \theta \left(1 - \frac{\sin \theta_0}{\sin \theta_0}\right) + \cos \theta_0 + \theta_0 \sin \theta_0 - \cos \theta - \theta \sin \theta_0\right] .. (13c)$$

and

$$r = \frac{\sigma + \frac{P}{2} \sin \theta_0}{\theta_0 \sin \theta_0 + \cos \theta_0} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

Eliminating A and r in Eqs. 6, 13*b*, and 14,

$$P^{0.6}\left(\sigma + \frac{P}{2} \sin \theta_0\right) = 2\,(\theta_0 \sin \theta_0 + \cos \theta_0)\,K^{0.6} \ldots\ldots\ldots (15)$$

from which P may easily be obtained by trial for given values of σ, θ_0, and K. With P known, Eqs. 14, 6, 13*a*, and 12 yield values of r, A, θ, and y_h, respectively. The water-surface width is given by

$$b_w = 2\,r \csc \theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

(3) *Circular Segment Cross Section.*—The properties of this cross section are completely specified by r and θ, as shown in Fig. 6. Thus

$$A = r^2\,(\theta - \sin \theta \cos \theta) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (17a)$$

$$P = 2\,r\,\theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17b)$$

in which θ is expressed in radians, and

$$\sigma = r\,(\cos \theta_0 + \theta_0 \sin \theta_0 - \theta \sin \theta_0 - \cos \theta) \ldots\ldots\ldots\ldots (17c)$$

Using Eq. 6 (condition (*a*)), sufficient equations are available to determine r

and θ for given values of σ, θ_0, and K. This is done by trial from the relations

$$P = \frac{2\,\theta\,\sigma}{\cos\theta_0 + \theta_0 \sin\theta_0 - \theta \sin\theta_0 - \cos\theta} \qquad (18a)$$

and

$$\frac{P^2}{4\,\theta^2}(\theta - \sin\theta\cos\theta) - K^{0.6}\,P^{0.4} = 0 \qquad (18b)$$

which are derived from Eqs. 6 and 17.

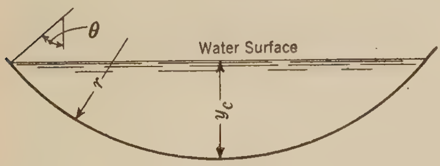

Fig. 6.—Circular Segment Cross Section

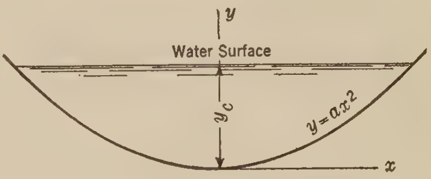

Fig. 7.—Parabolic Cross Section

(*4*) *Parabolic Cross Section.*—Referring to Fig. 7, the properties of the cross section are determined for given values of the constant a in the formula

$$y = a\,x^2 \qquad (19)$$

and the depth y_c at the center. In terms of y_c and a,

$$A = \frac{4\,y^{1.5}_c}{3\,a^{0.5}} \qquad (20a)$$

$$P = \sqrt{\frac{y_c}{a} + 4\,y^2_c} + \frac{1}{2\,a}\left[\log_e 2\,\sqrt{a\,y_c} + \sqrt{1 + 4\,a\,y_c}\right] \qquad (20b)$$

and

$$\sigma = y_c + \sin\theta_0 \left[\frac{1}{4\,a}\log_e(\tan\theta_0 + \sec\theta_0) - \frac{P}{2}\right] \qquad (20c)$$

In conjunction with Eq. 6 (condition (a)) for specific values of a, K, and θ_0, values of y_c are found from Eqs. 20*a*, 20*b*, and 6. The corresponding values of σ may then be determined by Eq. 20*c*. Different values of a are assumed until the required value of σ is obtained.

(*5*) *Semicubical Parabola Cross Section.*—The computation procedure for the semicubical parabola

$$y = \alpha\,x^{3/2} \qquad (21)$$

is similar to that for the parabola. Referring to Fig. 8, the area, perimeter, and steepness index are:

$$A = 1.2\,\frac{y^{5/3}_c}{\alpha^{2/3}} \qquad (22a)$$

$$P = \frac{0.5926}{\alpha^2}\left[\sqrt{(1 + 2.25\,\alpha^{4/3}\,y^{2/3}_c)^3} - 1\right] \qquad (22b)$$

and

$$\sigma = y_c - \frac{8}{27}\,\frac{\tan^3\theta_0}{\alpha^2} + \sin\theta_0\left[\frac{0.2963}{\alpha^2}(\sec^3\theta_0 - 1) - \frac{P}{2}\right] \qquad (22c)$$

With known values of K and θ_0, an α is assumed, and σ is computed, first by determining y_c and P from Eqs. 6, 22a, and 22b by trial, and then substituting in Eq. 22c. This procedure is continued for several values of α, and the curve α versus σ is plotted. From this curve the value of α for an arbitrary σ may be obtained.

(6) *Catenary Cross Section.*—The particular catenary curve

$$y = \frac{1}{\beta}(\cosh \beta x - 1) \qquad (23)$$

as shown in Fig. 9 is selected so that the perimeter may be obtained easily by integration. Values of β and y_c completely determine the cross section. The area, perimeter, and steepness index are expressed more simply in terms of x_0, half the water-surface width b_w. These relations are

$$A = \frac{2\,x_0}{\beta}\cosh \beta\,x_0 - \frac{2}{\beta^2}\sinh \beta\,x_0 \qquad (24a)$$

$$P = \frac{2}{\beta}\sinh \beta\,x_0 \qquad (24b)$$

and

$$\sigma = \frac{1}{\beta}[\cosh \beta\,x_0 - \sin \theta_0 \sinh \beta\,x_0 - \cos \theta_0] \qquad (24c)$$

From Eqs. 24 and 6, σ may be determined by trial for assumed values of β when K and θ_0 are known. Plotting σ against β, the values of β are determined for a predetermined σ.

EVALUATION OF PROPERTIES OF CROSS SECTIONS FOR A SPECIAL CASE

In this section, Eqs. 6 to 24 are applied to a specific problem, in which $K = 4{,}150$; and $\theta_0 = \tan^{-1} 2/3$. If a slope of 1 on 1.5 is the maximum upon which any length of the concrete may be placed without danger of slumping, the steepness index is given by (see Eq. 2a):

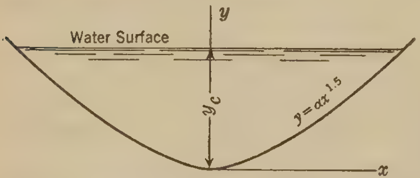

FIG. 8.—SEMICUBICLE PARABOLA CROSS SECTION

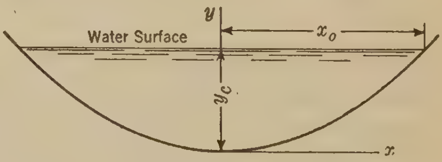

FIG. 9.—CATENARY CROSS SECTION

$$\sigma = y_0 - \frac{l}{\sqrt{3.25}} \qquad (25)$$

in which y_0 is the vertical distance from the water surface to the point where the cross-section slope is 1 on 1.5, and l is the length along the perimeter of the cross section from this point to the water surface. The six cross sections are determined for $Q = 3{,}000$ cu ft per sec, with the canal slope $S = 0.00004$ and a value of canal roughness $n = 0.013$. These values result in $K = \frac{Q\,n}{1.486\,S^{0.5}} = 4{,}150$ (see Eq. 3). Three values of steepness index are used for each section: $\sigma = 0.75$, 1.50, and 2.25. The equations for the curvature of sections 4, 5, and 6 are given in Table 1. The various properties of the cross sections are given in Table 2.

TABLE 1.—MODIFIED EQUATIONS FOR CURVED CROSS SECTIONS IN ILLUSTRATIVE EXAMPLE

$Q = 3{,}000$ cu ft per sec; $S = 0.00004$; $n = 0.013$; $K = 4{,}150$; and $\theta_0 = \tan^{-1} 2/3$

See Table:	σ	Section 4, Eq. 19 and Fig. 7	Section 5, Eq. 21 and Fig. 8	Section 6, Eq. 23 and Fig. 9
2*a*	0.75	$y = 0.01166\,x^2$	$y = 0.09234\,x^{3/2}$	$y = \frac{1}{0.0211}(\cosh 0.0211\,x - 1)$
2*b*	1.50	$y = 0.01456\,x^2$	$y = 0.10584\,x^{3/2}$	$y = \frac{1}{0.026}(\cosh 0.026\,x - 1)$
2*c*	2.25	$y = 0.0175\,x^2$	$y = 0.1187\,x^{3/2}$	$y = \frac{1}{0.03083}(\cosh 0.03083\,x - 1)$

[a] Bottom width of trapezoid. [b] Minimum wetted perimeter for the types indicated.

As a means of illustrating the method of comparing sections, assume the cost of concrete lining in place to be $c_c = \$15.00$ per cu yd, the cost of excavation to be $c_e = \$0.15$ per cu yd, and the lining thickness, t, to be 0.33 ft. Substituting into Eq. 5 the values of A, b_w, and P obtained for the cross sections for $\sigma = 0.75$ (Table 2(*a*)), it is seen that section 5, the semicubical parabola, costs less than the others for y_z less than 18 ft. Section 2, with straight sides and circular bottom, costs less than the others for y_z greater than 18 ft. Since y_z enters linearly into the cost equation its average over the length of canal in cut may be used.

For $\sigma = 1.50$ (see Table 2(*b*)), substitution of A, b_w, and P into Eq. 5 shows that section 5, the semicubical parabola, is most economical for all values of y_z. For $\sigma = 2.25$ (Table 2(*c*)), section 4, the parabola is most economical for y_z less than 6.4 ft, whereas section 5, the semicubical parabola, is most economical for y_z greater than 6.4 ft.

Although these comparisons take into account the more important factors in selection of a cross section, there are other factors which should be carefully considered by the designing engineer. For strength against uplift the radius of curvature at the vertex would be important. The average velocity for partial capacities would affect the deposition of sand and silt. In some cases the cost of excavation might be more costly for the deeper cross sections. All of these factors cannot be evaluated in terms of dollars, but should be given careful consideration before the final cross section is decided upon.

Conclusions

With the availability of paving machines for the lining of long canals, curved canal cross sections may be placed at no greater expense than the customary trapezoidal sections. In addition, if a canal cross section is selected which has less water-surface width and less perimeter than the trapezoidal section, both excavation and concrete yardages will be reduced. The most economical canal cross section from the standpoint of concrete yardage is a semicircle. This section, however, could not be used generally because the excavation would not retain this shape, and the concrete would require a fixed cover form.

In order to set up a criterion that would allow the comparison of various sections, a "steepness index" was developed. Two cross sections having the same value of steepness index are assumed to require the same speed of paving machine.

Six particular types of cross sections were investigated to demonstrate methods of determining the properties of sections with a given value of steepness index. The general methods employed will apply to different cross sections and to other capacities than those used in the example. If the same six types of sections were analyzed for a smaller channel, it is likely that different types would prove to be most economical.

Acknowledgments

The study of economical canal cross sections was first undertaken by the writer while employed at the headquarters office of the International Boundary Commission, United States and Mexico, United States Section, at El Paso, Tex. The work was under the supervision of Richard Stephens, Assoc. M. Am. Soc. C. E., and under the general direction of J. L. Burkholder, M. Am. Soc. C. E. L. M. Lawson, Hon. M. Am. Soc. C. E., is the United States Commissioner. The writer wishes to express his appreciation for their aid and suggestions in making this study.

DISCUSSION

V. A. ENDERSBY,[5] M. AM. SOC. C. E.—The conclusions, arrived at analytically by Professor Streeter and substantiated by field studies made by the writer, are of particular interest in connection with flexible types of canal linings.

Some Field Observations.—The problem of an optimum canal section arose in connection with the investigation of the possible use of asphaltic lining membranes to fit the needs of laterals and other small canals that cannot carry the capital costs of cement or asphalt concrete linings of the thicker types (2 in. to 4 in.). Since the proposed thin linings can be expected only to serve as impermeabilizing agents and not as slope stabilizers, except in a minor degree, the matter of self-stabilizing canal sections is of primary importance. The thin, flexible linings will prevent erosion, weathering, and raveling of the surface soil, etc., but will give no appreciable resistance to hydrostatic pressures or mass soil movements.

The observations of ditches in use revealed a tendency for sections that were constructed as trapezoids to become modified by nature, in four different ways:

Case 1.—Cohesive soil of an unstable type will bulge into the canal near the bottom, and will slump near the top. This bulge slumps further as it becomes soaked, tending to assume a talus formation.

Case 2.—Granular, noncohesive soil erodes below the water line, thus releasing slides that fill in and overrun the eroded cavity.

Case 3.—Granular, cohesive soil, resistant to erosion, often weathers and ravels above the water line, moves down the slope, and forms a talus.

Case 4.—In combination with case 1, 2, or 3, vegetable growth tends to build out a berm at the water line. Since all cases result in rounded bottom corners, this combination of factors tends to form a semicircular cross section; and in fact sections are often found which are nearly perfect semicircles.

All other factors being equal, a section, originally build to the form most acceptable to nature, will be the most likely to escape natural changes. A rounded section is mechanically stable against gravitational forces because it forms a series of inverted elementary arches. The weakness of sharp angles in any structure, as compared with that of rounded forms, has long been established in relation to rigid structures and in fact to tunnel work. If a section that is fundamentally stable is constructed, the problem of maintaining it is merely that of preventing changes in the mechanical properties of the materials composing it. In this case the sole agent materially active in producing such changes is moisture, either by increase or reduction of content, or by erosion. Thus, the sole need for meeting the problem is one of adequate waterproofing.

Application to Thin or Flexible Linings.—Professor Streeter develops his theory in relation to the tendency of fresh concrete to slump on a slope. The fundamental principles are applicable to granular materials such as sand, to granular-plastic materials such as plastic soils, and to bituminous linings. The latter are granular-plastic in nature rather than rigid, especially while being placed hot, or when exposed to very hot weather.

---

[5] Research Engr., Shell Development Co., Emeryville, Calif.

It also happens that a great part of such flexible linings as have been placed has been compacted by transverse rolling. To roll transversely, it is necessary to round the corners to some degree; and, although this may not be a consideration when more suitable means of compaction are employed, the fundamental structural considerations remain.

During the recent construction of an asphalt-lined canal for military uses, the lining was placed by machinery in a trapezoidal section, but the problem of the rounded corner was approached by the subsequent addition of fillets, indicating an appreciation, by the authorities concerned, of the underlying structural considerations.

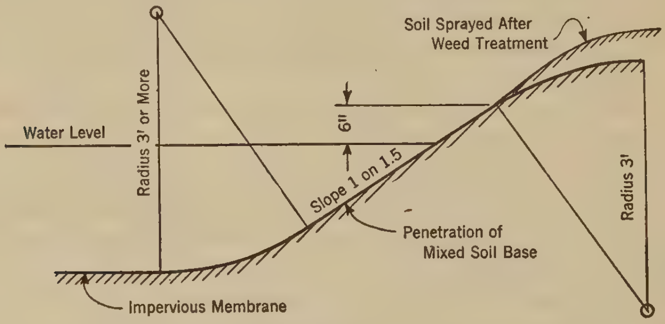

Fig. 10.—Ideal Canal Section for Low-Cost Linings

Professor Streeter expresses the greater stability of the rounded section in Eq. 2*a* and in Fig. 2, in which σ is the steepness index. In the case of a trapezoidal canal, y_0 becomes the full depth of the canal and θ_0 becomes zero except in the case where $\int (t \gamma_0 \sin \theta - F) \, dl$ is zero or minus. In other words, the trapezoidal section gives the maximum slumping force; and, even where the frictional resistance is greater than the accumulated slumping force, the rounded section gives greater resistance to possible ground movements under the lining.

The Ogee Section.—The logical section devised by the writer was determined both by the foregoing considerations as to the economy of the wetted perimeter, and by the special needs of a thin, flexible lining, and is shown in Fig. 10. The total thickness of base and membrane should be not less than 1 in. except when the section is located on firm and cohesive soil. The reversed curve at the berm is intended to prevent edge damage to the lining from stock, etc., and to prevent the infiltration of surface water behind it. The wetted permeter may equally well be any one of the sections discussed by Professor Streeter—circular, parabolic, or catenary.

Summary.—Professor Streeter's conclusions appear to be sound from the points of view of the stability of fresh concrete on the canal slopes, of economy of construction, and of hydraulic efficiency. Furthermore, they conform to the section which nature appears to produce for reasons of inherent stability, and have a special importance where thin, plastic, or flexible linings are used.

Julian Hinds,[6] M. Am. Soc. C. E.—The author has introduced a new member into the family of criteria for "best shapes" of water conduits. Engineers generally are familiar with "best shapes" as determined from minimum area and minimum hydraulic radius alone, and know that only for pipe lines and flumes do these shapes have a great deal of practical significance. For lined excavated conduits (the type considered by the author), the best hydraulic shape usually is poor from a cost-of-construction viewpoint. The engineer is interested in the cheapest and most practical conduit rather than the one with the smallest waterway area and perimeter. For this reason, constructed canal sections usually bear little resemblance to the theoretically "best sections."

If all of the elements affecting costs were included in the theory, a complete formula for the "cheapest section" might be written. Generally, the results are so involved and conditions so variable from place to place that it is preferable to depend on trial-and-error procedure. However, knowledge of the theory of best shape is useful.

Modern development of machines for placing concrete lining has stabilized, or at least limited, some of the variables. The author has taken advantage of this fact to move a step nearer complete determination of the best shape for this particular type of conduit. This is a laudable proposal and the results deserve the careful consideration of engineers interested in problems of this kind.

Although the author's statement of basic principles is clear, the writer wishes to restate them from a slightly different point of view. Consider a differential mass of concrete standing alone on a sloping bank, as at dl, Fig. 1. This mass tends to move down the slope under the influence of gravity. Its movement is resisted by friction along the surface of the bank. If the sliding force exceeds the resisting force, the mass will move unless some other form of support is provided.

If the slab is filled in above and below the mass in question, as indicated in Fig. 1, the differential mass may be made stable by the compressive strength of the concrete below it. The top surface of the mass must in turn support the accumulated excess of sliding force over resistance for the concrete above. Thus the required crushing strength of the differential block will increase as its position moves downward from the top. If the slope is straight, the maximum is reached at the bottom or wherever an outside support occurs. If the slab is curved, the maximum occurs at the position where the individual mass is just stable within itself (against sliding), that is, where $\theta = \theta_0$, using the author's notation.

If the unit weight of the concrete, the resistance to sliding, and the form and dimensions of the bank are known, the required internal resistance can be computed; or, if the permissible internal stress is known, the allowable slope and dimensions may be determined.

The author finds the total force to be resisted in a unit width of slab down to $\theta = \theta_0$ by integration. This he divides by the thickness, t, to get unit stress, and by the weight of a cubic unit of the concrete to get a "steepness factor." The last division is not essential. An "allowable stress" is perhaps more comprehensible to most engineers than a "steepness factor."

---

[6] Gen. Mgr. and Chf. Engr., The Met. Water Dist. of Southern California, Los Angeles, Calif.

It is noted that Eq. 2*a* gives σ in linear units—that is, in feet, for American usage. If the weight is left in, the results are in pounds per square foot, which might be converted to pounds per square inch. The numerical values of σ from Eq. 2*a* are very nearly equal to the allowable stress in pounds per square inch if the canal dimensions and t are in feet, as a 1-in. by 1-in. by 12-in. prism of concrete weighs approximately 1 lb.

The writer is of the opinion that making the sliding resistance, F, constant, regardless of slope, is incorrect. In other sliding problems, the resistance is assumed to be proportional to the normal force against the supporting surface. If this change is accepted, F becomes $F' \cos \theta$ and Eq. 2*a* becomes

$$\sigma' = y_0 - x_0 \tan \theta_0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

in which x_0 is the horizontal projection of the portion of the lining above the point where $\theta = \theta_0$.

If applied to a vertical concrete wall, Eq. 26 gives a stress at the bottom of the wall equivalent to that corresponding to the weight of the wall. For Eq. 2*b*, the stress (or steepness factor) is less than half that corresponding to the weight of the wall; that is, more than half the weight of the lining would have to be held by friction on the vertical bank. The author perhaps does not contemplate a vertical wall but it comes within the theoretical scope of his equations. Also, the effect noted applies in lesser degree to other slopes. Maximum slopes for some of the channels of Table 2 appreciably exceed 1 : 1. The resistance offered by securely anchored, imbedded steel may be more or less independent of slope, which might call for a compromise between Eqs. 2*a* and 26 for heavily reinforced linings. The writer knows of no data on which such a compromise could be based.

Changing from Eq. 2*a* to Eq. 26, or to a compromise, if found desirable, would not vitiate the general idea of the paper but would change some of the detailed computations.

Apparently a placing machine with a tailpiece or apron to smooth and temporarily support the freshly placed lining is contemplated. It is also presumably contemplated that concrete has some resistance to deformation when first placed, and that this resistance increases with passing minutes. Therefore, the slower the machine moves, other things being equal, the stronger will be the concrete as it clears the apron. Thus the speed of machine operation, the height and slope of the bank, and the strength of the soft concrete are interrelated.

Ignoring for the moment the probability that Table 2 should be revised to conform to Eq. 26, it is possible to select the "best" of the listed sections in any of the groups, Table 2(*a*), 2(*b*), or 2(*c*). However, no means for choosing between the three groups is offered. Such a choice requires a knowledge of the details of the machine, the original consistency and rate of hardening of the concrete, and the effect of speed on the cost of lining. The details of the machine are known or determinable. The consistency of the concrete and the rate of stiffening, for the first 10 min or so, are controllable to some extent and are no doubt ascertainable under fixed conditions. The effect of permissible speed of placement on the cost of lining requires careful study. The costs of materials, of trimming banks, of troweling surfaces, and of other items are more or less independent of speed. Nevertheless, other cost items are reduced by rapid placement. By balancing, properly, all the cost and time factors for lining against variations in excavation quantities and other items, if there are any, a "cheapest" section can be devised. Here, as in the more usual case of "best shape," topography and other variables are likely to complicate theoretical formulas beyond the limit of practicability, requiring resort to trial-and-error methods.

As a matter of fact, the average computer will find most of the equations beyond Eq. 8 too complicated for routine use. This is not because the theory is complicated but because of involved mensuration. The use of these equations in a theoretical study, such as that presented in this paper, is entirely permissible, but "practice" is likely to revert to "trial and error."

Another practical point that should be considered is that a good lining machine is costly and durable. Unless the job to be done is large, it will be desirable to salvage the machine for subsequent use or to use a machine salvaged from previous work. This can be accomplished more readily with a trapezoidal machine than with one of circular, parabolic, catenary, or other curved form. Curved fillets of unchanging radius at the bases of the trapezoidal side slopes are permissible and beneficial.

Everything considered, the trapezoidal section—possibly with slight modification—is likely to remain the preferred section for excavated concrete-lined canals. However, it is important that "everything" actually be "considered," in order that the extent of the sacrifice to practicability may be evaluated fully. To this end this paper will be a helpful one.

D. C. McConaughy,[7] Esq.—For the numerical example chosen, the author finds that the parabola and the semicubical parabola are the most economical shapes. However, the slopes at the water surface for these sections, given in Table 2, vary from 0.86 to 1.20. These slopes, in some cases, would not be practicable for the excavation. The slopes at the water surface for the trapezoidal section and for the section with straight sides and curved bottom vary, respectively, from 1.25 to 1.42 and from 1.20 to 1.40, which ranges are more desirable for some soils. It becomes of interest, therefore, to compare the cost of the most economical section with that of the sections more nearly resembling those ordinarily used. If the term C in Eq. 5 is assumed the same for all sections, relative costs in the author's illustrative example are obtained from the remaining terms and are shown in Table 3. The volume of excavation is, roughly, 60 cu yd per ft, so that a small additional cost of excavation for the curved sides would offset any supposed economy due to the shape. The lining thickness is taken as the same for all sections. Whether this would be the case, assuming that the excavated slopes could be maintained at least temporarily, would depend on the judgment of the designer as to whether or not the slope could be regarded as permanent.

---

[7] Senior Engr., U. S. Bureau of Reclamation, Denver, Colo.

In Eq. 2, the stiffness factor σ seems to be a measure of the total force tending to slide the lining down the side slopes; in other words, an increase in σ seems to mean that there is less friction of the concrete on the sides of the excavation. This might result from a low coefficient of internal friction for the ground. In that case, the author's example shows that the section should be made deeper and the sides steeper—a rather peculiar result.

If the example chosen may be considered representative, the curved bottom with straight sides would seem nearly as cheap as the more elaborate sections, and more practicable.

The author deserves the thanks of the profession for making available a method either of designing a section of minimum cost or of ascertaining how much the cost of any given section that may be considered desirable departs from the absolute minimum.

TABLE 3.—COST, IN DOLLARS PER FOOT, OF CANALS WITH VARIOUS CROSS SECTIONS

Section	Type	VALUES OF y_z:				
		0	10	15	20	25
(a) STEEPNESS INDEX (σ) = 0.75						
1	4	20.57	24.57	26.57	28.56	30.55
2	5	20.40	24.40	26.40	28.39	30.39
5	8	20.33	24.35	26.35	28.36	30.37
(b) STEEPNESS INDEX (σ) = 1.50						
1	4	20.30	24.19	26.13	28.07	30.02
2	5	20.06	23.90	25.82	27.75	29.67
5	8	19.80	23.58	25.47	27.37	29.26
(c) STEEPNESS INDEX (σ) = 2.25						
1	4	20.03	23.81	25.70	27.59	29.48
2	5	19.71	23.41	25.26	27.11	28.96
4	7	19.38	23.07	24.91	26.76	28.60
5	8	19.44	23.04	24.84	26.64	28.44

C. J. POSEY,[8] ASSOC. M. AM. SOC. C. E.—According to the author, concrete can be placed higher on the side slopes of a canal, without using cover forms, than would be permitted by friction alone. This seems quite reasonable, although contrary to the textbook statements that freshly poured concrete has the properties of a fluid. The extra force necessary to hold the concrete up along the slope must be a compressive resistance in the fresh concrete. For a V-shaped cross section, with sides too steep to support the concrete by friction, this force would increase uniformly to a maximum at the bottom. If the concrete were placed too high on the sides, failure would result when the accumulated compressive force in the concrete at the bottom became so great as to cause the section to bulge out of shape and allow the concrete on the sides to slip down. For the V-shaped cross section, the compressive force from one side is balanced entirely by the compressive force from the other, assuming, of course, that the lining was poured to the same height on each side.

---

[8] Associate Prof., Hydraulics and Structural Eng.; Research Engr., Iowa Inst. of Hydr. Research, State Univ. of Iowa, Iowa City, Iowa.

If the section were trapezoidal, with sides steeper than the angle of friction, the failure would follow nearly the same pattern. The compressive force at the base of the slope would have to be resisted by a compressive force in the bottom lining. The intensity of this force would decrease away from the corner, due to friction on the bottom, becoming zero in the central part if the bottom were wide enough.

In the author's more general case, the compressive force in the concrete increases from zero at the top to a maximum at some point part way down the slope. Below this point the frictional forces exceed the component of the weight. At this point the frictional forces acting on a differential length dl are equal to the component of the weight along the slope. The compressive stress in the fresh concrete at this point, a distance y_0 from the water surface, helps support the concrete of the upper lining, which is on too steep a slope to remain there by friction alone.

In the development of the "steepness index," the author assumes that the frictional force resisting motion is independent of the angle of the subgrade. This use of a constant value for the frictional force, as given in Eq. 1, permits a very simple integration for the maximum accumulated force, but is open to question, for it is equivalent to assuming that the frictional force is all cohesion. It is difficult to think of the concrete as being capable of sustaining any appreciable accumulated compressive force if its properties do not include internal friction as well as cohesion. The frictional force between the concrete and the subgrade must vary, at least to some extent, with the normal pressure. The author's assumption of a constant value throughout may or may not be satisfactory. Experiments simulating the action of the paving machines in depositing concrete on different slopes would be helpful in evaluating the adequacy of the steepness index.

In Eq. 5, it would seem reasonable to assume that the cost of excavation varies as the nth moment of the cross section about the natural ground surface, n having a value near unity. For the comparison of canals of generally similar proportions, n might be taken as zero (as the author has done, since the area is the 0th moment), but, in considering deeper cross sections, the increased power requirement for elevating the excavated material should be taken into account.

The author is to be commended for his pioneering effort in a field which is destined to become more active as the labor of canal digging and paving is more completely mechanized. He is undoubtedly correct in suggesting that the old sharp corners, which are inefficient from both hydraulic and structural viewpoints, will be eliminated in favor of curves. It is well that the theoretical investigations keep ahead of the immediate demands of practice. Otherwise, designers might specify old-style cross sections in order to avoid the labor of computing the characteristics of a section better suited to their particular problems. On the other hand, the theoretical investigations should be based on as solid a foundation as possible. It might be important, for this problem, to examine critically the hydraulic friction formulas used, since results may be very sensitive to changes in formulas, and present confidence in the Manning and Kutter formulas may be based on data from too few types of cross sections. The writer has computed tables for the section illustrated in Fig. 5.[9] While making these computations, he wondered whether the Manning formula would give reliable results, when applied to such a cross section. No evidence either way has come to his attention.

Victor L. Streeter,[10] Assoc. M. Am. Soc. C. E.—Much interesting information on the application of the analytical approach for determining the best canal cross section has been presented in the discussions. The writer was pleased that the competent designing engineers who submitted discussions supported his method.

Mr. Hinds' suggestion that the stress in the material be used as a relative index of stability is an important improvement over the steepness index. Messrs. Posey and Hinds both question the use of a friction force proportional to the normal force instead of a constant. Resistance to slumping will depend on the mix, the reinforcing steel, the earth surface, and the time and vibration under the cover forms. The friction developed at the surface of contact would probably be close to Coulomb friction, but the other factors appear to be independent of the normal force. Before studies of this type can be applied quantitatively to a particular canal, full-scale tests should be performed on strips of canal lining to determine the formula more accurately and to ascertain the expected paving machine speed for a given steepness index.

Mr. Endersby has discussed an interesting application of the study to flexible linings. The cross section below the water line mentioned in his discussion conforms closely to the cross sections in the paper which proved economical. Certain safety features, such as resistance to hydrostatic uplift and mild earth pressures, are inherent in the curved section.

Mr. McConaughy's analysis shows that the cost is not greatly different for any of the sections listed. However, all these sections have been carefully selected. As an example, the lining of a trapezoidal section with side slopes of 1 on 1 and a steepness index of 1.50 would cost much more than the sections in the paper. In general, a "most economical" solution involves the selection of a design that is near the minimum cost. In this manner, other factors too complicated for analysis may be computed by the designing engineer without materially raising the cost due to economic factors.

This analytical study can certainly be no more accurate than the Manning formula upon which it is based, as stated by Professor Posey. Additional data regarding the extension of the Manning formula to unusual sections will improve any analytical studies on open-channel economy.

The writer feels that analytical methods should be applied to engineering structures in such a way that all factors may be expressed in mathematical form. Thus, such factors would no longer depend upon engineering judgment, and the designing engineer would be able to concentrate on less explicit factors.

RIGIDITY AND AERODYNAMIC STABILITY OF SUSPENSION BRIDGES

By D. B. Steinman,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Edward Adams Richardson, R. K. Bernhard, J. M. Robertson, C. H. Gronquist, F. B. Farquharson, H. Reissner, Blair Birdsall, Hardy Cross, Frederick C. Smith and Hermann Friedlaender and George S. Vincent, Louis Balog, and D. B. Steinman.

Synopsis

Coefficients of rigidity, natural oscillation periods, excitation and amplification of vertical and torsional oscillations, aerodynamic forces and moments, lift and torque graphs, velocity relations, energy relations, positive and negative damping effects, critical wind velocities, rates of amplification, limiting amplitudes, effects of phase difference, and methods of predicting, testing, checking, and preventing aerodynamic instability—all of these factors are treated herein, as they affect the design of suspension bridges against aerodynamic effects.

New basic formulas for computing the various modes of oscillation are presented, which are believed to be simpler and more complete, at the same time being of equal or greater accuracy, than those hitherto available to the profession.

The physical relations affecting analysis and design are expressed in working formulas of a form convenient for direct application by bridge engineers. New graphic solutions that broaden scope and clarify conception supplement the analysis. The formulas derived from fundamental theory and those deduced empirically from available data are illustrated and checked by numerical examples applied to known structures.

Introduction

Investigation and analysis have been concentrated in the recent past on the related problems of the rigidity and aerodynamic stability of suspension bridges.

Note.—Published in November, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr. (Robinson & Steinman), New York, N. Y.

The analysis presented herein has been found useful in explaining past experiences and in predicting new results. By such verification, the mathematical and physical relations developed and coordinated appear to have high consistency and validity—both as a diagnosis and as a guide for correction and prevention. At the same time the writer recognizes the gaps that still remain to be filled by further experimental investigation and the empirical deductions that need to be made more accurate.

Notation.—The letter symbols used in this paper follow customary notation as far as practicable, and are assembled in the Appendix for convenience of reference.

PART 1.—OSCILLATIONS OF SUSPENSION BRIDGES AND MEASURE OF RIGIDITY

The Spring Constant (K).—The "spring constant" K of any span is a measure of the elastic resistance of the structure to deformations or oscillations. It is used in the formula for natural period P or frequency of oscillations N:

$$P = \frac{1}{N} = 2\,\pi \sqrt{\frac{m}{K}} \qquad (1)$$

in which K is defined as the mean effective ratio of the distributed force of restitution or "loading increment" Δw to displacement η, m = mass of the span per unit length, and N = natural frequency of vertical oscillations. The equation of kinetic and potential energy in a simple harmonic cycle yields the general formula

$$K = \frac{\int_0^l \eta\,\Delta w\,dx}{\int_0^l \eta^2\,dx} \qquad (2)$$

in which x = abscissa of any point of the span, measured from one end.

Application to Suspension Bridges.—For a suspension span, by simply substituting the fundamental equilibrium equation

$$\Delta w = -\frac{d^2}{dx^2}(H\,\eta + y\,\Delta H) + \frac{d^2}{dx^2}\left(E\,I\,\frac{d^2\eta}{dx^2}\right) \qquad (3)$$

in Eq. 2, the general formula—

$$K = \frac{-\int_0^l \eta\,\frac{d^2}{dx^2}(H\,\eta + y\,\Delta H)\,dx + \int_0^l \eta\,\frac{d^2}{dx^2}\left(E\,I\,\frac{d^2\eta}{dx^2}\right)dx}{\int_0^l \eta^2\,dx} \qquad (4)$$

—is obtained. In Eqs. 3 and 4: H = horizontal component of tension in one cable; E = modulus of elasticity of the stiffening girders; I = moment of inertia of the section of one stiffening girder; and y = coordinate of any point of the cable, measured from the cable chord. This yields K per cable.

The Sine Wave Curve.—In any span l vibrating in n equal segments, if the displacements follow a sine curve,

$$\eta = a_m \sin\frac{\pi\,n}{l}\,x \times \sin 2\,\pi\,N\,t \qquad (5)$$

in which a_m is the vertical amplitude at the middle of a segment. In this case the elastic increments of loading Δw and their resulting bending moments M are proportional to the displacements η, and follow proportionate sine curves with the same nodes, period, and phase.

For any case in which $\Delta H = 0$, Eq. 3 then yields

$$K = \frac{\Delta w}{\eta} = \frac{\pi^2 n^2}{l^2} H + \frac{\pi^4 n^4}{l^4} E I \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

For an unstiffened suspension bridge, the H-term alone remains. For an unsuspended span, or for a self-anchored suspension span, the EI-term alone remains.

If n is a multiple of 4, also for other even values of n if the midpoint of the cable is free to move horizontally, Eq. 6 is complete, since the condition of inextensibility of the cable ($\Delta l_c = 0$) then is satisfied without involving the adjoining spans and without requiring elastic stretch of the cable.

Other Deflection Curves.—Corresponding expressions for K for other assumed curves of displacement η may be written directly from Eq. 4.

For displacements following, in each segment, the elastic curve of a uniformly loaded beam of constant cross section,

$$K = \frac{306}{31} \frac{n^2}{l^2} H + \frac{3{,}024}{31} \frac{n^4}{l^4} E I \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

which is almost identical numerically with Eq. 6.

For displacements following parabolic curves between nodes,

$$K = 10 \frac{n^2}{l^2} H + 96 \frac{n^4}{l^4} E I \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which I is the mean effective value of the variable moment of inertia. This value of K varies less than 1.6% from the value by Eq. 6.

K for Odd Number of Segments.—If $n > 1$ is odd, the governing requirement $\Delta l_c = 0$ may be satisfied, without involving the adjoining spans, by superimposing a single-segment oscillation of relative amplitude $\frac{1}{n}$, yielding

$$\eta = a_m \sin \frac{\pi n x}{l} \mp \frac{a_m}{n} \sin \frac{\pi x}{l} \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Substituting in Eq. 4,

$$K = \frac{\pi^2}{l^2} \left(\frac{n^4 + 1}{n^2 + 1} \right) H + \frac{\pi^4}{l^4} \left(\frac{n^6 + 1}{n^2 + 1} \right) E I \ldots\ldots\ldots (10a)$$

(Compare Eqs. 9 and 10*a* with the solution offered by H. M. Westergaard,[2] M. Am. Soc. C. E.)

Eq. 10*a* may be generalized for any case of superimposed undulations of different values of n (including even values of n). If the same relation is maintained—namely, that the respective amplitudes of the component harmonics are proportional to their values of n—the generalized form reduces to

---

[2] "On the Method of Complementary Energy," by H. M. Westergaard, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), pp. 786–793.

$$K = \frac{\pi^2}{l^2}\frac{\Sigma n^4}{\Sigma n^2} H + \frac{\pi^4}{l^4}\frac{\Sigma n^6}{\Sigma n^2} E\,I \qquad (10b)$$

The resulting value of Δl_c or Δl will be the algebraic sum of the component values.

Three Spans Coupled.—The main and side spans may oscillate in unison, with a single segment or any odd number of segments (n and n_1, respectively) in each span. If the bridge is symmetrical, the relative amplitudes are determined by balancing $\Delta l/2$ with Δl_1 at each tower top. If K_0 and K_1 are the values by Eq. 6 for the respective spans, the energy equation yields, for the three spans coupled:

$$K = \frac{K_0 + q\,K_1}{1 + q} \qquad (11a)$$

or

$$K = \frac{\pi^2 \left[\dfrac{n^2}{l^2} + q\dfrac{(n_1)^2}{(l_1)^2} \right] H + \pi^4 \left[\dfrac{n^4}{l^4} + q\dfrac{(n_1)^4}{(l_1)^4} \right] E\,I}{1 + q} \qquad (11b)$$

in which the coupling factor q is given by

$$q = \frac{(n_1)^2\,l}{2\,n^2\,l_1} \sec^4 \gamma_1 \qquad (11c)$$

in which γ_1 is the slope of the cable chord in the side span. Eqs. 11 also may be written by extending the integrations in Eqs. 2 and 4 over all three spans. If $l_1/n_1 = l/n$, the main and side spans are in resonance and $K = K_0 = K_1$.

If $n = 2, 6, 10, \cdots$, $\Sigma\Delta(l/n)$ is zero for the full span but is not zero for the half span. If the midpoint of the cable is not free to take the longitudinal motion $\Delta(l/2)$, as when effectively anchored by center stays, the lengthening and shortening of the respective half spans will tend to be taken up by side-span participation to produce $\Delta l_1 = \Delta(l/2)$ at each tower top. Eqs. 11*a* and 11*b* then will apply, with

$$q = \frac{2\,(n_1)^2\,l}{n^2\,l_1} \qquad (12)$$

Oscillations with Longitudinal Motion of Span.—If $n = 2, 6, 10, \cdots$, without participation of the side spans, the longitudinal motion $\Delta(l/2)$ of the midpoint of the cable (Fig. 1) may be imparted to the suspended span through any physical coupling at midspan, as when center stays are provided. The energy equation then yields

$$K = \frac{K_0}{1 + 2\left(\dfrac{16}{3}\dfrac{f}{n\,l}\right)^2} \qquad (13)$$

in which f = the vertical sag of the cable. If the two side spans oscillate in opposite phase, with the main span free of vertical oscillation, the parallel and synchronous movement Δl_1 of the two tower tops produces longitudinal motion of the main span equal to Δl_1. For this case the energy equation yields

$$K = \frac{K_1}{1 + \frac{l}{l_1}\left(\frac{16}{3}\frac{f_1}{n_1}\frac{}{l_1}\cos^2\gamma_1\right)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

Eqs. 13 and 14 express an apparent reduction in K as the equivalent of an increase in the effective value of the oscillating mass m in Eq. 1.

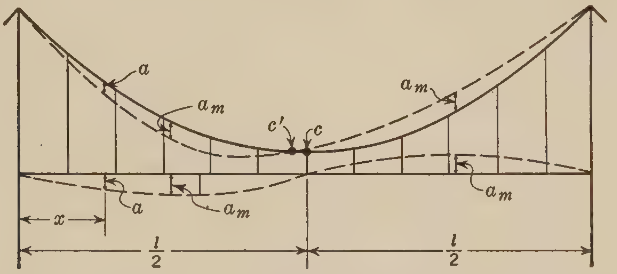

FIG. 1.—SPAN OSCILLATING IN TWO SEGMENTS ($n = 2$) SHOWING CENTER OF CABLE DISPLACED TOWARD THE DEPRESSED SEGMENT

Single Span with Straight Backstays.—For this case, for any odd number of segments including $n = 1$, the necessary increment Δl_c of the cable curve is provided by an increment of cable tension, ΔH, to produce an equal elastic elongation Δl_c of the cable between anchorages. Eq. 4 then yields:

$$K = \frac{\pi^2 n^2}{l^2}\left[H + \frac{32}{\pi^3}\frac{1}{n^4}\frac{E_c A_c}{1 + \frac{3\,l}{16 f^2}(l + 2\,l_1 \sec^2\gamma_1)}\right] + \frac{\pi^4 n^4}{l^4} E\,I \quad . . (15)$$

in which E_c = modulus of elasticity of the cables and A_c = the section area of the cable.

Example 1: Numerical Application of Formulas for K.—In Table 1 the pertinent formulas for K are applied to the recorded modes of vertical oscillation of the bridge across Tacoma Narrows in the State of Washington (1940). Remarkably consistent agreement between the corresponding calculated and observed frequencies is indicated, within the range of variations of observed and assumed data.

(The accuracy of the foregoing formulas for the various modes of oscillation is attested by the exceptionally close agreement noted in Table 1. Compare the results with those from formulas by W. D. Rannie[3] and others. For this comparison, the same assumed value of I = 1,000 has been used.)

For the bridge engineer, it is useful to note that, for $n > 1$, the values of K and N are given with sufficient accuracy for all practical purposes by simply using Eq. 6 without further correction. In fact, for values of n from 2 to 8, inclusive, the values of K given by Eq. 6, without correction, appear to check the observed frequencies of oscillation even more closely than do the values of K calculated more scientifically (except when the effect of center stays in forcing side-span participation needs to be considered).

---

[a] Note effect of center stays, by forcing side-span participation, to raise K from 62 to 83 (if fully effective).

Use of K for Estimating Deflections.—The deflection at the quarter point of a span produced by applied load p covering that half span is given approximately by the formula

$$\eta \approx \frac{p}{K} \qquad (16)$$

using K as given by Eq. 6 for $n = 2$. When the applied load p is large relative to the dead load, K needs to be recomputed for the increased H before use in Eq. 16.

As a rule, the greatest deflections of a suspension bridge occur under half-span loading, and the comparative rigidity of suspension bridges is gaged by such deflections. The value of K as defined, simply calculated and conveniently applied, may therefore, appropriately, be used as the "coefficient of rigidity" of a suspension span.

Example 2: Use of K for Estimating Deflections.—For the Tacoma main span, for $p = 100$ and $K = 62$, Eq. 16 yields a quarter-point deflection $\eta \approx 1.61$ ft, as compared with a computed value of 1.59 ft by the deflection theory. For $p = 750$, K is increased to 69, and Eq. 16 yields $\eta \approx 10.9$ ft (as against 10.9 ft by the deflection theory).

Values of K for Various Suspension Bridges.—Numerical values of the coefficient of rigidity K per cable (or per group of cables), calculated by Eq. 6 for $n = 2$, for various suspension bridges, are recorded in Table 2. For equal applied loads per square foot (live load or aerodynamic pressure), the significant value is K per foot of width (b), or $2\,K/b$. In Table 2, the values of K per foot range from 32.40 to 2.56. The physical meaning of $2\,K/b$ is the loading increment or vertical pressure in pounds per square foot required to produce 1-ft deflection.

It is a significant fact that all of the plate-girder suspension bridges with K per foot less than 15, and all of the open-truss suspension bridges with K per ft less than 6, have been subject to undesirable or dangerous aerodynamic oscillations. (The George Washington Bridge in New York, N. Y., is considered as belonging in neither category.) Both of these indicated critical values happen to coincide with the normal design values for suspension bridges with a vertical slenderness ratio (l/d) of 100 (see Fig. 2). For assured safety at high wind velocities, considerably higher values of K per foot are indicated (see Parts 2 and 3).

TABLE 2.—VALUES OF K FOR VARIOUS SUSPENSION BRIDGES

(K BY EQ. 6, FOR $n = 2$)

Date	Bridge	K per cable	K per foot	PERCENTAGE DUE TO: Cable	PERCENTAGE DUE TO: Girder (R)
1903	Williamsburg	1,082	32.40	22	78
1939	Wabash River[a]	327	26.20	0	100
1909	Manhattan	618	25.76	31	69
1931	Maumee River[a]	648	22.00	51	49
1926	Philadelphia	735	16.52	44	56
1931	Waldo-Hancock	212	15.14	56	44
1929	Grand Mère	188	14.48	34	66
1930	Mid-Hudson	262	12.50	56	44
1929	Mount Hope	201	11.82	54	46
1936	Triborough	547	11.18	66	34
1936	Transbay	324	9.81	62	38
1931	St. Johns	252	9.70	65	35
1938	Thousand Islands[a]	141	9.25	74	26
1938	Thousand Islands[a]	127	8.30	78	22
1929	Detroit	212	7.13	71	29
1939	Deer Isle[a]	69	5.85	80	20
1938	Vancouver	112	5.62	67	33
1931	George Washington	244	4.60	100	0
1939	Bronx-Whitestone[a]	141	3.81	97	3
1940	Tacoma[a]	62	3.16	98.5	1.5
1937	Golden Gate	116	2.56	95	5

[a] Denotes construction with solid-web stiffening girders.

The last two columns in Table 2 record the percentage contributions of the cables and the stiffening girders, respectively, to the coefficient of rigidity K. The proportionate contribution of the stiffening girders or trusses, designated by the ratio R, ranges from 100% in a self-anchored suspension bridge and 78% in the Williamsburg Bridge in New York City to 1.5% in the Tacoma span and practically to zero in the George Washington Bridge. Girder or truss suspension bridges with values of R less than 0.25 are peculiarly sensitive to aerodynamic oscillations.

Approximate Formulas for K and N.—Using the cable term alone, the foregoing formulas yield the convenient approximate relations:

$$K \approx 1.234\, n^2 \frac{w}{f} \qquad (17a)$$

and

$$P = \frac{1}{N} \approx \frac{1}{n} \sqrt{f} \qquad (17b)$$

in which f is simply the sag of the cable. These simplified formulas may be used for estimating the coefficient of rigidity and the natural period or frequency of an unstiffened suspension bridge or of one with negligible stiffening system, for all values of $n > 1$.

Similarly, using the girder term alone:

$$K \approx 1.27\, n^4 \frac{w}{\eta_w} \ldots\ldots\ldots\ldots\ldots\ldots (18a)$$

and

$$P = \frac{1}{N} \approx \frac{1}{n^2} \sqrt{\eta_w} \ldots\ldots\ldots\ldots\ldots\ldots (18b)$$

in which η_w is the central deflection theoretically producible (with E constant) by the dead load w acting on the span as a simple beam. Eqs. 18 may be used for simple spans and for self-anchored suspension spans, for all values of n.

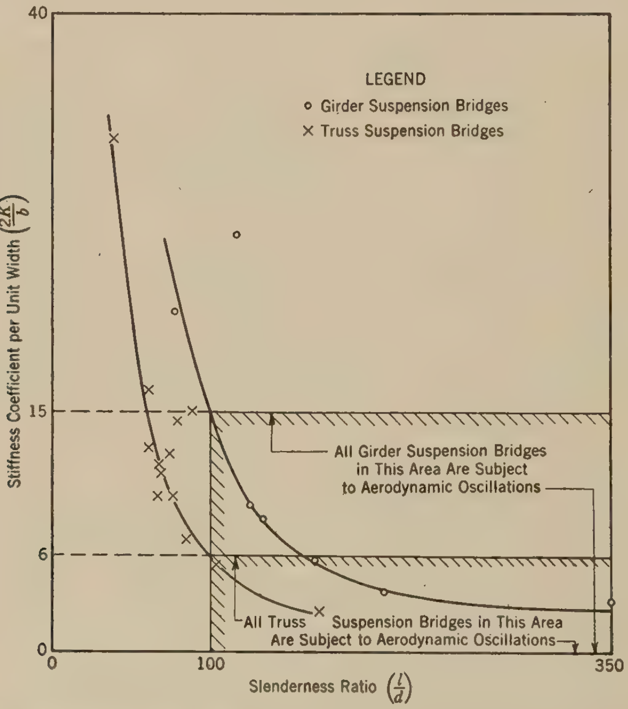

FIG. 2.—CORRELATION OF STIFFNESS COEFFICIENTS (2 K/b) WITH SLENDERNESS RATIOS (l/d) OF VARIOUS BRIDGES, SHOWING RANGE OF BRIDGES SUBJECT TO AERODYNAMIC OSCILLATIONS

For a stiffened suspension bridge (except the self-anchored type), the composite rigidity K is the sum of the respective contributions (Eqs. 17a and 18a) of cable and stiffening girder. Hence

$$\frac{1}{P} = N \approx \sqrt{\frac{n^2}{f} + \frac{n^4}{\eta_w}} \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

Example 2a: Calculation of Rigidities and Frequencies by Simple Approximate Formulas.—For the Tacoma main span, for $n = 2$, with $f = 232$ ft and

$\eta_w = 61{,}400$ ft:

By Eq. 17*b*, the natural frequency of cable = 7.9 cycles per min.
By Eq. 18*b*, the natural frequency of girder = 1.0 cycle per min.
By Eq. 19, the natural frequency of combination = 7.96 cycles per min.
Also, by Eqs. 17*a* and 18*a*, $K = 60.6 + 0.98 = 61.58$.

The foregoing results are almost identical with those given by Eqs. 1 and 6.

Fundamental Equations for Torsional Oscillations.—The general equation of torsional oscillations of a span is

$$\theta = \frac{2\,a_m}{b} \sin \frac{\pi\, n}{l}\, x \times \sin 2\,\pi\, N_t\, t \qquad (20)$$

in which θ is the instantaneous angular displacement of any section x at time t, N_t is frequency of torsional oscillations, and a_m is the maximum vertical displacement of cable or girder at the middle of each segment, since torsional oscillation may be treated simply as out-of-phase vertical oscillation of the two cables.

The values of K and N determined for vertical oscillations, multiplied by simple dimensional constants, yield with sufficient accuracy the corresponding values for torsional oscillations. The spring constant of the span in torsion, or the coefficient of torsional rigidity, will be

$$K_t = \frac{b^2}{2} K \qquad (21a)$$

and the natural frequency will be

$$N_t = \frac{b}{2\,r} N \qquad (21b)$$

in which r is the polar radius of gyration of the mass of the cross section of the span. It is important to note that, for torsional resistance of a suspension bridge, the polar moment of inertia ($r^2\, m$) pertains, not to a localized built-up cross section at the panel points, but to the average cross section throughout, including the long ranges between panel points. For the usual proportions, $b/(2\,r) = 1.3$ to 1.5.

Example 3: Calculation of Natural Frequency of Torsional Oscillations.—For the Tacoma Narrows Bridge, for $n = 2$, Table 1 gives two values: $N = 9.3$ (per min) with center stays forcing side-span participation, and $N = 8$ (per min) without center stays. Applying Eq. 21*b* to these frequencies, and using an indicated effective value of $b/(2\,r) = 1.5$, one obtains $N_t = 14$ and 12 (per min), respectively, which are identical with the two successive frequencies recorded at the time of the failure. The higher frequency was observed at the commencement of the torsional oscillations and corresponds to the functioning of the center stays to force side-span participation. Hold-down stays in the side spans prevented their normal participation beyond a limited amplitude. After failure of the center stays, the torsional oscillations, released from their initial coupling restraint, assumed the lower natural frequency of $N_t = 12$ cycles per min.

Use of K_t for Estimating Torsional Deflections.—When the applied torsional loading is relatively small, the angular deflection θ at the quarter point of a span, produced by applied uniform torsional loading T covering that half of the span, is given approximately by the formula

$$\theta \approx \frac{T}{K_t} \qquad (22)$$

in which K_t is the coefficient of torsional rigidity of the span (calculated for $n = 2$).

Example 4: Use of K_t for Estimating Torsional Deflections.—For the Tacoma main span, for $T = 10{,}000$ ft-lb per lin ft and $K_t = 47{,}000$, Eq. 22 yields $\theta \approx 0.213$ radians, as compared with a computed value of $\theta = 0.209$ by the deflection theory.

PART 2.—AERODYNAMIC EXCITATION OF VERTICAL OSCILLATIONS

Initiation of Oscillations.—Small vertical oscillations of a span may be initiated by traffic, by wind gusts, or by the longitudinal component of the wind acting on the cambered span as an aerofoil. The importance of the last cause is confirmed by the fact that the recently built spans that have given trouble all had been provided with steep camber (for reasons of economy), and by the further fact that the oscillations usually have started with a quartering wind. The longitudinal component of the wind initiates the oscillations and the transverse component then rapidly amplifies them in a logarithmic ratio.

Effect of Vertical Oscillations Upon Aerodynamic Lift.—The instantaneous vertical velocity of any point in the span is

$$v = \frac{d\eta}{dt} = 2\,\pi\,N\,a\cos\,(2\,\pi\,N\,t) \qquad (23a)$$

in which a, the local amplitude, is ordinarily defined by

$$a = a_m \sin\frac{\pi\,n}{l}\,x \qquad (23b)$$

Composition of the wind velocity V and its relative vertical velocity, $-v$, yields a resultant change in effective angle of attack (α):

$$\Delta\alpha = -\frac{v}{V} \qquad (23c)$$

Downward velocity of the section will thus produce or augment an upward angle of attack. In an "aerodynamically unstable section," such upward angle of attack tends to produce a downward resultant pressure, in the direction of the motion.

In the following basic analysis (Eqs. 24 to 36, inclusive), high relative wind velocity V is assumed; the effect of phase difference across the section is introduced subsequently.

The change $\Delta\alpha$ in the effective angle of attack will change the instantaneous lift force on a unit length of the span by an amount

$$\Delta L = s'\left(\frac{\rho}{2}V^2 b\right)\Delta\alpha = -s'\frac{\rho}{2}v\,V\,b \ldots\ldots\ldots\ldots\ldots (24)$$

in which ρ is the mass density of air and s' is the corrected slope of the lift graph:

$$s' = s + C_D \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

This correction is necessary because L, the vertical lift force, and D, the horizontal drag force, in the wind tunnel are measured perpendicular and parallel to the wind whereas ΔL in Eq. 24 is measured vertically. The correction represented by Eq. 25 may be made directly upon the lift graph (Fig. 3) by simply augmenting each ordinate (C_L) by the vertical component $C_D\,\alpha$.

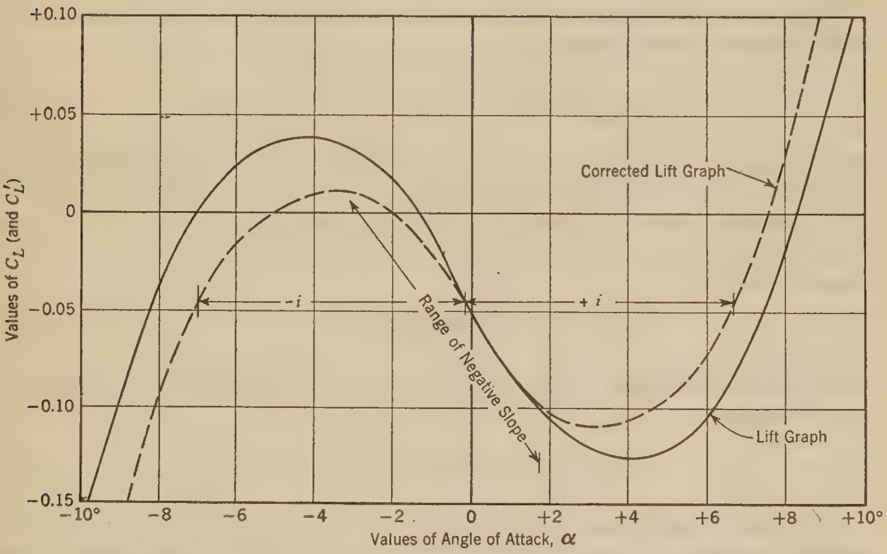

FIG. 3.—LIFT GRAPH (AND CORRECTED LIFT GRAPH)

If the slope s of the lift graph is negative and numerically exceeds the drag coefficient C_D, then s' will be negative and, by Eq. 24, ΔL will be positive when v is positive, and negative when v is negative. This will produce amplification of vertical oscillations. Such a condition constitutes aerodynamic vertical instability.

From the foregoing relations, the maximum value, in a cycle, of the amplifying force ΔL acting on a unit length of the span will be

$$\Delta L(\max) = -\pi s' N \rho b V a \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Self-Excited Amplification of Vertical Oscillations.—Since the increment of lift ΔL is automatically resonant with the harmonic motion of the vertical oscillations and, moreover, is 90° out of phase with that harmonic motion, it will produce an increment of energy in each cycle. This increment of energy, per unit length, will be

$$\Delta W = \pi \, \Delta L(\max) \, a = -\pi^2 s' \rho a^2 b N V \qquad (27a)$$

and, over the span l,

$$\Delta W(\text{total}) = -\frac{\pi^2}{2} s' \rho (a_m)^2 b N V l \qquad (27b)$$

The maximum kinetic (or potential) energy W in a cycle, per unit length, is

$$W = K a^2 \qquad (28a)$$

Hence, over the entire span,

$$W(\text{total}) = \tfrac{1}{2} K l (a_m)^2 \qquad (28b)$$

The relative increase per cycle in the amplitude, or the logarithmic increment per cycle, is denoted by δ:

$$\delta = \frac{\Delta a_m}{a_m} = \frac{\Delta a}{a} = \frac{\Delta W}{2W} = -\frac{\pi^2}{2} s' \rho \frac{b}{K} N V \qquad (29a)$$

If s' is negative, δ will be positive, representing a self-excited amplification of oscillations. By Eq. 29*a*, the amplification ratio δ increases with the width b, or inversely with the coefficient of rigidity per foot of width, $2K/b$ (see Table 2 and Fig. 2). Substituting numerical values for ρ and g, Eq. 29*a* may be written:

$$\delta = -0.0096 \frac{s' b V}{w N} \qquad (29b)$$

The negative damping coefficient, or the logarithmic increment per second, is denoted by λ:

$$\lambda = (1 + \delta)^N - 1 \approx N \delta = -0.0096 \frac{s' b V}{w} \qquad (30)$$

Limiting Amplitude of Vertical Oscillations.—The amplitudes of self-excited vertical oscillations, under aerodynamic negative damping, are limited. As the amplitudes increase, they will cause the resultant values of α, by Eq. 23*c*, to extend more and more beyond the range of negative slope of the lift graph, until the positive contribution of ΔW from the range of negative slope is balanced by the tapering negative contributions of ΔW from the flanking ranges of positive slope.

To take into account the variation of slope s', Eq. 27*a* is replaced by the more general equation

$$\Delta W = \oint L' \, d\eta \qquad (31a)$$

in which $\oint$ denotes integration over the cycle and in which $L' = L + D \alpha$, corresponding to the corrected lift graph. This expression for energy input may also be written

$$\Delta W = \oint \eta \, dL' \qquad (31b)$$

The condition $\Delta W = 0$ will define a limiting local amplitude a_o; and the condition,

$$\int_0^l \Delta W \, dx = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

will define the limiting segment amplitude a_{om}.

If the lift graph is not readily expressible as a mathematical function, graphic or tabular methods are best adapted for the solution of Eqs. 31 and 32. A graphic solution of Eq. 31*a* is shown in Fig. 4. The variation of ΔW with amplitude a is first found by any of these methods, and is then plotted for the sine-curve amplitudes a over a span segment, using trial values of a_m at mid-segment, until the limiting value a_{om} satisfying Eq. 32 is found.

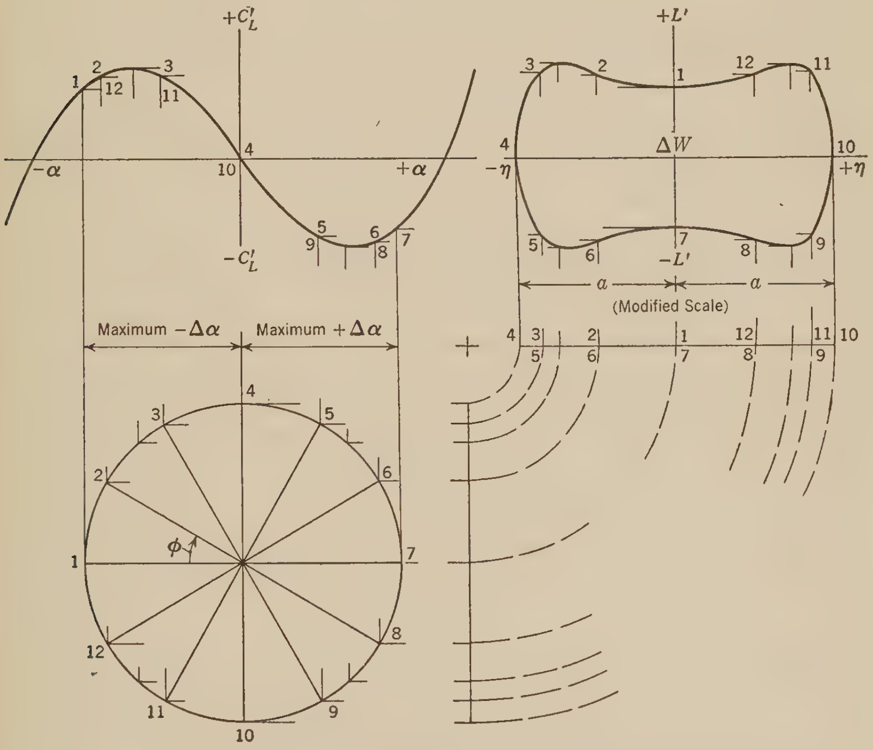

FIG. 4.—GRAPHIC DETERMINATION OF ENERGY INPUT (ΔW) FOR A GIVEN AMPLITUDE (a) OF VERTICAL OSCILLATIONS

If the lift graph is of the typical form shown in Fig. 3, identified with aerodynamic instability, it may be represented by a cubic equation:

$$(C_L)' = s' \alpha \left(1 - \frac{\alpha^2}{i^2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

in which $-i$, 0, and $+i$ are the intercepts on the horizontal axis. (The curve is assumed centered through the origin. This merely changes the inclination datum from which α is measured, and otherwise does not affect the final results.) When used in Eqs. 31 and 32, this yields

$$a_o = \sqrt{\frac{4}{3}\, i} \left(\frac{V}{2\,\pi\, N} \right) \qquad (34a)$$

and

$$a_{om} = \frac{4}{3}\, i \left(\frac{V}{2\,\pi\, N} \right) \qquad (34b)$$

in which a_{om} is the limiting segment amplitude without structural damping.

Structural Damping.—Accurate information on the structural damping of suspension bridges is lacking. For oscillations of flexible suspension spans, the structural damping is represented by a varying logarithmic decrement δ_s of the indicated order of magnitude of 0.002 to 0.130. It is essentially a function of R (the proportion of K due to the stiffening girder), since the principal contribution is from the energy dissipated in deformations of the stiffening system whereas the gravitational resistance to deformation of cable curve (without increment of cable stress) contributes little to damping. Moreover, the energy in the structure (compare Eq. 28*b*) is proportional to $(a_m)^2$, whereas the energy loss due to structural hysteresis is proportional to a fractionally higher power of a_m—$(a_m)^{2.3}$ according to some recorded tests[4]; hence δ_s is a function of a fractional power of a_m (multiplied by $n^2\, d/l^2$ in order to translate a_m into a function of strain). If other losses by dissipation of energy are included, such as those caused by secondary vibrations, roadway deformations, atmospheric damping, joint and bearing frictions, and cable hysteresis, the expression for the structural damping decrement will include terms independent of R and a_m.

In the light of the limited data thus far available, the following semi-empirical expression for the logarithmic decrement δ_s is indicated:

$$\delta_s \doteq (0.001 + 0.06\, R) \left(1 + 1{,}700\, \frac{n}{l} \sqrt{a_m\, d} \right) \qquad (35)$$

An indicated increase with increasing amplitudes is provided by the second factor in the formula. The coefficients and exponents in this formula are written to fit available data and are subject to future revision. A higher value of δ_s is indicated when trusses are used instead of girders.

The critical wind velocity at which aerodynamic amplification of vertical oscillations can commence, defined by the condition $\delta - \delta_s = 0$, will then be, by Eq. 29*b*,

$$V_c = -\, 104\, \frac{w\, N}{b\, s'}\, \delta_s \qquad (36a)$$

in which δ_s is calculated for zero amplitude. At any wind velocity lower than V_c, the aerodynamic negative damping factor is insufficient to overcome the structural damping. Eq. 36*a* may be written in the significant form,

$$V_c = -\, \frac{1 + 60\, R}{15\, s'} \sqrt{\frac{w}{b}} \sqrt{\frac{2\, K}{b}} \qquad (36b)$$

---

[4] "Mechanical Vibrations," by J. P. Den Hartog, McGraw-Hill Book Co., Inc., New York, N. Y., 2d Ed., 1940, pp. 253–254.

in which $2\,K/b$ is the coefficient of rigidity per foot of width. Correcting for structural damping, the net energy input per cycle will be, by Eqs. 28*b* and 29*a*,

$$\Delta W = K\,l\,(\delta - \delta_s)\,(a_m)^2 \qquad (37)$$

Limiting Amplitude Corrected for Structural Damping.—At some limiting amplitude below a_{om}, the increasing value of δ_s will become equal to the diminishing value of δ, terminating further self-excited amplification. For the typical lift graph with reversals of slope (Eq. 33 and Fig. 3), the diminished δ will be

$$\delta = \delta_0 \left[1 - \frac{(a_m)^2}{(a_{om})^2} \right] \qquad (38)$$

in which δ_0 is the value at zero amplitude (or maximum effective s'). The limiting amplitude corrected for structural damping then will be given by the relation:

$$a_r = a_{om} \sqrt{1 - \frac{\delta_s}{\delta_0}} \qquad (39)$$

in which a_r is the limiting vertical amplitude reduced by structural damping. This yields for the Tacoma span a maximum limiting amplitude of 1.5 ft (for any mode), which checks the recorded observations.

The Effect of Phase Difference on Vertical Oscillations.—The following relations, whereby aerodynamic instability at low wind velocities may be created by the phase difference across the width of the section, hitherto have been unsuspected and unexplored.

The aerodynamic disturbance traveling across the width of the vertically oscillating section, especially at low wind velocities, encounters a progressive phase difference, with both relative displacements and relative velocities of the different points along the width when referred to the respective instants of successive impingement. The total phase difference across the section, in cycles, is represented approximately by $N\,b/V$. To correct for the effect of this phase difference, a correction factor β needs to be inserted in the formulas based on the lift graph of a stationary model in order to obtain the relations for an oscillating section, similar to the corresponding correction factor subsequently used in the formulas for torsional oscillations in Part 3.

In the case of vertical oscillations, the indicated critical wind velocity due to phase difference is $V_p \approx 2\,N\,b$, corresponding to a total phase difference of one half of a cycle; and a corresponding indicated expression for the correction factor (assuming a single $-\beta$-range below V_p) is of the form,

$$\beta \approx \frac{V^2 - (V_p)^2}{V^2 + (V_p)^2 \left(0.2 + 0.45\,\frac{V_p}{V} \right)} \qquad (40)$$

asymptotic to unity at higher velocities. This yields $\beta = 0$ at $V = V_p$, and β negative in the low-velocity range from $V = 0$ to $V = V_p$. This negative value of β means a reversal of stability or instability in this range. If the section is aerodynamically stable as previously defined (s' positive), the application of the negative value of β in the formulas for ΔL, ΔW, and δ, will reverse the stability and create a condition of aerodynamic instability in the low-velocity range. The wider the bridge, the greater will be the range of wind velocity to which the normally stable section will be aerodynamically sensitive.

Analytical Derivation of β for Vertical Oscillations.—The physical concept underlying the correction factor β may be visualized as an initiated pressure impulse traversing the width of the section in the time dimension (measured in cycles or fractions of a cycle). If $V \geqq 4\,N\,b$, the action extends through one fourth of a cycle or less, so that the traversing pressure impulse does not encounter any reversal of phase; hence β remains positive. If $V = 2\,N\,b$, the action extends through one half of a cycle, and therefore enters a reversal of phase (direction of motion) at the midpoint of this range and if the pressure impulse traverses the section with undiminished intensity, the integrated effect will be zero ($\beta = 0$ at $V_p = 2\,N\,b$). If $V = 4\,N\,b/3$, the action extends through three fourths of a cycle; the pressure impulse traverses the first third of the width in assumed phase with the direction of motion and the remaining two thirds with the motion in reversed or opposed phase, so that the integrated effect will be negative ($\beta = -$). This concept may be expressed mathematically in simple form:

$$\beta = \frac{\int_0^{\phi'} \cos\phi \, d\phi}{\int_0^{\phi'} d\phi} = \frac{\sin\phi'}{\phi'} \qquad (41)$$

in which the numerator represents the integration of the action traversing the oscillating section and the denominator represents the corresponding integration (over the same assumed transit time) across the stationary section. Here $\phi = 2\,\pi\,N\,t$ is the relative phase angle at any instant of the action, and ϕ' is the total effective phase difference across the width of the oscillating section. Assuming unmodified V and undiminished effectiveness of the traveling pressure impulse throughout the range,

$$\phi' = 2\,\pi\,\frac{N\,b}{V} \qquad (42)$$

Eq. 41 yields:

Velocity V	Correction factor β	Velocity V	Correction factor β
∞	$+1$	$\frac{4}{5}N\,b$	$+\frac{2}{5\,\pi}$
$4\,N\,b$	$+\frac{2}{\pi}$	$\frac{4}{6}N\,b$	0
$\frac{4}{2}N\,b$	0	$\frac{4}{7}N\,b$	$-\frac{2}{7\,\pi}$
$\frac{4}{3}N\,b$	$-\frac{2}{3\,\pi}$	$\frac{4}{8}N\,b$	0
$\frac{4}{4}N\,b$	0	...	...

thus making $V_p = 2\,N\,b$. In the low-velocity range below V_p, the resulting values of β (or $V\,\beta$) follow an oscillating curve converging toward the origin. This yields a series of critical ranges for vertical oscillations at low wind velocities. The Tacoma Narrows Bridge likewise showed a series of critical ranges for oscillations at low wind velocities (see Table 3). The actual correspondence (covering all of the observed modes) is too striking to be accidental. Table 3 is the distribution for an aerodynamically stable section—one for which

TABLE 3.—COMPARISON OF THEORETICAL AND OBSERVED RANGES OF VERTICAL OSCILLATIONS

Values of $V/(N\,b)$	First Critical Range	Intermediate Range	Second Critical Range	Intermediate Range	Third Critical Range	Intermediate Range	Fourth Critical Range
	$\beta = -$	$\beta = +$	$\beta = -$	$\beta = +$	$\beta = -$	$\beta = +$	$\beta = -$
By Eq. 41	2.00–1.00	....	0.67–0.50	....	0.40–0.33	....	0.29–0.25
Observed	2.35–0.93	....	0.89–0.53	....	0.43–0.37	....	0.30–0.26
Number of observations	79	0	56	0	4	0	3

s' is positive. The vertical oscillations are limited to the ranges in which β is negative. For an aerodynamically unstable section (s' negative), the distribution would have been reversed.

Eq. 41 may be improved toward perfect correspondence with the observed critical ranges by advancing the integration limits by the amount of the phase lag between any instant of incidence of wind pressure on the outside of the section and the actual traverse of the interior width by the consequent vertical pressure reaction. Assume that the mean path of the deflected air flow is lengthened from b to $d + b$, and that, in partial compensation, the linear velocity of the deflected air flow is speeded up in the proportion of b to $b + 0.4\,d$. For the Tacoma section, the following integration limits are thus obtained:

$$\beta = \frac{\displaystyle\int_{0.19\phi'}^{1.11\phi'} \cos\phi\,d\phi}{\displaystyle\int_{0.19\phi'}^{1.11\phi'} d\phi} = \frac{\sin 1.11\,\phi' - \sin 0.19\,\phi'}{0.92\,\phi'} \quad \text{.........(43)}$$

This yields, for the critical ranges, $V/(N\,b) = 2.60\text{–}0.92$, $0.87\text{–}0.52$, $0.46\text{–}0.37$, $0.31\text{–}0.29$, etc., or a practically perfect correspondence with the ranges of the observed oscillations.

Eq. 43 also yields striking agreement with the preliminary empirical formula, Eq. 40, from $V = \infty$ to V at the middle of the first critical range (see Table 4). Below V_p, Eq. 40 approximately envelopes the oscillating graph representing the critical ranges.

By advancing the integration limits as in Eq. 43, the major critical ranges are widened, and tend to coalesce. Only the widths and ordinates above or below a secant line representing δ_s will be critical. The recorded observations of oscillations in the third and fourth critical ranges (and one in the fifth) show that, in the Tacoma span, the structural damping was almost negligible.

Conclusions Relative to Vertical Aerodynamic Oscillations.—The foregoing results confirm the significance and validity of the β-concept and its suggested analytical evaluation. Moreover, there now appears to be a conclusive and completely consistent diagnosis of the action of the Tacoma span:

TABLE 4.—AGREEMENT BETWEEN VALUES OF β COMPUTED BY EQS. 40 AND 43

Equation No.	VALUES OF $V/(N\,b)$								
	∞	8	6	4	2.6	2	1.85	1.7	0
40....	1	0.86	0.75	0.48	0	−0.31	−0.38	−0.43	0
43....	1	0.86	0.75	0.48	0	−0.30	−0.38	−0.43	0

(*a*) For vertical oscillations, the section was aerodynamically stable. The span was therefore aerodynamically unstable at low wind velocities (below V_p) and stable at high wind velocities (above V_p).

(*b*) For torsional oscillations (as will be developed in Part 3) the entire picture was exactly reversed, since the torque graph, unlike the lift graph, had a range of negative slope.

The validity of the series of lift graphs obtained in the wind-tunnel tests at the California Institute of Technology at Pasadena also is confirmed. These point to a critical ratio of girder depth to section width for vertical oscillations: If $d/b > 1/4$, with solid girders, aerodynamically unstable sections are indicated, and such bridges (if K and R are inadequate) may be expected to show vertical aerodynamic instability in the high-velocity range (above V_p) and possibly, to a limited extent, in the low-velocity range (below V_p). If $d/b < 1/4$ (or a higher ratio with open trusses), the section is aerodynamically stable, and any self-amplified vertical oscillations will be limited to the low-velocity range. The Tacoma span belonged to the latter category.

Critical Velocities Calculated with β.—Eq. 29*b*, with β inserted, may be written

$$\delta = -\,0.025\,\beta\,s'\,\frac{b^2}{w}\,\frac{V}{V_p}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(44a)$$

in which $V_p = 2.6\,N\,b$. All critical velocities, defined by $\delta - \delta_s = 0$, will then be given by

$$\frac{V_c}{V_p} = -\,40\,\frac{w}{b^2}\,\frac{\delta_s}{\beta\,s'}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(44b)$$

From Eq. 40 or 43, a simplified expression for β may be written, sufficiently accurate in the useful range from $V/V_p = 0.8$ to 4:

$$\beta = 1.3\,\frac{V - V_p}{V}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(45a)$$

(Compare Eq. 58*b* introduced subsequently.) Eq. 44*b* then yields

$$\frac{V_c}{V_p} = 1 - 31\,\frac{w}{b^2}\,\frac{\delta_s}{s'}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(45b)$$

At very low wind velocities (up to $V/V_p = 0.2$), Eq. 40 yields, with sufficient accuracy,

$$\beta = -2\frac{V}{V_p} \qquad (46a)$$

Hence, by Eq. 44*b*,

$$\left(\frac{V_c}{V_p}\right)^2 = 20\frac{w}{b^2}\frac{\delta_s}{s'} \qquad (46b)$$

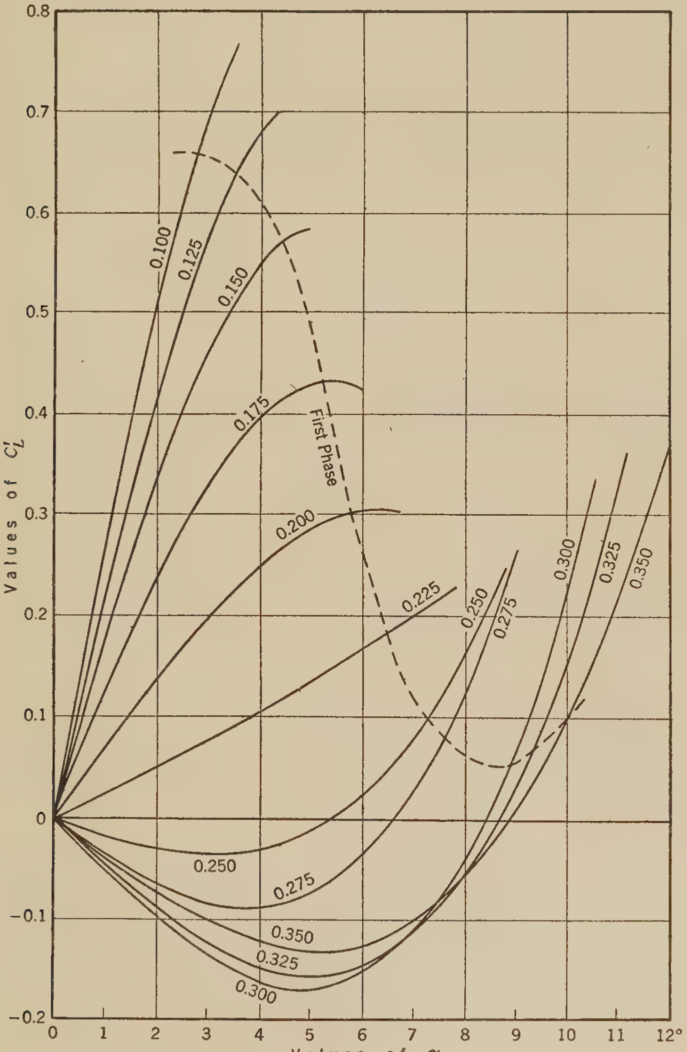

FIG. 5.—LIFT GRAPHS (CORRECTED FOR DRAG) FOR VARIOUS VALUES OF d/b

Example 5: Critical Velocities Calculated with β.—For the Tacoma Narrows Bridge (with $s' = +3.50$, $\delta_s = 0.002$, $b^2/w = 0.53$), Eq. 45*b* yields a maximum critical velocity of $V_c = 2.51\,N\,b$, or 42 miles per hr for $n = 9$, as compared with 40 miles per hr reported, and Eq. 46*b* yields a minimum critical velocity of $V_c = 0.38\,N\,b$, or 1.3 miles per hr for $n = 1$ or 2, as compared with a minimum reported velocity of 1 mile per hr for observed oscillations.

For the Deer Isle Bridge in Maine (without stays), with $s' = -2.52$, $\delta_s = 0.013$, and $b^2/w = 0.46$, Eq. 45*b* yields a minimum critical velocity of $V_c = 3.50\,N\,b$, or 12.2 miles per hr for $n = 1$ or 2, which agrees with observations. For the Toledo Bridge, with $s' = +7.3$, $b^2/w = 0.535$, and $\delta_s = 0.030$, Eqs. 44 yield $\delta < \delta_s$ and $V_c > V$ for all values of V, representing aerodynamic stability at all wind velocities.

Method of Predicting Lift Graphs.—From a study of recorded lift graphs of bridge cross sections, the parameters s' and i (or s'/i^2) of these graphs may be written as functions of the ratio d/b of the H-section. Accordingly, referring to Eq. 33, a single formula is obtained for this entire family of lift graphs:

$$(C_L)' = \frac{28 - 118\dfrac{d}{b} + 0.045\dfrac{b}{d}}{1 + 21{,}500\left(\dfrac{d}{b}\right)^8 + 0.012\dfrac{b}{d}}\,\alpha - \frac{1{,}300 - 5{,}900\dfrac{d}{b}}{1 + 33{,}000\left(\dfrac{d}{b}\right)^8 + 0.005\dfrac{b}{d}}\,\alpha^3 \quad \ldots (47)$$

This is plotted in Fig. 5, giving the lift graphs for values of d/b from 0.100 to 0.350. (The antisymmetrical half for $-\alpha$ is omitted.)

As the angle of attack increases from $\alpha = 0$, the aerodynamic action is in its first phase (bridge floor completely screened by the front girder) up to $\alpha = d/2\,b$, which is the angle of attack at which air-stream lines, if they continued straight, would first impinge upon the horizontal member of the H-section. Beyond this value of α, the lift graph changes in form, usually with a point of inflection. Eq. 47 and Fig. 5 give the lift graphs (corrected for drag) with sufficient accuracy up to $\alpha = 0.6\,d/b$. The range of Eq. 47 may be extended to cover higher values of α by including terms of higher power (α^5 and α^7).

It is significant to note that, as indicated in Fig. 5, all negative lifts and negative slopes are limited to the first phase, $\alpha < d/(2\,b)$. If the horizontal member of the H-section is not at midheight, the lift graphs will not be centered through the origin. More wind-tunnel results are needed to determine such variations.

All known lift graphs for girder suspension bridges fit Eq. 47 and Fig. 5. The known lift graphs for truss suspension bridges also fit Eq. 47 and Fig. 5, provided $0.50\,d$ is used instead of d. This relation is significant and warrants further tests for confirmation or modification of this truss factor.

Following the same general procedure as illustrated by Eq. 47 and Fig. 5, torque graphs for all values of d/b may be similarly formulated and plotted for use in predicting, reducing, or avoiding torsional aerodynamic instability.

PART 3.—AERODYNAMIC EXCITATION OF TORSIONAL OSCILLATIONS

Self-Excited Amplification of Torsional Oscillations.—It is primarily and principally the frontal angle of attack at the leading edge that determines the deflection and disturbance of the air stream, including any eddies produced. The instantaneous vertical velocity v of the leading edge of the cross section (the front girder), combined with the horizontal velocity of the wind V, will change the effective frontal angle of attack by an amount $\Delta\alpha$, given by Eq. 23*c*. Downward velocity of the leading edge thus will produce or augment an upward angle of attack. On an aerodynamically unstable section, such upward angle of attack produces a torque in the direction of the motion. (As the angle of attack increases—due to increasing amplitude—the negative lift increases to a maximum, and then diminishes and reverses; but the negative torque continues to increase through an additional range.)

The change $\Delta\alpha$ in the effective angle of attack will change the instantaneous torque acting on a unit length of the span by an amount

$$\Delta T = -\beta s_t \left(\frac{\rho}{2} V^2 b^2 \right) \frac{v}{V} \qquad \text{(48)}$$

in which s_t is the slope of the wind-tunnel torque graph, and β is a correction factor from the stationary model in the wind tunnel to the oscillating structure.

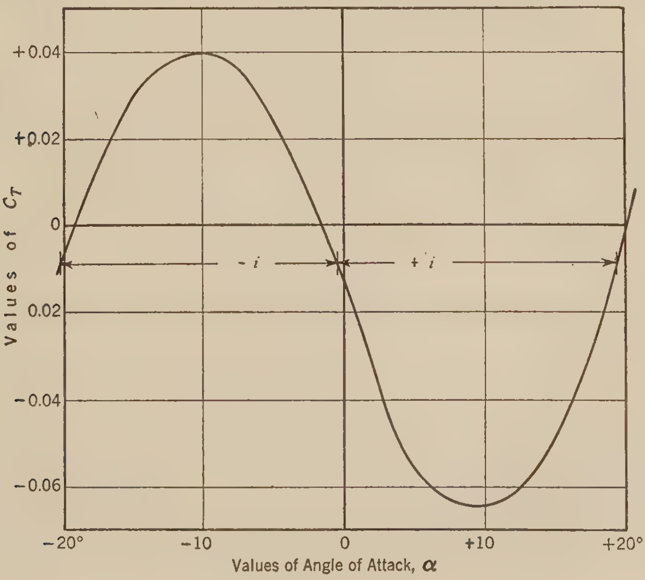

Fig. 6.—Torque Graph

Consideration of the effect of phase difference indicates that the relative vertical motion across the section will modify and actually may augment the aerodynamic torque effect produced by $\Delta\alpha$ at the leading edge, and wind-tunnel tests on oscillating models confirm this conclusion.

If the slope s_t of the torque graph (Fig. 6), when multiplied by β, is negative in the range of oscillation, ΔT by Eq. 48 will be positive (clockwise) when v is positive (upward at the left or leading edge) and negative when v is negative. This will produce self-excited amplification of torsional oscillations. Such condition constitutes aerodynamic torsional instability.

The maximum value, in a cycle, of the amplifying torque ΔT on a unit length of the span will be

$$\Delta T(\max) = -\pi \beta s_t N_t \rho b^2 V a \dots\dots \tag{49}$$

Since the increment of torque ΔT is automatically resonant with the harmonic motion of the torsional oscillations and is, moreover, 90° out of phase with that harmonic motion, it will produce an increment of energy in each cycle:

$$\Delta W = \pi \Delta T(\max) \frac{2a}{b} = -2\pi^2 \beta s_t \rho b a^2 N_t V \dots\dots \tag{50a}$$

and, over the span l,

$$\Delta W(\text{total}) = -\pi^2 \beta s_t \rho b (a_m)^2 N_t V l \dots\dots \tag{50b}$$

The total kinetic plus potential energy in torsional oscillation, per unit length and over the span, will be given by Eqs. 28.

The relative increase, per cycle, in the amplitude of oscillation, or the logarithmic increment per cycle, then will be

$$\delta = \frac{\Delta a}{a} = \frac{\Delta a_m}{a_m} = \frac{\Delta W}{2W} = -\pi^2 \frac{b}{K} \beta s_t \rho N_t V \dots\dots \tag{51a}$$

If βs_t is negative, δ will be positive, representing a self-excited amplification of torsional oscillations. By Eq. 51a, the torsional amplification ratio δ increases with the width b, or inversely with K/b.

Substituting numerical values for ρ and g, Eq. 51a reduces to

$$\delta = -0.0048 \frac{\beta s_t b^3 V}{r^2 w N_t} \dots\dots \tag{51b}$$

and the negative damping coefficient (λ), or the logarithmic increment per second, then will be

$$\lambda \approx -0.0048 \beta \frac{s_t b^3 V}{r^2 w} \dots\dots \tag{52}$$

Limiting Amplitudes of Torsional Oscillations.—The self-excited amplification of oscillations will continue until the positive contribution of ΔW from the range of negative slope of the torque graph is balanced by the tapering negative contribution from the flanking ranges of positive slope (see Fig. 7). The limiting local amplitude (θ_o or a_o) then is defined by the condition $\Delta W = 0$, in which

$$\Delta W = \oint T\, d\theta \dots\dots \tag{53a}$$

which also may be written

$$\Delta W = \oint \theta\, dT \dots\dots \tag{53b}$$

The limiting segment amplitude (θ_{om} or a_{om}) then is defined by Eq. 32. A graphic solution of Eqs. 53 is shown in Fig. 7.

If the torque graph is of the typical form (Fig. 6) represented by a cubic equation similar to Eq. 33, with intercepts $-i$, 0, and $+i$, then

$$\theta_o = \sqrt{\frac{4}{3}}\,i \qquad (54a)$$

and

$$\theta_{om} = \frac{4}{3}\,i \qquad (54b)$$

Fig. 7.—Graphic Determination of Energy Input (ΔW) for a Given Torsional Amplitude (θ_o)

The limiting angular amplitudes (θ_o at any point, and θ_{om} at midsegment) thus are independent of wind velocity, span length and rigidity, and modes of oscillation, but depend only on the form of the torque graph. Wind-tunnel tests yield similar torque graphs for all sections having torsional aerodynamic instability, with $i = 21°$ to $36°$, and therefore $\theta_{om} = 28°$ to $48°$. (The value of i appears to be a function of d/b.) The corresponding vertical amplitudes of torsional oscillations then will be

$$a_o = \frac{b}{2} \sin \theta_o \quad \text{(55a)}$$

and

$$a_{om} = \frac{b}{2} \sin \theta_{om} \quad \text{(55b)}$$

in which a_{om} is the limiting amplitude before correction for structural damping.

The torque graph obtained (1943) for the Tacoma cross section by Harold A. Thomas, M. Am. Soc. C. E., at the Carnegie Institute of Technology in Pittsburgh, Pa., has $i = 34°$. Hence, by Eq. 54*b*, the limiting torsional amplitude would be 45°, which checks the reported value for the Tacoma bridge and which also checks the oscillating-model test results obtained by Professor Thomas.

Change of Period by Forced Vibrations.—In any range of constant or mean effective s_t, the aerodynamic torque T varies in phase with the angular displacement θ:

$$T = \left(s_t \frac{\rho}{2} b^2 V^2 \right) \theta + T_{\theta=0} \quad \text{(56a)}$$

This will not affect the energy or amplitude, but will change the frequency N_t from natural frequency to a "forced" frequency:

$$N_t = \frac{1}{2\pi} \sqrt{\frac{K_t - s_t \frac{\rho}{2} b^2 V^2}{2 r^2 m}} \quad \text{(56b)}$$

If s_t is negative, the frequency N_t thus is increased. At high wind velocities, this increase in N_t may amount to 2% or 3%; normally it is negligible.

As a suggested explanation of self-excited amplification, this effect may be eliminated, since the amplitudes are unaffected. The work diagram follows the torque graph through the angular range and then retraces the same path, and is therefore reduced to a line of zero area. It is only the ΔT-effect, represented in Eqs. 48 to 53, that produces a relative displacement of the two tracings of the path along the torque graph (Fig. 7), similar to the displacements in a "hysteresis diagram." In one half of the cycle the torques are $T + \Delta T$, in the other half, $T - \Delta T$. The resulting intercepts through the angular range produce ΔW, the increment of energy that amplifies the oscillations.

Effect of Phase Difference.—Significant torsional instability associated with a negative slope of the torque graph does not occur at low wind velocities. Wind-tunnel tests on oscillating models, with the effect of structural damping eliminated by subtraction, show that there is a critical wind velocity at which aerodynamic amplification (negative damping) appears. This critical velocity V_p is explained by the relative phase difference (represented by

$N_t\,b/V$) of aerodynamic disturbance and torsional oscillation between the two sides of the cross section.[5] The theory of aerodynamic damping further indicates that the "density-mass ratio" $\rho\,b^2/(2\,m)$ of the structure has some influence on V_p, and this is confirmed by the model tests. The recorded values of $V_p/(N_t\,b)$ actually ranged from 3.3 to 5.1 for different values of the density-mass ratio. The limited test results thus far available yield, approximately,

$$V_p = N_t\,b\left(4.8 - 82\,\frac{\rho\,b^2}{2\,m}\right) \qquad (57a)$$

On substitution of numerical values for ρ and g, this reduces to

$$V_p = 1.41\,\frac{b}{r}\,\frac{b}{\sqrt{w}}\left(1.53 - \frac{b^2}{w}\right)\sqrt{K} \qquad (57b)$$

(For the Tacoma span, for $N_t = 12$ cycles per min, Eq. 57*a* or 57*b* gives $V_p = 16.6$ miles per hr. With omission of the correction for density-mass ratio in Eq. 57*a*, or its reduced form b^2/w in Eq. 57*b*, either formula gives $V_p = 25.4$ miles per hr. This significant correction has been overlooked by other investigators.)

The correction factor β in the negative damping formulas for the oscillating structure is also a function of the phase difference across the section; hence it is a function of V_p/V. A qualitative analysis of the aerodynamic action, as confirmed and supplemented by the test results, indicates that β is negative for $V < V_p$; is zero at $V = V_p$; then increases to a maximum greater than unity; and finally diminishes toward unity as a limit at high wind velocities. This variation is represented by the following empirical formula (which fits the test results):

$$\beta = \frac{5.5\left(\dfrac{V}{V_p} - 1\right) + 0.005\left(\dfrac{V}{V_p} - 1\right)^2}{\dfrac{V}{V_p} + \dfrac{V_p}{V} + 0.005\left(\dfrac{V}{V_p} - 1\right)^2} \qquad (58a)$$

or, with close accuracy from $V = 0.8\,V_p$ to $V = 4\,V_p$,

$$\beta = 5\,\frac{V - V_p}{V} \qquad (58b)$$

For various cross sections of the Tacoma type, the wind-tunnel torque graphs are almost identical in their middle parts of negative slope, with $s_t \approx -0.50$, very closely. Substituting this value of s_t, and the value of β from Eq. 58*b*, Eq. 51*b* may be written

$$\delta = 0.012\,\frac{b^3}{r^2\,w\,N_t}\,(V - V_p) \qquad (59)$$

This is identical with the plotted results obtained in wind-tunnel tests on oscillating models.

---

[5] "The Failure of the Tacoma Narrows Bridge," a report to the Hon. John M. Carmody, Administrator of the Federal Works Agency, Washington, D. C., March 28, 1941, by a board of engineers consisting of O. H. Ammann, Theodor von Kármán, and Glenn B. Woodruff, Appendix VIII (analysis by Louis G. Dunn).

Analytical Derivation of β for Torsional Oscillations.—Analogous to Eq. 43 for vertical oscillations and representing a similar physical interpretation, a tentative analytical derivation of β may be written for torsional oscillations:

$$\beta = \frac{\int_{0.19\phi'}^{1.11\phi'} (1 - u\,\phi^3)\,(0.65\,\phi' - \phi)\cos\phi\,d\phi}{\int_{0.19\phi'}^{1.11\phi'} (1 - u\,\phi^3)\,(0.65\,\phi' - \phi)\,d\phi} \quad \text{.........} \quad (60a)$$

In this case a factor of the indicated form $(1 - u\,\phi^3)$ is included to represent a variation of the intensity or effectiveness of the vertical pressure impulse as it traverses the section; and the factor $(0.65\,\phi' - \phi)$ must be included to represent the varying lever arm about the center of the section. Values of β as computed by Eq. 60*a* are given in Table 5. In conformity with the test results, values of β exceeding unity are obtained. Varying values of $V_p/(N_t\,b)$ are also obtained, as follows:

TABLE 5.—ANALYTICAL DERIVATION OF β FOR TORSIONAL OSCILLATIONS ($u = 1/3$)

Equation No.	VALUES OF $V/(N_t\,b)$						
	12	8	4	3	2.5	2.0	1.5
60*a*......	3.7	2.8	0.7	−0.1	−0.6	−0.9	−0.6
60*b*......	3.7	2.5	0.8	−0.02	−0.5	−0.8	−0.5

u	$\frac{V_p}{N_t\,b}$
1/7	2.57
1/5	2.80
1/3	3.13
1	3.66
∞	5.34

The value of $V_p/(N_t\,b) = 3.13$ (and therefore $u = 1/3$) corresponds to the Tacoma section.

Each integrand in Eq. 60*a* consists of two modified triangular influence areas, concentrated toward the outer edges of the section. By considering these influence areas as concentrated at their respective centroids, an approximate equivalent formula is obtained as a welcome short cut:

$$\beta = \frac{\cos 0.3\,\phi' - [1 - 0.9\,u\,(\phi')^3]\cos\phi'}{0.9\,u\,(\phi')^3} \quad \text{............} \quad (60b)$$

for which the computed values are given in Table 5. The denominator is the algebraic sum of two resultant pressure forces acting near the outer edges of the section, and the numerator is the algebraic sum of the same two resultants corrected for phase difference by their respective cosine factors.

The several theoretical and empirical formulas for β yield remarkably consistent results. Any further refinement of the values in Table 6 would not be warranted by the present available data.

TABLE 6.—COMPARISON OF THEORETICAL AND EMPIRICAL FORMULAS FOR β

Equation No.	VALUES OF V/V_p							
	∞	5	4	3	2	1	0.5	0
60*a*........	1	3.9	3.8	3.2	2.1	0	−0.6	0
60*b*........	1	4.4	3.8	2.9	1.8	0	−0.5	0
58*a*........	1	4.2	3.8	3.3	2.2	0	−1.1	0
58*b*........	....	4	3.8	3.3	2.5	0	....	....

The coefficient u, introduced in Eq. 60*a* to represent a rate of progressive reduction or modification in pressure reaction by transfer of energy as the air disturbance traverses the section, is related to the density-mass ratio $\rho\, b^2/(2\, m)$, and therefore to the critical dimensional ratio b^2/w. The indicated relation (based on the comparison for the known data of the Tacoma section) is

$$\frac{1}{u} = 355{,}000 \left(\frac{\rho\, b^2}{2\, m}\right)^3 = 20 \left(\frac{b^2}{w}\right)^3 \ldots\ldots\ldots\ldots\ldots (61a)$$

In the useful range, the derived variation of V_p with u, as recorded under Eq. 60*a*, is given very closely by

$$\frac{V_p}{N_t\, b} = 4.8 - 1.16 \sqrt[3]{\frac{1}{u}} \ldots\ldots\ldots\ldots\ldots\ldots (61b)$$

With the correlation recorded in Eq. 61*a*, Eq. 61*b*, independently derived, proves to be identical with the empirical Eqs. 57 previously written from the wind-tunnel tests on oscillating models.

The development of the concepts and relationships introduced herein offers many interesting possibilities and will repay further exploration by both experiment and analysis.

Determination of Required K for any Specified Critical Velocity V_p.—Eqs. 57 enable the required design value of K to be determined for any specified value of V_p (the critical velocity before correction for structural damping). From Eq. 57*b*

$$K = \frac{r^2}{2\, b^2} \frac{w/b^2}{(1.53 - b^2/w)^2} (V_p)^2 \ldots\ldots\ldots\ldots\ldots (62a)$$

As a rule, for the suspension bridges under consideration, w/b^2 ranges from 1.67 to 2.50; and, for this range, the function of w/b^2 and b^2/w in Eq. 62*a* remains practically constant (between 1.88 and 1.93) and may be taken as approximately equal to 1.90. Using this value, and $r^2/b^2 \approx 0.125$, Eq. 62*a* yields

$$K = 0.12\, (V_p)^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (62b)$$

Hence, for $V_p = 50$ miles per hr, the required K is 645.

Wider bridges (unless made heavier per square foot) fall outside of the values of w/b^2 assumed herein, and require a higher K. (For the Bronx-Whitestone Bridge in New York City, the required K by Eq. 62*a* is 80% higher than that given by Eq. 62*b*, or $K = 1{,}170$ for $V_p = 50$ miles per hr.)

Critically Dangerous Value of b^2/w.—Eq. 62*a* indicates that there is a critical value of b^2/w for aerodynamically unstable bridges, namely $b^2/w = 1.53$ (equivalent to $\rho\, b^2/(2\, m) = 0.0585$). For bridges having this dimensional ratio, V_p will be zero for all values of K. As b^2/w approaches the critical value of 1.53, sensitiveness to torsional aerodynamic instability increases and becomes more difficult to cure. (The structure that comes nearest to this critical ratio is the Bronx-Whitestone Bridge, with the abnormally high value of $b^2/w = 1$. The prevailing values of b^2/w for other suspension bridges of this type are close to the optimum value of 0.51, for which the required K is a minimum, as given by Eq. 62*b*.) The observed high aerodynamic sensitiveness of certain suspension bridges during erection, with floor forms in place and before pouring the concrete, is also explained by the critical value of b^2/w in that stage.

Structural Damping.—Until more adequate experimental data are available, the tentative indicated expression for δ_s, Eq. 35, previously written for vertical oscillations, also may be used for torsional oscillations of flexible suspension bridges.

The critical velocity due to structural damping, defined by the condition $\delta - \delta_s = 0$, then will be given by

$$V_c - V_p = \frac{r^2\, w\, N_t}{0.012\, b^3}\, \delta_s \tag{63a}$$

where δ_s is calculated for zero amplitude, and the limiting amplitude corrected for structural damping will be given by

$$a_r = a_{om} \sqrt{1 - \frac{V_c - V_p}{V - V_p}\left(1 + 1{,}700\, \frac{n}{l}\, \sqrt{a_r\, d}\right)} \tag{63b}$$

This yields for the Tacoma span, at $V = 40$ miles per hr, with $i = 34°$, a maximum limiting torsional amplitude of 13.1 ft, compared with 14 ft estimated as observed.

Corrected for structural damping, the net energy gain per cycle will be given by Eq. 37.

Determination of Required K for Any Specified Critical Velocity V_c.—From Eqs. 57*b* and 63*a*,

$$\sqrt{K} = \frac{V_c}{1.41\, \frac{b}{r}\, \frac{b}{\sqrt{w}}\left(1.53 - \frac{b^2}{w}\right) + 37.7\, \frac{r}{b}\, \frac{\sqrt{w}}{b}\, (0.001 + 0.06\, R)} \tag{64a}$$

For the prevailing values of $b^2/w = 0.45$ to 0.55, and $r/b \approx 0.354$, Eq. 64*a* reduces to

$$\sqrt{K} = \frac{V_c}{2.93 + 1.13\, R} \tag{64b}$$

Hence, for $R = 0$,

$$K = 0.116\ (V_c)^2 \quad \text{(64c)}$$

and, for $R = 1$,

$$K = 0.061\ (V_c)^2 \quad \text{(64d)}$$

or a reduction of 3% to 49% in the required value of K, as given by Eq. 62*b*, when structural damping is taken into account. To make $V_c = 50$ miles per hr, the required value of K ranges from 626 for $R = 0$, down to 328 for $R = 1$.

With abnormally high values of b^2/w, higher values of K will be required. At the critical value of $b^2/w = 1.53$, to make $V_c = 50$ miles per hr (which then will be due to structural damping alone), the required value of K ranges from 12,500 for $R = 1$, to 46,500,000 for $R = 0$. The obvious measure is to increase R and w or to eliminate the cause of the aerodynamic instability.

PART 4.—METHODS OF SECURING RIGIDITY AND AERODYNAMIC STABILITY

Anticipating Aerodynamic Instability.—The phenomena of aerodynamic instability, both vertical and torsional, are a combined function of flexibility of the span and disposition of the cross section.

The conventional H-type of cross section, with solid floor between vertical stiffening girders, tends to produce the effects of aerodynamic instability. Modification of the section by moving the floor slab to the top or to the bottom of the cross section may reduce the effect, but will not necessarily eliminate it.

Wind-tunnel tests on a scale model of the cross section will yield characteristic curves, useful in analysis, and offer a method of testing or predicting aerodynamic instability of the section. If the graph of aerodynamic lift for varying angles of attack has a range of negative slope, aerodynamic vertical instability of the section may be anticipated. Similarly, if the graph of aerodynamic torque for varying angles of attack has a range of negative slope, aerodynamic torsional instability of the section may be anticipated. In addition, an aerodynamically stable section may develop aerodynamic oscillations (limited to a range of low wind velocities) if the structure has a low value of R. For a complete investigation, wind-tunnel tests on oscillating models are desirable.

The use of open trusses instead of solid-web girders for the stiffening construction reduces, but does not necessarily eliminate, susceptibility to aerodynamic instability.

Influence of Rigidity.—Susceptibility to the effects of aerodynamic instability is obviously reduced by increasing the rigidity of the structure—primarily the rigidity of the main span. Rigidity of the side spans and towers is helpful in the lowest mode ($n = 1$), and may be helpful in some higher modes ($n = 2, 6, \cdots$) if center stays are provided.

For resistance to these aerodynamic effects, the most significant single factor is the coefficient of rigidity, K, or the coefficient of rigidity per foot, $2\,K/b$.

In a bridge with solid-web stiffening girders, the numerical value of K should be kept well above 300, and the numerical value of $2\,K/b$ should be kept well above 15 (lb per ft^3), unless aerodynamic stability is otherwise assured (see Eqs. 36, 62, 63, and 64, and the related text).

In a bridge with open-web stiffening trusses, the numerical value of K should be kept well above 120, and the numerical value of $2\,K/b$ should be kept well above 6 (lb per ft^3), unless aerodynamic stability is otherwise assured (see Table 2 and Fig. 2).

Another significant factor is R, the ratio of the rigidity contributed by the stiffening construction to the total rigidity. Higher values of R, by increasing the structural damping, raise the critical wind velocity, restrict the maximum amplitudes, and prevent development of oscillations at low wind velocities. The value of R should preferably be kept well above 0.25, unless aerodynamic stability is otherwise assured. With low values of R, the required values of K and $2\,K/b$ may be two or more times the foregoing values (see Eqs. 64).

The depth of the stiffening truss or girder, in proportion to the span, is also directly effective in augmenting structural damping and thereby restricting amplitudes (see Eq. 35). Experience to date indicates the hazard of making the depth of the stiffening truss or girder less than 1/100 of the span, unless the cross section is aerodynamically stable or unless other means of resisting oscillations or assuring aerodynamic stability are provided (see Fig. 2).

Lateral flexibility of the span does not appear to be a factor in aerodynamic instability. A suspension span is inherently stable against lateral displacement.

Use of Center Stays.—In amplitudes attainable and magnitude of kinetic energy accumulated, two-segment (single-node) torsional oscillations are generally the most dangerous potential manifestation of aerodynamic instability.

A highly effective method of preventing or resisting such two-segment torsional oscillations is the provision of adequately proportioned center stays or other equivalent means of preventing relative longitudinal motion of cable and suspended structure at midspan.

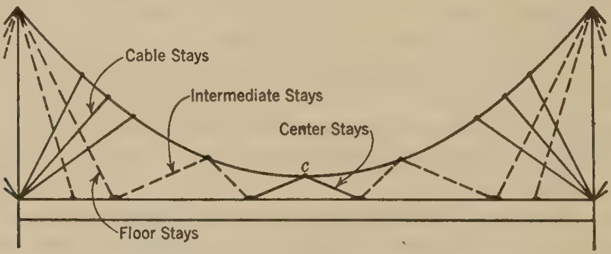

FIG. 8.—VARIOUS SYSTEMS OF LONGITUDINAL STAYS FOR STIFFENING SUSPENSION BRIDGES TO INCREASE THEIR AERODYNAMIC STABILITY

Without such center stays or their equivalent, two-segment ($n = 2$) oscillations of a main span cable involve longitudinal displacement of its midpoint (see Fig. 1). If both cables are in phase, as in vertical oscillations of the span, the longitudinal displacements of their midpoints will be in phase, tending to produce corresponding longitudinal oscillation of the suspended span. If the two cables are out of phase, as in torsional oscillations of the span, the longitudinal displacements of their midpoints will be out of phase, tending to move in opposite directions. Such relative longitudinal movements of the midpoints of the two cables in opposite directions are prevented by anchoring the two midpoints to the suspended span (Fig. 8). When such midspan anchorage of the cables is provided, by center stays or their equivalent, two-segment torsional oscillation is resisted. It cannot then take place without the concurrence of substantial increments of cable tension (such increments being of opposite sign in the two halves of the span), synchronous related torsional distortions of the towers, and synchronous related torsional deformations of the side spans.

The resisting force to be provided by the center stays can be calculated, and they should be proportioned accordingly.

Apparently no substantial two-segment aerodynamic torsional oscillations have developed in any span equipped with center stays as long as such stays and their connections have remained firm and intact.

Use of Longitudinal Diagonal Stays.—An economical method of providing concentrated, localized resistance to vertical or torsional oscillations is the use of longitudinal diagonal stays, inclined in either direction, in the planes of the cables (Fig. 8). Such stays may be located either above or below the roadway and may have their attachment to points of the cable or to points of the stiffening girder, or to both.

If such longitudinal diagonal stays run from the main tower ends of the span upward to the quarter points or other intermediate points of the cable, they are equivalent to stays running in the same direction under the roadway from shore or piers to corresponding points of the stiffening girders. The effect will be a direct resistance to upward displacement or upward swing of the points of attachment and an indirect and lesser resistance to downward displacement or downward swing of the same points of attachment, by virtue of any symmetrically disposed stays in opposing segments or in adjacent spans. Also there is a direct resistance to downward swing, by virtue of any initial tension in the stays, since a member under tension is elastically equivalent to a compression member (until it becomes slack).

If the longitudinal diagonal stays run downward from the tops of the towers to the quarter points or other intermediate points of the stiffening girders, their effect will be a direct resistance to downward deflection or downward swing of the points of attachment, and indirect and direct resistance to upward deflection or upward swing of the same points of attachment, for the same reasons as the foregoing.

In either case, the effect of the longitudinal diagonal stays will be equivalent to a substantial increase in the coefficient of rigidity K during one half of the cycle and to a smaller or equal increase in the value of K during the other half of the cycle. Inadequate values of K may thereby be brought up to safe values. The late John A. Roebling, M. Am. Soc. C. E., had this concept in mind when he designed the Niagara (New York), Cincinnati (Ohio), and Brooklyn (New York) bridges.

With the increase in the value of K, there is a sharp concomitant increase in the value of R, since the cable contribution to K remains unchanged. This increase in the value of R, which will be relatively very substantial when the initial value of R is small (as it is in flexible suspension bridges), will tend to increase structural damping and thereby will raise critical velocities and reduce the amplitudes attainable.

The relative merits of different types of longitudinal diagonal stays are not discussed herein.

For maximum effectiveness, the two types or directions of longitudinal diagonal stays may be combined, so as to provide maximum resistance to both directions of displacement or swing.

If the individual stays, in either a single or double system, are given sufficient initial tension to prevent reversal of their stress in the cycle for any anticipated amplitude of oscillation, then each stay will act with full effectiveness throughout the cycle.

The augmentation of K contributed by each individual stay can be calculated for any given mode of oscillation. A convenient simplified formula is

$$\Delta K \approx \frac{3+n}{5} \frac{E_s A_s}{l_s l} S \left(\frac{a_2 - a_1}{a_m} \right)^2 \sin^2 \psi \qquad (65)$$

in which a_1/a_m and a_2/a_m are the relative amplitudes at the two ends of the stay in terms of any unit amplitude at midsegment, ψ is the angle of the stay with the horizontal, and S is a multiplying factor (ranging from 1 to 2) depending upon the initial tension (and any initial sag) in the stay. The multiplier S has its minimum value of $S = 1$ if the initial tension is zero, and its maximum value of $S = 2$ if the initial tension is high enough to prevent reversal or if the amplitudes of any remaining oscillations of the stiffened structure are too small to cause reversal of the tension in the stay. (Any small initial sag in the stay will produce a slight reduction in S.)

Example 6: Increase in K by Longitudinal Diagonal Stays.—For the data and dimensions of the Tacoma main span, a single system of longitudinal diagonal stays near each end of the span, with a mean effective slope of 45° and made of wire rope strand with an aggregate cross section of $A_s = 16$ sq in. with sufficient initial tension to make $S = 2$, will produce, by Eq. 65, $\Sigma\Delta K = 270$ for $n = 2$. Thus the effective value of K will be increased from the original value of 62 to a mean augmented value of 332, and the corresponding value of R will be increased from 0.015 to 0.816. A double system of longitudinal diagonal stays, of the foregoing proportions running in both directions, will produce $\Sigma\Delta K = 540$ for $n = 2$, so that the effective value of K will be increased from 62 to 602, and the value of R will be increased from 0.015 to 0.900. This would bring K, $2\,K/b$, and R to relatively safe values.

Use of Transverse Diagonal Stays.—Another economical method of providing concentrated, localized resistance to torsional oscillations is the use of transverse diagonal stays (Fig. 9) located between opposite suspenders in the transverse planes near the quarter points and at other intermediate points of the span. The function of such stays is to prevent or resist out-of-phase displacement of the two sides of the span. Transverse horizontal struts between the cables may be used in conjunction with such transverse diagonal stays (see Fig. 9).

Stiffening the cross section of the suspended deck structure at the panel points, as has been suggested by some engineers, resists distortion of that cross section but does not prevent relative vertical displacement of the two sides of the undistorted cross section. In this respect a suspension bridge differs from other types. Resistance to distortion must be distinguished from resistance to torsion. Relative vertical displacement of the two sides of the section does not require distortion of the cross section but does require relative vertical displacement of the two cables, and this is resisted by transverse diagonal stays, with or without transverse struts between the cables.

Such transverse diagonal stays and horizontal struts do not help against vertical oscillations, since they do not affect the value of K against vertical oscillations; but they do help against torsional oscillations, since they directly augment the value of K_t.

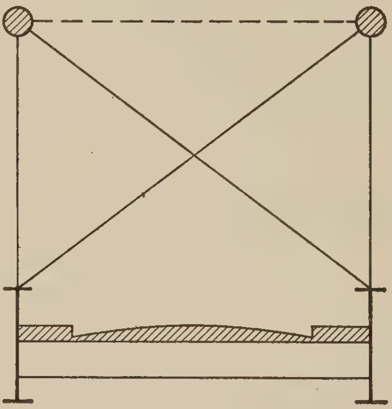

FIG. 9.—TRANSVERSE DIAGONAL STAYS TO RESIST TORSIONAL DEFORMATION

The action of transverse diagonal stays at any vertical section is effectively to resist or prevent distortion of the rectangle between cables, suspenders, and bridge floor (Fig. 9), so that torsional displacement (consisting of relative vertical displacement of the cables) then cannot take place without forcing a lateral displacement of the cables. This evokes a substantial additional force of restitution, which means a commensurate augmentation of K_t. For an adequate system of such transverse stays, with top struts included, a convenient simplified formula is

$$\Delta K_t \approx w \left[\left(\frac{4 + n^2}{5} \right) f + (4 + 2\,n^2)\,c + 5\,n^2 \frac{c^2}{f} \right] \ldots\ldots (66a)$$

in which c is the mean effective height of roadway below horizontal cable tangent. For proportioning the transverse diagonal stays, their maximum tension (per foot of span) producible by any assumed amplitude a_m is given by

$$S_t \approx 4 \frac{w}{b} \left(1 + \frac{n^2}{4} + \frac{c\,n^2}{f} \right) a_m \sec \psi \ldots\ldots\ldots\ldots (66b)$$

Without top struts, the values given by Eqs. 66 are halved.

(For the Tacoma span, Eq. 66*a* yields $\Delta K_t = 2{,}640{,}000$, corresponding to $\Delta K = 3{,}470$, and Eq. 66*b* indicates that a section of less than 1 sq in. per panel point will be adequate if no subsequent torsional amplitudes exceed 1 ft.)

Use of Damping Devices.—To supplement structural damping, artificial damping devices may be installed, for increased absorption of the energy of undulations or oscillations. Such friction damping devices have been used against the longitudinal oscillations of the span. For greater direct effectiveness, these friction damping devices can be used in connection with longitudinal diagonal cable stays or floor stays and also in connection with transverse diagonal stays.

Use of Open-Floor Construction.—The principal aerodynamic vertical pressure forces causing vertical or torsional instability originate in the horizontal floor sections near the inside faces of the stiffening girders. By opening these horizontal sections—either by leaving open spaces or by using open-grating construction—the aerodynamic forces causing amplification of undulations or oscillations can be eliminated or reduced to negligible proportions.

Experiments indicate that the required horizontal width of such open space adjacent to the inside face of each girder is not less than one half the depth of the girder.

By eliminating the solid sidewalk or roadway over this indicated width inside of each girder, differences of pressure above and below the section are largely equalized, and the area on which such differences of pressure would act is eliminated or materially reduced. Without considering the equalization of pressures, but considering only the elimination of the critical areas on which the largest pressure differences would otherwise act, a simple calculation based on the influence areas represented in Eqs. 60 shows that two lateral vents of width $3\,b/16$ to $b/4$ will reduce aerodynamic lift by at least 60% to 75% and aerodynamic torque by at least 75% to 87%; and, in addition, by Eqs. 60, the multiplier β due to phase difference across the net effective width of section will be reduced by 40% to 60%.

The entire roadway width may be made of open-decking construction, but it appears preferable to limit the open construction to the aforementioned lateral strips. The solid middle strip of roadway contributes to aerodynamic stability by atmospheric damping action. Its weight is also desirable to increase the rigidity of the span.

Use of Outside Sidewalks.—Subject to experimental verification, another indicated method of eliminating or reducing aerodynamic instability is the use of wide horizontal fins on the outside faces of the girders. Such horizontal fins conveniently may take the form of outside sidewalks or roadways on cantilever brackets or floor beams.

The purpose of such outside horizontal fins is to reverse the aerodynamic effect otherwise produced. Downward velocity of the windward girder combined with horizontal velocity of the wind then would contribute an upward pressure resultant, opposing and damping the oscillation, instead of a downward pressure resultant, amplifying the harmonic motion.

As with the use of open construction, the negative slopes of lift and torque graphs would be reduced, eliminated, or reversed.

Very conveniently, the use of open construction in the normal sidewalk spaces and the removal of the sidewalks to outside brackets may be combined in the modification of the cross section.

CONCLUSIONS

By increasing weight, depth, rigidity, and bracing, by adding center stays, longitudinal diagonal stays, transverse diagonal stays, or other stays, and by introducing artificial damping devices, resistance to the effects of aerodynamic instability may be built up to any desired amount. These methods resist or check the effects, but do not eliminate the cause.

By modification of the cross section, as by using open spaces in the floor or by adding horizontal fins or other wind-deflecting elements to the vertical faces of the girders, the cause of aerodynamic instability may be eliminated and an aerodynamically stable section may be secured.

The one line of attack places the emphasis on providing increased resistance to a dangerous inherent characteristic; the other line of thought is devoted to avoiding or eliminating the dangerous characteristic—aerodynamic instability of the cross section.

It is more scientific to eliminate the cause than to build up the structure to resist the effect.

In conclusion, the writer asks his readers to share with him his faith and conviction that suspension bridges of all span lengths can be designed economically to any desired degree of rigidity and with assured aerodynamic stability.

APPENDIX

NOTATION

The following letter symbols, adopted for use in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials,[6] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932; supplemented by customary symbols used in Aerodynamics and in the Theory of Vibrations:

A_c = section of cable (square inches);
A_s = section of diagonal stay (square inches);
a = vertical amplitude at any point of span (feet);
a_m = vertical amplitude at middle of segment (feet);
a_o = limiting local vertical amplitude producing zero ΔW;
a_{om} = limiting midsegment amplitude producing zero ΔW;
a_r = limiting midsegment amplitude reduced by structural damping;
a_1 = local amplitude at first point of attachment of a diagonal stay;
a_2 = local amplitude at second point of attachment of a diagonal stay;
b = width of section, center to center of cables (feet);
C_D = aerodynamic drag coefficient (nondimensional);
C_L = aerodynamic lift coefficient (nondimensional);
$(C_L)'$ = lift coefficient corrected for drag (nondimensional);
c = mean height of roadway below horizontal cable tangent (feet);

---

[6] ASA—Z10a—1932.

D = horizontal aerodynamic drag force on section (pounds per foot);
d = vertical depth of stiffening girders (feet);
E = modulus of elasticity of stiffening girders (pounds per square inch);
E_c = modulus of elasticity of cables;
E_s = modulus of elasticity of diagonal stays;
f = vertical sag of cable (feet);
f_1 = vertical sag of cable in side span;
g = gravity acceleration $\approx$ 32.2 ft per sec^2;
H = horizontal component of tension in one cable (pounds);
I = moment of inertia of section of one stiffening girder (inches^2-feet^2);
i = horizontal intercept of lift or torque graph (radians);
K = coefficient of rigidity of the span or structure (per cable) = spring constant for vertical oscillations (pounds per square foot);
K_t = spring constant of the span or structure for torsional oscillations (pounds);
K_0 = K for main span alone;
K_1 = K for side span alone;
L = vertical aerodynamic lift force on section (pounds per foot);
L' = aerodynamic lift force corrected for drag (pounds per foot);
l = length of span (feet);
l_c = length of cable (feet);
l_s = length of a diagonal stay (feet);
l_1 = length of side span (feet);
m = mass of the span per linear foot per cable = w/g;
N = natural frequency of vertical oscillations (cycles per second);
N_t = frequency of torsional oscillations (cycles per second);
n = number of segments in span l;
n_1 = number of segments in span l_1;
P = natural period of vertical oscillations (seconds) = $1/N$;
p = applied load per cable (pounds per foot);
q = coupling factor for coupled oscillations of main and side spans (nondimensional);
R = proportion of K due to stiffening girders (nondimensional);
r = polar radius of gyration of mass of the cross section (feet);
S = factor depending upon the initial tension in a stay (nondimensional);
S_t = stress in transverse diagonal stay for torsional amplitude a_m;
s = slope of lift graph = ΔC_L per radian;
s_t = slope of torque graph;
s' = slope of lift graph corrected for drag = $s + C_D$;
T = torque acting on any section of span (foot-pounds per foot);
t = time from beginning of a cycle (seconds);
u = variation factor of pressure impulse traversing the section (nondimensional);
V = horizontal velocity of wind (feet per second);
V_c = total critical wind velocity including structural damping (feet per second);

V_p = critical wind velocity due to phase difference (feet per second);
v = instantaneous vertical velocity of any point of span (feet per second);
W = energy of oscillations (foot-pounds);
w = dead load of span per cable (pounds per foot);
Δw = increment of load per cable (pounds per foot);
x = abscissa of any point of span, measured from one end (feet);
y = ordinate of any point of cable, measured from cable chord (feet);
α = angle of attack of wind, positive when upward (radians);
β = correction factor in aerodynamic amplification formulas, to correct for phase-difference effects on oscillating sections (nondimensional);
γ_1 = slope of cable chord in side spans;
δ = logarithmic increment per cycle = $\Delta a/a$ (nondimensional);
δ_s = logarithmic decrement per cycle, by structural damping (nondimensional);
δ_0 = value of δ at zero amplitude;
η = instantaneous vertical displacement of any point of span (feet);
η_w = theoretical vertical deflection of a simple beam by dead load w (feet);
θ = instantaneous angular displacement of any point of span (radians);
θ_a = angular amplitude at any point of span (radians);
θ_o = limiting local angular amplitude producing zero ΔW;
θ_{om} = limiting midsegment amplitude of torsional oscillations producing zero ΔW;
λ = negative damping coefficient = logarithmic increment per second;
ρ = air density, in units of mass per cubic foot ≈ 0.00238;
ϕ = phase angle = $2\,\pi\,N\,t$ or $2\,\pi\,N_t\,t$ (radians);
ϕ' = effective phase difference across the width of the section; and
ψ = angle of diagonal stay with horizontal.

DISCUSSION

EDWARD ADAMS RICHARDSON,[7] ESQ.—Although this discussion must be limited primarily to aerodynamical considerations, the calculation of vibrating systems deserves comment. For example, the work of H. Reissner,[8] on modes of vibration, should be cited. Mr. Reissner represents the period of oscillation of the cable alone (P_{cn} in seconds) by the equation

$$P_{cn} = \left(\frac{1}{n}\right) C\, 0.9968\, \sqrt{f} \ldots\ldots\ldots\ldots\ldots\ldots (67a)$$

in which (in addition to the notation of the paper), C is a coefficient, depending on the sag ratio $\left(\frac{f}{l}\right)$, not greatly different from 1.0. With $C = 1.0$, this equation can be derived from that given in the *Encyclopædia Britannica*[9] for taut strings; hence it applies to any flexible suspended cable, string, or chain of uniform weight. Theodor von Kármán, M. Am. Soc. C. E., and M. A. Biot[10] have shown that the period of vibration P_{gn} of a uniform beam, uniformly loaded, supported at the ends, may be represented by the equation

$$P_{gn} = \left(\frac{1}{n}\right)^2 \left(\frac{2}{\pi}\right) l^2 \sqrt{\frac{w/g}{E\,I}} \ldots\ldots\ldots\ldots\ldots\ldots (67b)$$

in which w should be the dead load applied to one girder when I is the moment of inertia of that girder, excluding the corresponding weight of the cable and suspenders.

The combined period P_{Bn} of cable and its corresponding girder (in seconds) may be found from the fundamental cable period P_{c1}, the fundamental girder or truss period P_{g1}, and the ratio $q = \frac{P_{c1}}{P_{g1}}$ through use of the equation

$$P_{Bn} = \frac{P_{c1}}{n + (n\,q)^2} \ldots\ldots\ldots\ldots\ldots\ldots (67c)$$

This simple method of combining cable and either the girder or truss periods, to obtain a combined period equal to that of the bridge for vertical oscillations, yields substantially the same results as Eqs. 1 and 6. It is sufficiently accurate for bridges of interest from the standpoint of aerodynamic instability, as Mr. Steinman suggests. Torsional periods may be derived from Eqs. 67 by multiplying by a coefficient[11] of the form $\frac{2\,r}{b}$ provided it is remembered that the weight of cables and suspenders forms part of the span cross section whose polar radius of gyration is to be used.

[11] "The Failure of the Tacoma Narrows Bridge," a report to the Hon. John M. Carmody, Administrator, Federal Works Agency (see brief résumé in December, 1943, *Proceedings*, p. 1564).

It should be emphasized that the author's K-limits for flexible bridges, constructed in a similar manner and of similar materials (such that the several cable and girder systems are substantially independent) should not be considered to apply to structures departing materially from such type similarity in any important respect.

Part 3.—Aerodynamic Excitation of Torsional Oscillations.—It is regrettable that this paper contains so few references to the theoretical and experimental work that has been done in the field of aerodynamics.

This paper, furthermore, unnecessarily emphasizes the rôle of lift and moment curves, for bridge cross sections, having negative trends over part of their range. Yet such curves are probably never significant in the behavior of actual bridges, and it can be shown by the work noted in the *Encyclopædia Britannica*[9] on wires made to vibrate by uniform wind streams, by the work of D. Thoma[12] on the lateral vibrations of circular cylinders in uniform streams of water when the spring factor and damping were varied, as well as by papers of other writers, that no such necessity exists. Furthermore, the tests,[11] on which this characteristic was found, were made on a model of low aspect ratio (short compared with the model width) and do not agree with those made at the Guggenheim Aerodynamic Laboratory at Pasadena, Calif., on models of effectively higher aspect ratios (which tests were given in the same report).[11]

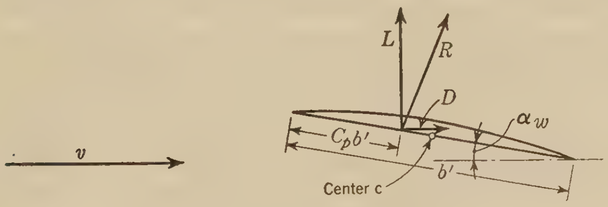

FIG. 10.—AIRFOIL CHARACTERISTICS

Referring to Fig. 10, an airfoil having a chord b' is set at an angle of attack α_w to the direction of the uniform wind stream which has a relative velocity v remote from the airfoil. The area of the airfoil projected on the plane of the chord and span is A_{ls}. The resultant force R crosses the chord at a distance $C_p\, b'$ from the leading edge. The vertical component of R is the lifting force L, and the horizontal component is the drag force D. As used in Fig. 10, q represents the pitot-tube pressure (impact pressure) of the air stream in pounds per square foot. Appropriate formulas for this case are: Impact pressure—

$$q = \tfrac{1}{2}\,\rho\, v^2 \quad \text{(68a)}$$

lift coefficient—

$$C_L = \frac{L}{q\, A_{ls}} \quad \text{(68b)}$$

---

[12] "Flatterschwingungen von Zylindern in gleichmässigen Flüssigkeitsstrom," by August Meier-Windhorst, *Mitteilungen des Hydraulischen Instituts der Technischen Hochschule*, Heft 9, München, 1939, p. 1.

drag coefficient—

$$C_D = \frac{D}{q\,A_{l_s}} \qquad \text{(68}c\text{)}$$

and, moment coefficient (any axis)—

$$C_M = \frac{M}{q\,A_{l_s}\,b'} \qquad \text{(68}d\text{)}$$

For bridge oscillations, the moment coefficient C_{Mc} about the center of the chord is desired, or, if found by the formulas—

$$r = C_L \cos \alpha_w + C_D \sin \alpha_w \qquad \text{(69}a\text{)}$$

and

$$C_{Mc} = r\,(0.50 - C_p) \qquad \text{(69}b\text{)}$$

—will approximate the desired value.

When the airfoil shown in Fig. 11 suddenly acquires a velocity v relative to the air at rest (or, when the air "at infinity" has the velocity v relative to the airfoil), a vortex is formed which travels away from the airfoil at a velocity less than v, swirling in the direction shown. Any change in relative velocity will cause the generation of a vortex of appropriate magnitude and sense. In Fig. 11, any sudden stoppage would set up a vortex equal in magnitude to that of the starting vortex, but of opposite rotation. As long as the airfoil maintains its velocity at a constant angle α_w, it will be found that the circulation remains constant around the airfoil.

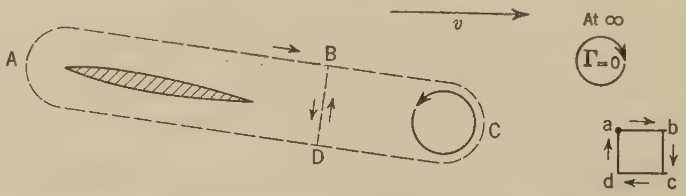

FIG. 11.—"STARTING" VORTEX

Circulation Γ_x may be assumed constant for an element of wing with a length dx along the span, in the plane, at x feet from some spanwise reference point, perpendicular to the span and parallel to the air stream. In vector notation,

$$\Gamma = \int \boldsymbol{v}\,d\boldsymbol{s} \qquad \text{(70)}$$

in which $\boldsymbol{v}$ is the vector point velocity on the path of integration, and $d\boldsymbol{s}$ is the vector element of the path of integration at the same point. Thus, circulation has the dimensions $\frac{\text{ft}^2}{\text{sec}}$.

Remote from the airfoil in a wind stream of uniform velocity v free from turbulence, from Fig. 10 and the square abcd the circulation may be seen to be zero. Since $\boldsymbol{v}$ is normal to $\overline{\text{da}}$ and $\overline{\text{bc}}$, the integral along these sides of the square is zero. Since $\boldsymbol{v}$ is the same for $\overline{\text{ab}}$ and $\overline{\text{cd}}$, whereas $\overline{\text{cd}} = -\,\overline{\text{ab}}$, the sum along these two sides is zero. Hence, for a uniform wind stream the circulation must be zero in any part of the wind stream where the path of circulation does not cut a vortex system.

Referring again to the starting vortex (Fig. 11), the path ABCD encloses the entire system of wing and starting vortices, and is remote from both, so the circulation along it is zero; but along the path BCD the circulation must correspond to the strength of the starting vortex. Hence, along the path ABD, the circulation must equal in magnitude that of the starting vortex, but be of opposite sense so that the sum may be the zero required for the path ABCD.

The theorem of Kutta-Joukowski requires that the lift of an airfoil element of span db'' shall have the value[13]

$$dL = \rho\, v\, \Gamma_x\, db'' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (71)$$

For a finite airfoil with free wing tips, the lift distribution spanwise may be represented by the ordinates of a semiellipse whose major axis is the span b'' and whose semiminor axis is Γ_0 at $x = 0$. The value of L takes the form of $\rho\, v$ times the integral of $\Gamma_x\, db''$ which in turn may be taken as $\Gamma_w\, b''$. Thus, any change in lift may be due either to a change in v, a change in $\Gamma_w \left(= \frac{\pi}{4}\, \Gamma_0 \right)$, or a combination of each.

Fig. 12 shows a rectangular wing with a chord b', and a span b'', in an air stream with a velocity v remote from the airfoil and directed normal to the span.

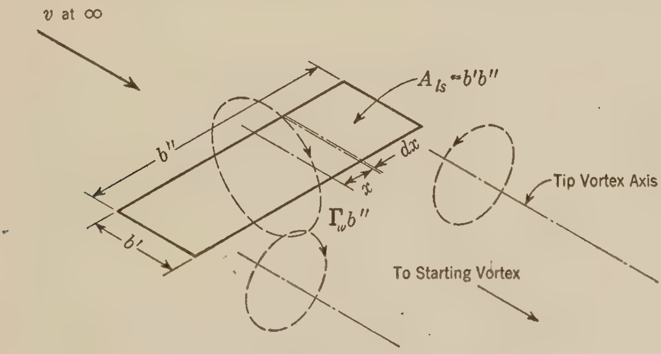

FIG. 12.—AIR FLOW FOR FINITE WING

The wind area A_{ls} equals $b'\, b''$. The total wing circulation producing lift is shown by the curve $\Gamma_w\, b''$, which is defined by:

$$\Gamma_w\, b'' = \frac{L}{\rho\, v} = 2 \int_0^{b''/2} \Gamma_x\, dx \ldots\ldots\ldots\ldots\ldots\ldots (72)$$

A tip vortex is being generated continuously. This is true only for the finite wing, since a wing of infinite span or one with shrouded tips would have no tip vortices. Work is required to generate these vortices. and a part D_i of the drag D furnishes the resistance required, or the induced drag. The remainder of the drag is the profile drag D_p, which is equal to $D - D_i$. The value of D_i may be found from the equation[13]

---

[13] "Applied Wing Theory," by Elliot G. Reid, McGraw-Hill Book Co., Inc., New York and London, 1932, Chapters III and IV.

$$D_i = \frac{L^2}{\pi q (b'')^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (73)$$

Eq. 73 is used in converting the data for a wing or wing model of one aspect ratio to those for some other aspect ratio. It would not apply very consistently to the models of the Tacoma Narrows Bridge due to the action of the longitudinal girders. The effect of the tip vortices is to produce a descending velocity component in the wake of the airfoil. For infinite span length, Eq. 73 becomes zero.

Assume a model (Fig. 13), for which the angle of attack is zero in a uniform wind stream of velocity v remote from the airfoil. Assume also that the entire drag D is now the profile drag D_p due to the friction of the air stream on the airfoil. Above the very lowest values of v, the trailing air stream contains vortex elements E and F whirling in one direction, alternating with others, as G and H, whirling in the opposite direction. The velocity u in the vortex system is less than v, relative to the airfoil. For a steady system of this type,[14] $\frac{h}{l} = 0.2803$. If l is known for the vortex period P_K, the drag, and the circulation of each vortex emitted, may be computed very closely. Knowing the circulation for the vortex E, for example (and it could be measured along a path BCD, Fig. 13), the circulation along the path ABD about the airfoil section must be of about the same magnitude as that for E but opposite in direction, since the circulation along ABCD is almost zero. The other vortex elements (F, G, and H) have slight influence. Hence the circulation about the airfoil section must vary with the same frequency as that for vortices E to F from $+\bar{E}$ to $-\bar{E}$. By the Kutta-Joukowski theorem, the lift L normal to the chord must vary correspondingly. Hence a periodic lateral force acts on any "lifting surface" (even a circular cylinder) when placed in a uniform air stream and this force acts without any reference to the airfoil characteristics of lift.

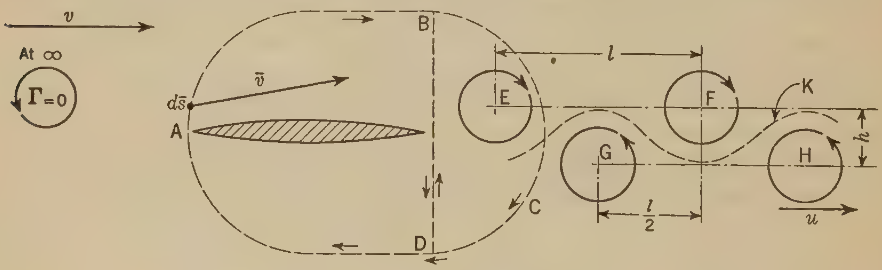

FIG. 13.—THE VON KÁRMÁN TRAIL

---

[14] "Applied Hydro- and Aeromechanics," based on lectures of L. Prandtl, by O. Tietjens, McGraw-Hill Book Co., Inc., New York, N. Y., 1934, p. 130 et seq.

It is convenient to use the parameter η introduced by Mr. Thoma to describe the behavior of airfoils, in which

$$\eta = \frac{b' P_K}{v} \text{.........................} (74)$$

Other writers[15] have used the parameter $\left(\frac{1}{k}\right)$ which is the same as $\frac{\eta}{\pi}$. In terms of this parameter, Mr. Thoma[12] found that $\eta = 5.0$ for a stationary circular cylinder. With low damping, oscillation of cylinders occurred at values as low as 4.73, initially, with maximum oscillations at values greater than 6.00; but amplitudes decreased rapidly, toward the end of the critical region, to about 6.8. The *Encyclopædia Britannica*[9] used 5.41 for the vibration of wires in a wind stream. In the case of bridge floors, it is probable that a value of 6.0 would be approximately correct. Tests on wing flutter,[16] and on the oscillation of bridge models,[11] all show the effect.

In other words when P_K, with $\eta = 6.0$, is the same as P_{Bn}, large oscillations may occur, and the corresponding optimum value of v may be found for the particular mode of oscillation. However, since the characteristic dimension, b', of an airfoil is measured parallel to the air flow (and therefore is correct only for wind directions normal to the span), the corresponding dimension for a wind making the angle γ with that normal is $b' \sec \gamma$. Thus the wind velocity must be increased in direct ratio to $\sec \gamma$ to keep the von Kármán trail period equal to that of the bridge. This is equivalent to retaining b' as the characteristic dimension, using with it only the normal velocity component of the wind, $v \cos \gamma$. As the energy of the wind increases with v, it is probable that the greater γ becomes, the more certain the wind will be in starting oscillations. For example, the tests of Louis G. Dunn[11] showed that the Tacoma Narrows Bridge would have negative aerodynamic damping, with torsion at $n = 2$ for values of v greater than 25 miles per hr. With $\eta = 6.00$, a value of v of 27 miles per hr would be needed. At failure, the wind velocity was 42 miles per hr, with $\gamma = 50°$, so that the normal component was 27 miles per hr. The agreement in this case is excellent. The von Kármán trail seems adequate to account for the motion of the bridge. It provides a method of approximating wind velocities at which failure, or serious vibrations, may occur, but no one can be sure that they will actually occur.

It is possible[14] to express the equation for profile drag in the form

$$D_p = 0.959 \left(\frac{l}{b'}\right) - \left(\frac{0.331}{\eta}\right)\left(\frac{l}{b'}\right)^2 - \left(\frac{0.628}{\eta^2}\right)\left(\frac{l}{b'}\right)^3 \text{......} (75)$$

which indicates that, at constant drag, l and η may take various values, with a tendency for the trail period to be unsteady. If, instead of a uniform approaching air stream, the air stream is turbulent, with a circulation changing irregularly in period and intensity, there are two factors tending to combine in producing the lifting surface circulation. It is quite possible that a massive structure (or one that is so stiff that the oscillation per cycle would be small compared with the range of disturbances in the circulation; or, one with large damping effect) would show no signs of oscillation at the critical velocity of air stream. Given a reasonably small starting oscillation, however, it would proceed to increase in amplitude with continued wind action because, when the surface does oscillate under the governing control of spring frequency, periodic "starting" vortices are superposed on the von Kármán trail tendency and the trail unsteadiness tends to disappear, favoring increasing oscillation amplitudes.[17]

[15] "General Theory of Aerodynamic Instability and the Mechanism of Flutter," by Theodore Theodorsen, *Report No. 496*, National Advisory Committee for Aeronautics, 1935.

[16] "A Study of Wing Flutter," by A. F. Zahm and R. M. Bear, *Report No. 285*, National Advisory Committee for Aeronautics, 1928.

If a bridge is so light or flexible that it tends to undergo forced oscillations of importance, even relatively small degrees of von Kármán trail or of turbulence in the air stream may suffice to set up important amplitudes of oscillation. This was true of the Tacoma Narrows Bridge which revealed many modes of oscillation when the wind velocity exceeded 5 miles per hr. Other bridges have shown trains of waves crossing the span, possibly set up by a short gust at some point of the bridge length (not a gust enveloping the entire structure), as in the case[11] of the Golden Gate Bridge in San Francisco, Calif.

In passing, it is to be noted that the action of wind on towers may be important because the towers generally have b'-values quite different from bridge floors.[18]

The low power input at very small amplitudes, and the rapid rise in power input as the amplitude increases, were demonstrated well by Mr. Dunn.[11] One example is given in Table 7. Since the kinetic energy varies as the square of the amplitude, the gain in energy is about 3.5 times as great in each second as in the preceding second. Many tests showed no certain starting from rest in a uniform wind stream, but did show this form of increase in amplitude when given small initial amplitudes.[17] The tests suggested strongly that turbulence has a marked effect. It should be remembered that in the case of the Tacoma Narrows Bridge there was very little damping in either the models or the prototype.

TABLE 7.—VARIATION OF POWER INPUT WITH AMPLITUDE

Time (sec) (1)	Amplitude (degrees) (2)	Col. 2 squared (3)	Gain in Col. 3 (4)
0	0.67	0.45	1.11
1	1.25	1.56	3.78
2	2.32	5.34	11.88
3	4.15	17.22	46.78
4	8.00	64.00	

Mr. Steinman has given equations for bridge damping that are not general, since material, type of construction (such as welding or riveting), and the introduction of damping devices may change structural behavior greatly. To reduce, or prevent, oscillations, high initial damping or friction is essential. Damping should be sufficiently high to limit oscillations if sudden impulses set up amplitudes which might otherwise lead to wider swings. For example, the dead load of the bridge floor and supports might be transferred to the trusses or girders through friction shoes resting on friction slides attached to these trusses or girders, so that a slight change in relative position, as on changes in deflection, would be opposed by the high starting friction of such sliding devices. Such an arrangement might be sufficient to prevent oscillations, escaping from the irregular turbulence range of forced oscillations, from growing, when the general air-stream speed is synchronized with some particular mode of oscillation.

---

[17] "Suspension Bridge Oscillations and Failure," by Edward Adams Richardson, a report to Advisory Board on Suspension Bridges, Bureau of Public Roads, Federal Works Agency, November 13, 1943 (revised).

[18] Reports to the Advisory Committee of the Bureau of Public Roads, Federal Works Agency, on Long Span Suspension Bridges, by Sterling Johnston, January 15 and May 25, 1943 (unpublished letters).

Oscillating airfoils have been studied extensively and, contrary to the author, so have the phase relations presented in the paper. It is unfortunate that Mr. Steinman's studies did not include the von Kármán trail effect, as that concept is essential to a workable theory of the starting of oscillations from rest by a wind stream. Tests under conditions appropriate to these studies and theories, in which the von Kármán effect was small, checked the theories quite well.[12,15,19,20,21]

It is essential that the theory of probability be considered in determining the possibility of oscillations being started by the wind stream. Resonance in general requires that, to produce its maximum effect, the oscillating force shall have a frequency varying, within narrow limits, from that of a given possible bridge frequency. The wind speed at such theoretical synchronism is calculable, as has been noted; but the trail frequency itself tends to be irregular, and for heavy and stiff bridges the force per cycle is capable of producing only a very small oscillation amplitude. Only at appreciable amplitudes will the governing effect of the bridge frequency, as an oscillating airfoil, produce trail frequency regularity. Hence, a light and flexible bridge, which can be given an appreciable amplitude with a short train of impulses that happen to be quite close to the frequency required, is much more likely to begin vibrating than a stiffer and heavier bridge for which the probability of a sufficiently long impulse train with proper frequency is small. The succeeding, out-of-frequency wave trains tend to dampen the slight motion started. If, in addition to the irregularities of the von Kármán trail, turbulence irregularities of the wind stream itself[22] are added (which there is no reason to expect will be of the proper frequency), the chance of producing oscillations greater than the irregular trail and turbulence effects is slight. Hence the Ammann criterion[23] separates the usual types of bridges and bridge construction into two classes (oscillating bridges and non-oscillating bridges) much more sharply than would appear reasonable. However, because a bridge has not oscillated or failed in a wind stream of critical velocity cannot be considered a guarantee that it may not fail, since turbulence varies considerably with conditions; and it may

[23] Report of March 15, 1943, by O. H. Ammann to the Subcommittee on Model Studies, Advisory Committee on the Investigation of Long Span Suspension Bridges, Bureau of Public Roads, Federal Public Works Agency.

be possible for vibrations to start with reduced turbulence It is of the utmost importance that von Kármán trails be studied further with respect to forces applied and steadiness. At the same time, turbulence at the bridge should be studied, for various wind velocities and directions at different times, so as to evaluate possible ranges and the relation of such phenomena to the magnitude of the von Kármán trail.[17]

In any case where oscillation can start, the limiting amplitude will be that at which the work done by the given wind on the bridge is just dissipated in damping. Of two winds with the same normal component, the one having the higher velocity will produce the larger oscillations, since the forces are larger. The tangential component has been neglected herein, but it cannot be ignored.

In general, vertical oscillations in phase with the wind will not be free from small torsional oscillations of the forced vibration kind, and vice versa.

Part 4.—Methods of Securing Rigidity and Aerodynamic Stability.—The fact that rigidity, of the kind discussed by Mr. Ammann,[23] is desirable needs no discussion. The statement by the author that R, the proportion of rigidity contributed by the stiffening structure, should be large, because of the accompanying increase in structural damping, is true enough and was well demonstrated[17] by the behavior of the Lions' Gate Bridge at Vancouver, B. C., Canada (R being about 0.32).

Although the Ammann type of rigidity is desirable, it is not essential, since the limits set assume substantially independent vibration by the two cables normally used. The transverse diagonal stays recommended by the author are intended primarily to prevent torsional oscillations and thereby the possibility of torsional failure. The action is perhaps somewhat different from that described by Mr. Steinman. If displacement of one cable relative to the other begins, anything that reduces the load on the descending cable and transfers it to the other cable will tend to keep the cables in phase. This effect of the interchange of load on stability was observed by A. F. Zahm and R. M. Bear.[16] Since a diagonal consisting of one half the suspenders will be fully loaded with a deflection of the order of 1/10,000th of the possible amplitude of oscillation, the stiffening effect of such diagonals is extremely great. Oscillations are prevented before they can start, and normal torsional moments are handled easily. No increase in suspender size is needed when half the suspenders are in the diagonals, for the action is similar to that of the lacing bars of a lattice column. Furthermore, since vertical oscillations cannot be totally independent of torsional ones (small and forced), such diagonals will reduce but not prevent vertical oscillations—that is, unless the amount of reduction limits the possible oscillations to the order of those forced by the irregular turbulence.

Obviously, the longitudinal diagonal stays of the intermediate type act somewhat similarly to the transverse diagonals, since two floor points are connected to one cable point. If one floor point tends to move downward, its load is transferred to a cable point farther along the span and tends to cause that point to follow suit. Hence, such a system of stays may very well act to prevent vertical oscillations. The two systems together should make a very flexible bridge act as though it were much more rigid. The additional weight involved is relatively small.

Clearance considerations might limit the use of diagonal stays to the end portions of the bridge. In that case[17] diagonal stays in the center section, from a cable across the adjacent walkway to the edge of the floor, could be added for measurable control. The center walkway is thus forced outside of the girders; but since bridge oscillations depend on the floor width, b', the use of one width in the center and another at the ends would in itself operate to limit oscillations. The two sections (having different von Kármán trail periods) would not be in synchronism at the same time.

The author's description of the outer floor construction and of open roadways is not clear. For instance, the statement (side heading, Part 4, "Use of Open-Floor Construction"), "The solid middle strip of roadway contributes to aerodynamic stability by atmospheric damping action" ignores the fact that no such effect occurs when most needed; that is, when the bridge and trail periods are in synchronism.

As noted, center stays are of value as long as they last; but localized control leads to large forces, whereas distributed control, as by the use of the two types of diagonal stays, permits no such forces to develop as may destroy the center-stay system.

Although differing materially from the author on many important points, the writer tends to agree with him in his final conclusion and might add that even much more slender bridges than Tacoma Narrows could be made to behave as if they were much stiffer, at the same time being both comfortable and safe.

R. K. BERNHARD,[24] M. AM. SOC. C. E.—In the author's unusually interesting paper the derivation of simple working formulas for the practicing engineer to predetermine the aerodynamic stability of suspension bridges represents, as far as the writer is aware, the first direct attempt to solve this difficult problem. The author has treated the entire range of this subject in a most comprehensive way. His primary aim—formulating positive rules to prevent failures due to aerodynamic instability or, as he expresses it, the prevention of this disease rather than its cure—seems of utmost importance.

In connection with the vibration of bridges, the logarithmic decrement for structural damping is of particular interest. The author presents a wide range of damping values for suspension bridges of the order of magnitude from 0.002 to 0.130. These damping decrements may be compared with damping values as cited in other publications.

In the Society's report on the Tacoma Narrows Bridge failure values from 0.0055 to 0.057 are published resulting from tests[25] by F. B. Farquharson, Assoc. M. Am. Soc. C. E., on a suspension bridge model.

Experiments, started as early as 1928 by the writer on actual bridges with the method of induced vibrations, yielded values for structural damping from 0.063 to 0.112.[26,27] The lower values refer to welded beams, the higher values to riveted trusses, and the values in between to riveted through girders. It seems obvious that higher stresses in the connections of riveted trusses cause some relative motion and hence energy losses, thus resulting in larger damping. For similar reasons an increase in damping with rising amplitudes could be experienced coinciding approximately with Eq. 35 which contains a factor $\sqrt{a_m}$ (a_m = amplitude). Furthermore a certain change of the damping capacity with respect to the number of vibrations induced in the structure or structural unit could be observed. During a series of long-time vibration tests at first a decrease and, at impending failure, an increase, in structural damping was noticeable. The same method of induced vibrations yielded somewhat similar results for the internal damping capacity in small mild steel specimens.[28]

In general, damping values determined by experiments on actual bridges of any type may indicate higher figures, not only when compared with metals but also with bridge models. The previously mentioned damping effect of structural connections, the damping of the foundations, and, finally, the damping of the surrounding soil, etc., will be noticeable, all these effects being rather difficult to imitate in model tests. Referring to the influence of soil characteristics, average damping values as high as 1.25 have been observed in actual field tests.[29]

In the Society's report of the Tacoma Narrows Bridge failure[25] (Appendix IV) an "accepted value of 0.3 for beam type bridges" is cited. According to this figure the logarithmic damping decrement for beam-type bridges is approximately 2.3 to 150 times higher than that for suspension bridges mentioned by the author. The value of 0.30 approaches rather closely the value of 0.31 as published in 1937.[29] It should be kept in mind that this high value, however, represented an average value for all types of structural units such as engine parts, ceilings, walls, towers, ship decks, masts, airplanes, and airship parts.

The author rightly emphasizes the fact that accurate information on the structural damping of suspension bridges is lacking. Furthermore a reduction of the wide range of damping values as published by the various investigators might be valuable. Both seem to indicate that experiments on actual suspension bridges are desirable.

In his conclusions the author states that a modification of the bridge cross section, by introducing open spaces in the floor, can be used to eliminate aerodynamic instability at the source.

This fact has also been observed by the writer on a simple model used for classroom demonstration at Pennsylvania State College, at State College, in 1940 and 1941. The model consisted essentially of a small wooden frame of approximately 10 in. by 10 in. suspended by four weak vertical springs, one in each corner. The conditions for a vibrating system with six degrees of freedom were fulfilled; in other words, oscillations of the sides or of the corners of the frame either in phase or in antiphase were possible. Since the wooden frame did not deform during the vibration, only the almost negligible internal damping of the four springs remained active. The front and rear bar of the wooden frame could be replaced by rods of aerodynamically stable or unstable cross section. A removable piece of cardboard, stretched horizontally between the front and rear bar of the frame, imitated, at least to a certain extent, the deck of one bridge panel. Thus an atmospheric damping factor, as mentioned by the author, was introduced. A constant horizontal wind stream, produced by an ordinary fan, was directed against the model. Different types of linear as well as torsional self-sustained vibrations could be built up. These experiments can be considered as elementary pilot tests only.

[29] "Dynamic Tests by Means of Induced Vibrations," by R. K. Bernhard, *Proceedings*, A.S.T.M., Pt. II, 1937, pp. 634–645.

A rectangular section of the front and rear bar of approximately 2 in. by 1 in., the larger side facing the wind stream, simulated unstable conditions for the individual girder. Whenever the cardboard deck remained in place the amplitudes increased up to a definite dynamically stable equilibrium. Removing this cardboard completely resulted in increased amplitudes, probably caused, in part, by the substantial reduction in atmospheric damping.

Another set of bars with half-moon cross sections of approximately 1-in. radius, the flat sides facing the inside of the frame, simulated dynamically stable conditions for the girder nearest the fan. No substantial reduction of the maximum amplitudes (that is, shielding effect) could be observed since the rear girder remained unstable.

Finally a change in cross section of the complete bridge panel, for example by cutting longitudinal holes in the cardboard deck, corresponding approximately to the width of the sidewalks, reduced rather effectively the excitation of any type of self-sustained vibration regardless of the cross section that was substituted for the individual girders.

J. M. ROBERTSON,[30] JUN. AM. SOC. C. E.—Until the phenomenon of the aerodynamic action of suspension bridges is understood in its fundamental aspects, attempts to prevent the destructive vibrations of such structures are just as apt to make the situation worse as better. This paper represents a considerable advance toward the ultimate solution. Structural engineers must now be familiar with aerodynamics and vibrations—subjects they did not need in the past.

Referring to Eq. 29a, the logarithmic decrement δ is only approximately equal to $\frac{1}{2}\frac{\Delta W}{W}$. On the basis of the usual assumptions as to the nature of W, the correct relation between the two expressions is:

$$\frac{\Delta W}{W} = 2\,\delta\,(1 + \delta + \tfrac{2}{3}\,\delta^2 + \cdots) \qquad (76)$$

Only for small values of δ is the relation used by the author accurate.

In the sentence following Eq. 34 the author states that "Accurate information on the structural damping of suspension bridges is lacking." This observation does not necessarily apply only to suspension bridges, as few data seem to be available on the damping of any except the very simplest of structures. Some data are available on the damping contributed by the material of which the structure is composed. An attempt will be made to summarize some of these data in this discussion.

---

[30] Asst. Prof., Dept. of Eng. Mechanics, Pennsylvania State College, State College, Pa.

Structural damping consists of at least two parts: The damping of the material in the structure created by the varying stress in the material; and the damping resulting from the comparative looseness of the joints in the structure. Little is known even as to the relative amount of damping attributable to each of these sources. In some vibrating machine structures, estimates of the damping effect of the material have indicated that in one case it was about 33% and in another 75%. Obviously, if the damping necessary to help keep the stress amplitudes in the structure within safe limits does not come from one source or the other the structure may fail at once or through fatigue. Few data are available on the damping effect of even the simplest of structural joints. O. Föppl[31] presents some test results in which the damping in a simple riveted joint was found to be about twice that in a solid member of similar strength. A welded structure, therefore, would have less damping effect than a riveted structure, at the same vibration amplitude.

The damping capacity of materials has been a subject of investigation since the days of Lord Kelvin. Hundreds of papers have been written on it, or on internal friction, or on "mechanical hysteresis," as it is sometimes called. Nevertheless, much information is still lacking on the damping capacity of engineering materials in the range of stresses of structural significance. Damping capacity is generally assumed independent of the frequency of vibration and has been shown to be a function of the stress or strain amplitude. As noted by the author, J. P. Den Hartog states[32] that the energy loss per cycle due to the damping in the material varies as $(a_m)^{2.3}$ "based on some experiments on soft steel in the dim past." Other writers have been more definite in indicating their supposed source for this relation. W. A. Tuplin,[33] for instance, attributes it to F. E. Rowett.[34] However, in his paper, Mr. Rowett noted that the loss per cycle varied as the third power of the stress amplitude and his data do not seem to indicate the 2.3-power law. The research of S. F. Dorey[35] among others has also verified this third-power variation for various steels. At Pennsylvania State College, in State College, the writer and A. J. Yorgiadis have also verified the third-power variation of damping capacity with stress amplitude for a considerable number of metals and plastics (not published).

Data on the variation of the damping capacity of steels ΔW_{sm}, energy loss per unit volume per cycle, with stress amplitude S_m, are shown in Fig. 14. Mr. Rowett's data were obtained on tubular specimens in torsion through static tests of great sensitivity and dynamic tests (by the decaying vibrations method) on a hard drawn (curve 2, Fig. 14) and an annealed mild (curve 1, Fig. 14) steel. Mr. Dorey's data (curves 3, Fig. 14) were obtained on solid cylindrical specimens in torsion by a static test similar to that by Mr. Rowett.

[35] "Elastic Hysteresis in Crank-Shaft Steels," by S. F. Dorey, *Proceedings*, Inst. Mech. Engrs., Vol. 123, 1932, pp 479–535.

Mr. Dorey studied steels of various compositions as may be noted from the key in Fig. 14. The data observed by the writer and Mr. Yorgiadis on a mild steel, obtained by the method of resonant vibrations using apparatus developed by B. J. Lazan,[36] are also shown. The same material, a normalized mild steel tubing, was tested in torsion (curve 4, Fig. 14) and in direct, tension-compression vibrations (curve 5, Fig. 14). For all the data shown there is no evidence of a frequency effect at least in the range of frequencies covered. Up to a certain stress amplitude (curves 3, Fig. 14) the variation of ΔW_{sm} with S^3_m is apparent.

The damping that occurs in solid specimens vibrating in torsion is much less than that in tubular specimens of the same material for the same maximum stress amplitude, due to the variation of the stress in the solid specimen. As shown by F. M. Lewis in his discussion of the Dorey paper,[35] and by W. Ker Wilson,[37] it is possible to relate the damping in solid and in tubular members under torsion if the energy loss is proportional to some definite power of the stress amplitude. For the third-power law, this indicates that the damping in the solid member should be two fifths that in a tubular member for the same stress amplitude in the outer fibers. If curve 3A, Fig. 14 (for a mild steel), is raised by the inverse of this ratio, there is a rough agreement with the other data given in Fig. 14 for mild steel tubular specimens in torsion. The type of stress as well as its magnitude has considerable effect on the damping capacity as may be seen from the data obtained by the writer and Mr. Yorgiadis on a mild steel (Society of Automotive Engineers (SAE) Specification 1025) under shear stresses and direct, tension-compression stresses. The damping under

[36] "Some Mechanical Properties of Plastics and Metals Under Sustained Vibrations," by B. J. Lazan, *Transactions*, A. S. M. E., Vol. 65, 1943, pp. 87–104.

[37] "Practical Solution of Torsional Vibration Problems," by W. Ker Wilson, John Wiley & Sons, Inc., New York, N. Y., 2d Ed., 1941, Vol. 2, p. 64.

shear stressing (torsional vibrations) is about seven times that under direct stress. In addition to the variation in damping capacity with the foregoing factors, Fig. 14 indicates the influence of the nature and condition of the material. For the mild steel tested by Mr. Rowett, annealing seems to have increased the damping (at the same stress amplitude) by a factor of about ten. Curves 3, Fig. 14, indicate a variation as great as ten times in the damping with the different compositions of steel. Apparently the higher the strength of the steel, the lower will be its damping capacity.

The damping capacity of steel is also a function of the previous stress history of the material. Continued cyclic stressing may cause an increase or decrease in the damping, depending upon the magnitude of the stress amplitude. This "cold working," as it is sometimes called, has been noted by Messrs. Dorey, Föppl, Lazan, and others, but there is little complete information on it. The most comprehensive study of this phenomenon for any material appears to have been made by A. U. Kutsay and Mr. Yorgiadis,[38] who noted a decrease as great as ten times in the damping capacity of a magnesium alloy as the result of cyclic "cold working." It is rather doubtful that one can expect steel to be affected quite this much, but it is well known to be affected.

Since considerable damping capacity is necessary to prevent excessive vibration amplitudes on a bridge subjected to vibratory forces, from the data given herein a low-strength steel with a high damping capacity may be superior to a high-strength steel with a low damping capacity. In Europe a considerable number of railroad bridge failures was attributed to the substitution of a high-strength nickel alloy steel of low damping capacity for an ordinary mild steel of higher damping capacity.

C. H. Gronquist,[39] Assoc. M. Am. Soc. C. E.—The coefficient of rigidity K in Table 2 is a measure of the resistance of the main span to sine-curve deflection under antisymmetrical sine-curve loading ($n = 2$) that is positive in one half span and negative in the other half span; the quarter-point deflection in either half span under such loading is p/K. It is of interest to compare this deflection with that for antisymmetrical uniform loading ($n = 2$) for which the resulting deflection may be obtained readily by use of a principle demonstrated elsewhere by the writer.[40]

That principle may be stated as follows: The deflection at the midpoint of a uniformly loaded simple beam, or at the midpoint of any uniformly loaded beam segment of constant moment of inertia between points of contraflexure with zero deflection, is equal to the bending moment at the midpoint divided by the buckling load of the beam, for elastic-curve deflection, as a strut of that length. For the loading considered, since the center of the main suspension span is a point of contraflexure with zero deflection and, moreover, since the value of the live load H is zero, each half span may be regarded as a simple beam under the applied uniform load p. The initial, elastic theory bending moment at the quarter point, consequently, is $\frac{p\,l^2}{32}$. The final buckling load for the suspension bridge is equal to the initial buckling load of the girder increased by the amount of the horizontal component of cable stress, in contrast to the buckling load for the arch, which is decreased by the amount of the thrust. The final value of the quarter-point deflection of the suspension span for this antisymmetrical loading (including the effect of deflection) is then:

[38] "On the Torsional Damping Capacity of Solid Magnesium-Alloy Rods as Affected by Cold-Working," by A. U. Kutsay and A. J. Yorgiadis, *Journal of the Aeronautical Sciences*, Vol. 10, 1943, pp. 303–310.

[39] Associate Engr., Robinson & Steinman, New York, N. Y.

[40] Discussion by C. H. Gronquist of "Rainbow Arch Bridge over Niagara Gorge: A Symposium." *Transactions*, Am. Soc. C. E., Vol. 110 (1945), p. 150.

$$\eta = \frac{M_e}{P_f} = \frac{\frac{p\,l^2}{32}}{4 \times 9.6\,\frac{E\,I}{l^2} + H_w} = \frac{p}{\frac{32}{l^2}\left(H_w + 4 \times 9.6\,\frac{E\,I}{l^2}\right)} = \frac{p}{K_u} \quad \ldots (77)$$

in which the amount of the horizontal component of cable stress remains unchanged, since the live load H remains zero, even considering the effect of deflection.

The stiffness constant for uniform antisymmetrical loading is practically the same as that of the author for sine-curve loading, except that the multiplier is 32 for the former as compared with $4\,\pi^2$ for the latter. This is in conformance with the greater deflection produced by the increase in load for the uniform load condition. A stiffness constant such as the one of Eq. 77, which is a measure of the resistance of the suspension bridge to deflection under antisymmetrical uniform load, was developed by the writer and later proposed for comparing the stiffness of suspension bridges in connection with a discussion on the stiffness of the self-anchored suspension bridge.[41]

The properties of the stiffness constant or final buckling load of the suspension bridge, with a two-hinged stiffening girder, for antisymmetrical loading, yield extremely simple data for computing the ratio of the final bending moment or deflection by the "deflection theory" to the moment or deflection by the usual elastic theory. The final moment is equal to the initial moment decreased by $(H_w + H)\,\eta$, thus:

$$M_f = M_e - H_w\,\eta = M_e\left(1 - \frac{H_w}{P_f}\right) = \frac{P_e}{P_f} \times M_e = R \times M_e \quad \ldots (78)$$

in which P_e is the initial buckling load of the girder, as by the elastic theory, unassisted by the cable pull. Such correction of the initial moment or deflection, by considering the effect of deflection, is analogous to that for a strut subjected to a lateral load or to initial deflection in addition to the direct loading. Formulas similar to Eq. 78 have been derived for the compression member,[42, 43] and are closely applicable to the case of the suspension bridge, when it is considered that the direct load is tensile.

The girder rigidity ratio R in Table 2, or $\frac{P_e}{P_f}$, therefore, is a close approximation of the ratio of the final moments and deflections in the stiffening girder to moments and deflections for antisymmetrical loading computed by the elastic theory. The ratio may be taken as practically constant over the length of the span, and it will change little for different loadings producing maximum live-load moments at various points along the span. The higher value of the ratio for the maximum center moment is accounted for by a reduction in the distance between points of contraflexure. A practically perfect check is obtained between the values of R in Table 2 and the Baker constant[44] for the ratio of the deflection theory to the elastic theory for moments. By including the value of the live load H for any particular loading in computing the final buckling load P_f, a closer approximation of the moment or deflection ratio will result.

---

[41] "Simplified Theory of the Self-Anchored Suspension Bridge," by C. H. Gronquist, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 989.

[42] "Buckling of Elastic Structures," by H. M. Westergaard, *ibid.*, Vol. LXXXV (1922), p. 576.

[43] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., 1936.

Deflection at the quarter points of the main span of a two-hinged girder suspension bridge produced by antisymmetrical concentrations at the quarter points is equal to 0.8 of the elastic theory moment under the load divided by the final buckling load, as for a simple beam with a central concentration. The final moment is:

$$M_f = M_e - H_w \eta = M_e \left(1 - \frac{0.8\,H_w}{P_f}\right) = \left(\frac{P_e + 0.2\,H_w}{P_f}\right) \times M_e \ldots (79)$$

indicating that the deflection effect for concentrated loads is less than that for distributed loading. The ratio derived in Eq. 79 for antisymmetrical concentrations may be applied approximately to any concentrated loading.

The foregoing formulas for deflections, stiffness constants, and deflection theory corrections, as derived for antisymmetrical main span loading, are applicable to the side spans of the suspension bridge, for which antisymmetrical full span loading ($n_1 = \pm 1$) is critical, when l_1 is substituted for $l/2$ in the formulas.

F. B. FARQUHARSON,[45] M. AM. SOC. C. E.—An extremely able mathematical treatment of the problem of aerodynamic stability of suspension bridges is contained in this paper. It appears, however, that some of the data available to the author relating to the behavior of the original bridge were in error and that the author was not informed on some of the uniform conclusions from laboratory tests conducted since the failure of the Tacoma Narrows Bridge. It is unfortunate that the pressure of wartime has made it impossible to release the results of certain very extensive investigations which, although not complete, clarify some important phases of the problem. The following discussion refers to corresponding parts of the paper.

Parts 2 and 3.—One of the most important errors in the information available to the public regarding the behavior of the Tacoma Narrows Bridge lies in the published log of observed modes of motion and associated wind velocities.[3] A most serious error arose in the velocities obtained with an anemometer for which no calibration curve existed. Subsequent calibration of this instrument revealed errors of about 50% in the lower velocity range.

---

[44] "Suspension Bridge Analysis by the Exact Method Simplified by Knowledge of Its Relations to the Approximate Method" by Arvid H. Baker, *Engineering and Science Series No. 24*, Rensselaer Polytechnic Inst., Troy, N Y., 1928.

[45] Prof., Civ. Eng., Univ. of Washington, Seattle, Wash.

No uniform procedure was followed in obtaining these readings of velocity. Many of them were taken on the top of the toll house, which was 1,400 ft distant from the nearest tower and where the influence of the terrain was such, in southerly winds, as to alter, completely, the velocity as well as the direction of the wind. Many other readings were taken just beyond the first tower on the main span and again offered no reliable indication regarding the average wind on the bridge as a whole. Furthermore, none of the direction readings was obtained with any accuracy. Each reading was a pure estimate, and no close correlation was maintained between observations of velocity and direction and readings of amplitude. In short, these recordings should be treated as only very sketchy records of the behavior of the wind whose true characteristics must remain forever in doubt.

The net result of the aforementioned discrepancies is that all of the velocity and direction readings in the log are subject to a correction. In general, the velocity error revealed by the anemometer calibration tapers from approximately 50% in the lower range to zero at about 30 miles per hr. It is impossible to estimate the magnitude of the errors due to location of the reading instrument, but it can be stated confidently that many of the readings were very low for that reason.

During the months following the failure of the Tacoma Bridge extensive research was undertaken in the Structural Research Laboratory at the University of Washington in Seattle under the joint sponsorship of the Washington Toll Bridge Authority and the Public Roads Administration. This program involved the building of a wind-tunnel laboratory capable of testing a 1 : 50 scale model of a suspension bridge of the proportions of the one lost at Tacoma Narrows. To date (June, 1944) two complete models have been built, the first a duplicate of the original bridge and the second in connection with the proposed new design. In conjunction with these full model studies, three section models have been constructed as a part of the investigation of the proposed new design for a bridge at Tacoma Narrows.

Paralleling this work at the University of Washington, a program was sponsored by the Washington Toll Bridge Authority at the California Institute of Technology under the direction of Theodor von Kármán, M. Am. Soc. C. E., using section models.

The difference between section and full models should be clarified. The full model is a complete duplication of the prototype, in every significant detail, and includes towers, cables, suspenders, and suspended structures constructed to appropriate model scale. The section model is composed of part of the suspended structure mounted on springs in such a manner that the various degrees of freedom existing on the prototype can be duplicated.

Several significant conditions have been revealed by the tests embraced in the two programs, and, although full correlation between section and full model has not yet been evaluated, on certain basic facts there is full agreement. With respect to the original Tacoma Narrows Bridge the most pertinent of these facts may be outlined as follows:

(*a*) A linear relationship exists between wind velocity V_c, corresponding to the velocity at which motion starts in a given mode, and the frequency of the several vertical modes.

(*b*) Each vertical mode appears twice but at the same frequency. The $V_c/(N\ b)$-value for the second appearance is twice that of the first. From this it follows that for a given configuration the critical velocity for the second appearance of any mode is twice that associated with the first appearance.

(*c*) For any given shape of the suspended structure and angle of attack of the wind, the value of $V_c/(N\ b)$ is constant for all vertical modes in their first appearance and constant at twice that value for all vertical modes in their second appearance.

(*d*) The first appearance of each vertical mode is very weak and difficult to isolate on the full model. These first appearances are readily observed on the section model.

(*e*) Each configuration and angle of attack of the wind has its own constant value of $V_c/(N\ b)$.

(*f*) The torsional modes also appear twice and at the same frequency. The first appearance is weak and damps out with increasing velocity, but the second appearance which occurs almost immediately following the damping of the first becomes catastrophic with increasing wind velocity. In general, the critical velocity for the first appearance of a torsional mode is half that of the second appearance. Some of the tests involving alterations in configuration suggest that this relationship may not always hold.

Oscillation Coefficients.—In aeronautical literature associated with the wind flutter problem the dimensionless ratio $V/(N\ b)$ is sometimes called the "reduced velocity." This ratio is also referred to as a "reduced wave length," the wave occurring in the wake. Some investigators have found it convenient to refer to the reciprocal of this ratio as a "reduced frequency."

Since the ratio is dimensionless and may be viewed as the ratio of two velocities, two distances, or two times, depending on the point of view of the individual or the requirements of the problem, it seems poor practice to limit the meaning of the label by making it too specific. It is proposed that in the developing field of suspension bridge aerodynamics the $V/(N\ b)$-ratio be called the "oscillation coefficient." A parallel practice has already been adopted by Theodore Theodorsen when he refers to the critical "flutter coefficient."[46]

A part of the information in Items (*a*) to (*f*) is in Fig. 15 which is obtained from the results of tests under several radically different conditions. In view of this evidence, Table 3 should not be accepted as valid since it involves a variation of $V_c/(N\ b)$ over a range of 2.00 to 0.25. Laboratory results indicate that this value is constant in the vicinity of 2.20 for the second appearance of the vertical modes and in the vicinity of 1.09 for the first appearance.

The linearity of critical velocity with frequency is completely confirmed by section model tests at the California Institute of Technology (unpublished report), which of course confirm as well the constant value of $V_c/(N\ b)$ for a given configuration.

---

[46] "The Mechanism of Flutter, a Theoretical and Experimental Investigation of the Flutter Problem," by Theodore Theodorsen and I. E. Garrick, *Report No. 685*, National Advisory Committee for Aeronautics, 1940.

In Example 5, the author's check for high velocity is good, but the minimum velocity check is in error by a factor of at least five. The writer has not found the time for a critical examination into the possibility of making this mathematical approach fit the known facts more exactly. It is to be hoped that the author may be able to do so.

If the tests reported in Figs. 15 and 16 had been extended to higher wind velocities and if means had been provided to prevent the development of the torsional mode, successive higher vertical modes would have developed. (In Fig. 16, N = frequency in cycles per second.) Following this procedure, motions involving eleven nodes have been noted with no indication that higher modes were not possible. The highest mode involved frequencies in excess of 360 cycles per min (since all field frequencies must be multiplied by the square root of the scale factor this would correspond to approximately 51 cycles per min in the field). These high frequencies were especially severe on the model. Therefore, they were never maintained for any long period of time and thus were never open to careful analysis.

The writer feels that there is no evidence to substantiate statement (*a*) (see heading in Part 2: "Conclusions Relative to Vertical Aerodynamic Oscillations"). There is every indication that vertical modes could have developed well above the eight-noded mode observed in the field at 42 miles per hr. If N is assumed at 0.85 cycles per sec for eleven nodes on the prototype and a value of $V_c/(N\,b) = 2.20$ is assumed from Fig. 15, then $V_c = 2.2 \times 0.85 \times 40 = 75$ ft per sec or 51 miles per hr.

In view of the accumulated evidence, the writer cannot agree with statement (*b*) either, since the evidence from both section and full model tests indicates that torsional tendencies are present on this structure from the time the velocity reaches about 6 miles per hr.

It should also be emphasized that torsional motions can develop on a section having a positive slope on the torque graph. Fig. 17 shows torque graphs for a large model of the original bridge which was tested at both the California Institute of Technology and the University of Washington. These curves show that a full circular fairing applied to the leading and trailing girders reversed the slope of the torque graph in both tests; yet when the full model was tested in this form the amplitude response curves were similar to those of Fig. 16. Recent section model tests at the University of Washington on sections involving trusses have shown a decided torsional motion under certain small angles of attack although the torque graph showed a definite positive slope.

The chief differences between the faired and the unfaired sections seem to be that on the faired section the $V_c/(N\,b)$-value for the vertical modes is considerably lower, and the maximum amplitudes developed in the various modes somewhat lower, than on the unfaired bridge. The degree of torsional instability was somewhat altered, and there is reason to believe that the second appearance of torsion may have damped out again after reaching an angle of about 10° and a wind velocity of approximately 20 miles per hr. These tests were run just before the model was dismantled. They were rather hurried and were never repeated for confirmation. Therefore, they should be taken as indications only. The test was not extended far enough to determine whether torsion appeared again at higher wind velocities.

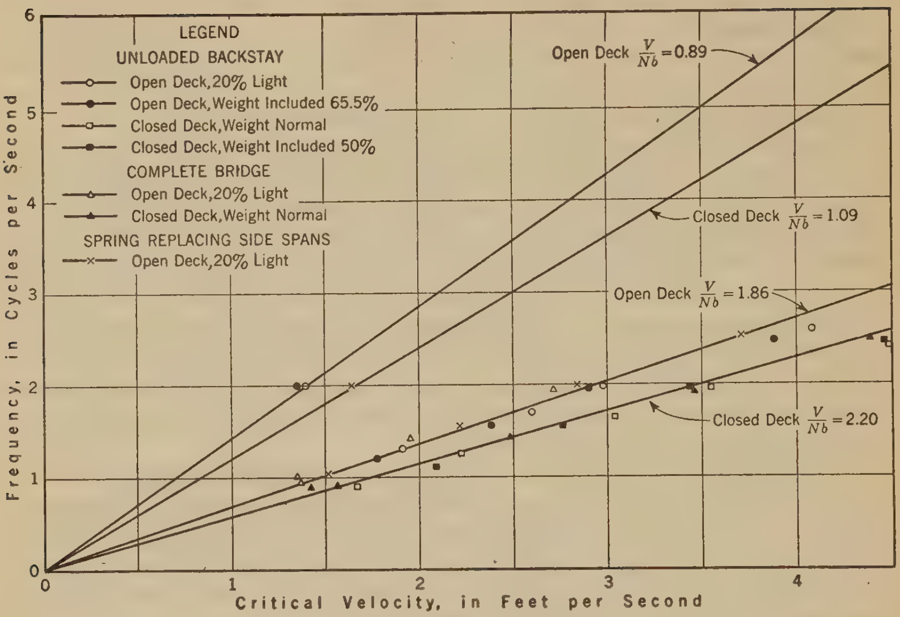

Fig. 15.—Vertical Oscillations

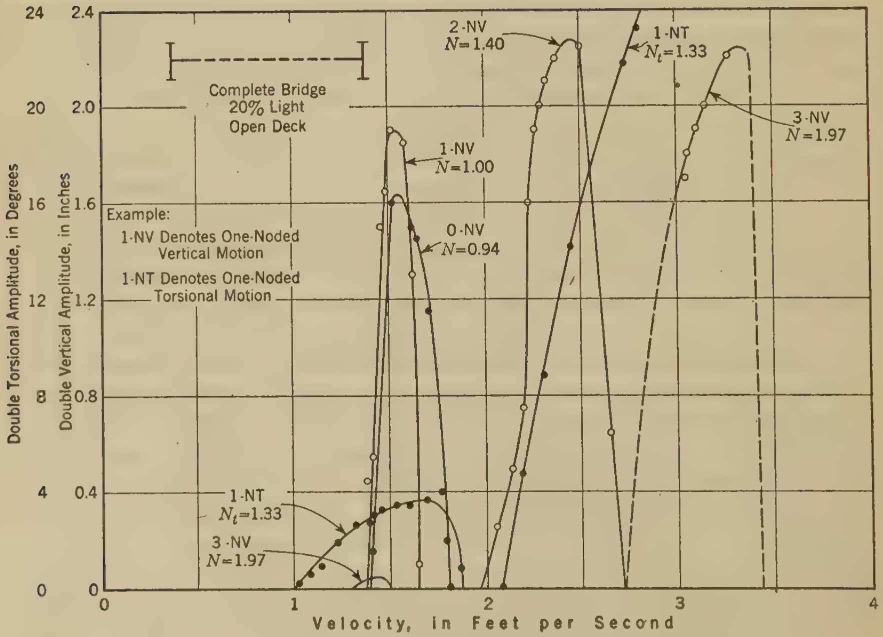

Fig. 16

No attempt has been made recently to explain the vertical motions observed on the basis of the static wind tunnel tests—that is, on the basis of negative aerodynamic damping. Experiment has demonstrated that only very slight differences showed in vertical modes between a section that had a definitely negative slope on the lift line (say, a d/b-ratio of 0.35) and the section of the original bridge (a d/b-ratio of 0.2) that showed a positive slope. Thus other possible sources have been investigated anticipating a more satisfactory explanation.

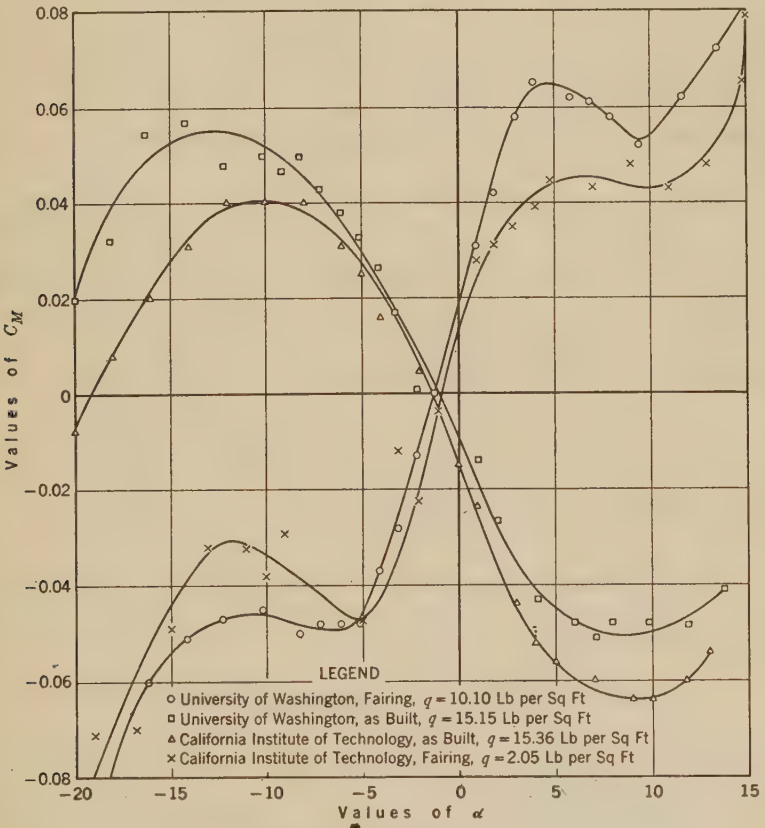

FIG. 17.—MOMENT COEFFICIENT, MODEL D

Early studies had led to the setting aside of the "vortex discharge" theory; but subsequent investigations have indicated that this theory is tenable in connection with the excitation of vertical modes on the basis of "subharmonic resonance"—that is, it has been demonstrated that excitation of a given mode can occur under starting conditions involving a vortex discharge at a rate that shows some multiple of the frequency of the resulting oscillation.

Numerous investigations of the flow were conducted using a hot-wire anemometer[47] of conventional form and recording the resultant velocity fluctuations through the use of a piezoelectric oscillograph. Typical records obtained in this manner are shown in Fig. 18.

---

[47] "Applied Hydro- and Aeromechanics," based on lectures of L. Prandtl, by O. Tietjens, McGraw-Hill Book Co., Inc., New York, N. Y., 1934.

As a result of these the hot-wire tests made simultaneously at the University of Washington and the California Institute of Technology (the latter used a

different means of recording), it is now felt that a reasonable explanation of the phenomenon is available.

As the wind strikes the section that is at rest, the rate of vortex discharge from the leading girder will be indicated at a multiple of some natural frequency of the structure, and the structure will begin to oscillate in an appropriate mode. If the velocity is maintained at a value close to the critical velocity for that mode, the amplitude will remain small and excitation will continue on a subharmonic basis. As the velocity is increased, however, the section begins to take charge of the flow, and subharmonic excitation yields slowly to harmonic excitation.[48] At some velocity, generally well below that associated with the maximum steady state, the excitation becomes harmonic and the vorticity is completely in phase with the motion. In other words, the section has taken complete charge of the flow. As velocity is increased still further, the section begins to lose its domination over the flow, the amplitude falls off, and the section approaches rest in so far as that particular mode is concerned. In general, there is no exact rest point in the amplitude response picture for any configuration since there is a certain overlapping of the modes.

---

[48] "Some Experimental Results on Wing Flutter," by William Bollay and C. D. Brown, *Journal of the Aeronautical Sciences*, June, 1941, pp. 313–318.

The domination of the flow by the section seems somewhat tenuous even at the maximum steady state since it is frequently noted that amplitude will decrease markedly without any change in velocity only to increase as constant velocity is maintained. In the case of the lower vertical modes especially, it has often been difficult to build the maximum amplitude under what appeared to be exactly similar conditions. For example, the response curves for the fundamental (0-N V) and single-noded (1-N V) modes recorded in Fig. 16 show amplitudes which were only noted on two occasions. During all other attempts the maximum steady amplitude indicated a considerably lower value. In general, the higher vertical modes could be built to maximum amplitude with little difficulty.

In Fig. 18(*d*), the motion of the model is in full control of the flow, and the maximum double amplitude has reached 1.4 in. (70 in. on the prototype). In the same run and at the same velocity a few seconds later, the amplitude has fallen off as shown in Figs. 18(*e*) and 18(*f*), and the record indicates that the control of the flow by the section is not complete—that is, some excitation on the subharmonic level is present again.

Only on the basis of the subharmonic theory of excitation can the double appearance of each of these modes be explained. There is some evidence, not yet well substantiated, that the first appearance is harmonically excited, whereas in the second appearance the excitation is subharmonic.

Part 4.—The author's general statements under the heading, "Anticipating Aerodynamic Instability," are not in full accord with experimental evidence derived from the full model which was tested with many variations of the configuration of the suspended structure. These configurations are listed in Table 8.

Lift, drag, and moment tests on fixed sections in the wind tunnel are available for all these configurations with the exception of sections 4, 5, 9, and 11, Table 8. It is significant to note that only in section 6 did a negative slope develop on the lift graph. Likewise, all these sections showed both vertical and torsional motions with the exception of section 10 in which no torsional motion developed in velocities up to a value greater than 110 miles per hr (prototype velocity). With great difficulty and only after very long runs, slight motion was observed in the two-noded and three-noded vertical modes in section 10. The maximum amplitude developed at the end of approximately 30 min (212 min, prototype) was 0.14-in. double amplitude in the two-noded mode.

Section 2 developed the most vigorous motion (see Fig. 16) in both vertical and torsional modes, and it is significant to note that the slope of its lift graph was strongly positive at all angles and that its moment graph was negative in slope over the middle range. All tests with girders of any depth showed negative slopes on the torque graph, and the only section that showed torsional stability (section 10) had a positive slope on the torque graph. In respect to the torque graph for girder bridges, the laboratory tests are in complete agreement with the author's claims.

However, recent tests on section models and full models of a new design using a truss for stiffening show a positive slope on the torque graph between the +12° and the −12° angles of attack; yet the model exhibits strong torsional instability when the angle of attack is approximately +7° or greater and a weaker manifestation of torsional instability when the angle of attack is −7° or greater. This positive slope on the torque graph and resultant instability

TABLE 8.—COMPARISON OF GIRDER SECTIONS

No.	Section	Description
1		The section of the bridge as built
2		Roadway slab completely removed leaving stringers and solid sidewalks with curbs
3		Section 2 with opening covered by screen of proper mesh to simulate a conventional open deck
4		Solid roadway slab with sidewalks and curbs removed
5		Both sidewalks and roadway slab removed, stringers still in place
6		Girder deepened to equivalent of 13 ft with deck open as in section 2
7		Full circular fairing on both girders, open deck as in section 2
8		Full circular fairing on both girders, closed deck as in section 1
9		Section 7 with bottom enclosed
10		Section 7 with top and bottom enclosed
11		Section 10 with circular fairing removed

of the section were likewise demonstrated in fixed model and section model tests at California Institute of Technology (unpublished report).

Use of Center Stays.—Center stays are only effective in inhibiting asymmetric torsional modes, and although they have been installed on a number of bridges it was never with this function in mind. They were first conceived as a means of reducing the longitudinal pendulum-like motion that is observed in connection with asymmetric vertical modes, and there is no evidence that they have ever been designed with regard to the stress that might arise in either the vertical or the torsional modes. There is some evidence to indicate that the center stays on the Tacoma Bridge failed (or yielded) in a strong eight-noded vertical motion which was active for some time before the transition to the first asymmetric mode in torsion. It is possible that this yielding during vertical motion permitted the development of a torsion with its accompanying much higher loading on the stays, which caused further yielding and ultimate failure (possibly accompanied by failure in the lateral system at midspan), leaving the structure quite unprotected against full development of catastrophic torsion.

Open-Floor Construction.—The writer is not so optimistic as the author regarding the beneficial effect of open-floor construction. Tests on the full model have been confined to the sections listed in Table 8, but it is significant that section 4 showed a strong three-noded vertical mode with an amplitude as great as that developed in section 2 (the lower modes were very weak) and with a single-noded torsional motion in excess of 15° of amplitude. A much higher velocity was required to bring in each of these modes but their amplitude was disquieting.

It was confidently expected that the complete removal of sidewalks and roadway slab (section 5, Table 8) would vastly improve the stability condition; but tests involving two complete runs showed three-noded and four-noded vertical modes of large amplitude and also developed a three-noded torsional mode of strong character. The three-noded torsion was especially violent and reached an amplitude in excess of 15°.

Conclusions.—The writer is in complete agreement with the author's concluding statement that the most scientific approach to this problem calls for the elimination of the cause of the motion.

H. Reissner,[49] Esq.—The publication of this paper gives a welcome opportunity for a discussion of the dynamics and particularly the aerodynamics of suspension bridges.

Part 1 is a treatment of free oscillations determined by means of the principle of work developed by Lord Rayleigh[50] for the purpose of finding approximate values of natural frequencies of a beam system of varying cross section to simplify the integration of differential equations with variable coefficients. Probable deflection curves (characteristic functions) could thus be introduced that would satisfy the boundary conditions but not necessarily the differential equations.

When the coefficients of the differential equation of the equilibrium condition are constant, the Rayleigh method becomes superfluous and the only difference (sometimes a convenient difference) is that the frequency equation appears as a quotient of integrals instead of as a determinant.

---

[49] Prof., Aerodynamics and Aerostructures, Polytechnic Inst. of Brooklyn, Brooklyn, N. Y.

[50] "The Theory of Sound," by John William Strutt, Baron Rayleigh, Vol. 1, Macmillan & Co., London, 1926, p. 287.

In the application of his method, the author for simplicity omits the cases of continuous or fixed-end girders and of variable stiffness and divides the suspension bridge systems in two classes—those for which the change ΔH of the cable thrust H is zero and those for which it is not zero—without explaining the significance of this division. The fact is that, as long as the horizontal inertia forces and the cable extension are neglected, the values of the frequencies are not influenced by ΔH and the value of ΔH remains indeterminate for symmetric oscillations and must be zero for antisymmetric oscillations.

If this change ΔH is to be determined, the horizontal inertia forces and the local horizontal displacements of the cable must be considered as demonstrated by the writer elsewhere.[51] The resulting differential equations become of the sixth order, because the cable must satisfy two conditions of horizontal displacements on the saddles, and because the girder must satisfy four equations for the vertical displacements and bending moments at the supports. The change ΔH is then no longer constant along the cable.

For the case of symmetrical oscillations in a structure with straight backstays, Mr. Steinman expresses ΔH in terms of the elastic extension. This is only necessary for the case of a one-segment oscillation, which special case has such a high frequency that it practically never occurs.

On the other hand, symmetrical multisegment oscillations in structures with straight backstays are possible without extension of the cable and in these cases the influence of extension (cable stretch) is negligible.

For the case of nonparticipating side spans and the case of the simply-supported girder, the writer has applied the Rayleigh method (Part 1 of the paper) to oscillations,[51] but only because consideration of the horizontal inertia forces, of the varying slope angle γ of the cable and of the local condition of inextensibility, introduces variable coefficients. The effect of inextensibility of a cable element is expressed by

$$\frac{d\zeta}{dx} = -\frac{d\eta}{dx}\frac{dy}{dx} = -\frac{d\eta}{dx}\frac{8f}{l^2}\left(\frac{l}{2} - x\right) \dots\dots\dots\dots\dots (80)$$

in which ξ denotes the horizontal displacement of any point of the cable. In this case the solution of the differential equation by a series development leads to extremely slow convergence and the Rayleigh method is indicated.

The Rayleigh method has been applied to the case of a two-segment oscillation by the writer[51] and elsewhere to the case of a three-segment and a four-segment oscillation by E. Sternberg in cooperation with the writer.[52]

The following expressions, taken from those analyses, show the influence of the aforementioned terms, which are usually neglected:

---

[51] "Oscillations of Suspension Bridges," by H. Reissner, *Journal of Applied Mechanics*, Vol. 10, No. 1, March, 1943, pp. A-23 to A-32 (preprinted and presented at the June, 1942, meeting in Cambridge, Mass., of the Applied Mechanics Div. of the A.S.M.E.).

[52] "Special Cases of the Oscillations of Suspension Bridges," by E. Sternberg, Master of Science thesis presented to the Illinois Inst. of Technology in Chicago, in 1942.

For $\eta_2 = a_m \sin \frac{2 \pi x}{l}$:

$$N_2 = \frac{1}{2} \sqrt{\frac{g}{2 f}} \sqrt{\frac{1 + 6.16 \left(\frac{f}{l}\right)^2 + 315 \frac{E I f}{w l^4}}{c_t + c_c 1.12}} \qquad (81a)$$

for $\eta_3 = a_m \left(\sin \frac{\pi x}{l} - 3 \sin \frac{3 \pi x}{l}\right)$:

$$N_3 = \sqrt{\frac{2.05}{4}} \sqrt{\frac{g}{2 f}} \sqrt{\frac{1 + 5.33 \left(\frac{f}{l}\right)^2 + \frac{700 E I f}{w l^4}}{c_t + c_c 1.05}} \qquad (81b)$$

and, for $\eta_4 = a_m \sin \frac{4 \pi x}{l}$:

$$N_4 = \sqrt{\frac{4.05}{4}} \sqrt{\frac{g}{2 f}} \sqrt{\frac{1 + 5.52 \left(\frac{f}{l}\right)^2 + 1{,}250 \frac{E I f}{w l^4}}{c_t + c_c 1.07}} \qquad (81c)$$

in which c_t and c_c are the respective relative contributions of truss and cable weight computed so that $c_t + c_c = 1$.

For the Tacoma Narrows Bridge, the numerator of the last factor in Eqs. 81 has the following relative magnitudes:

n	Numerator, Eqs. 81	N, in cycles per minute
2	1 + 0.038 + 0.01183	7.95
3	1 + 0.0328 + 0.0228	11.6
4	1 + 0.0364 + 0.0468	16.3

The second terms in this numerator give the influence of the horizontal inertia forces, and the third (last) terms, the influence of the girder stiffness. It is noteworthy that the girder stiffness for the two-segment oscillation contributes less than one third of the effect of the horizontal inertia forces of the cable in the case of the relative girder stiffness of the Tacoma Narrows Bridge.

These additional terms are less than 4% and the values without them fit very well into the approximate formula, Eq. 17*b*, although the writer would prefer to write this formula in consistent units—that is, in the form,

$$P \approx \frac{1}{n} \sqrt{\frac{32 f}{g}} \qquad (82)$$

which is true for any system of units.

The foregoing data demonstrate that the free oscillations of suspension bridges which have no redundant constraints, such as stays, can be computed by simple formulas. In fact, they can be computed by formulas which assume that a pre-stressed suspension bridge acts like a mathematical pendulum of length,

$$L = \frac{32}{\pi^2 n^2} f (1 + \epsilon) \qquad (83)$$

in which ϵ is a small quantity depending on the sag-to-span ratio, the cable and girder mass ratio, and the girder stiffness, as may be seen from Eqs. 81.

Under the heading (see Part 1), "Oscillations with Longitudinal Motion of Span," the girder is assumed to execute a free horizontal oscillation regardless of its fixing or friction at the pier supports. The reason for this assumption is not clear. The case in which there is horizontal interference between cable and girder should be treated like a system with redundant members. There is a possibility (worthy of investigation) that the short waves observed running along the girder of the Tacoma Narrows Bridge were started from a combined compression and bending effect caused by such interference.

Example 3, on torsional oscillations, needs clarification. In the cables the masses are concentrated, and only in the girder-roadway system are they distributed transversely. Hence, the transition in frequency from bending oscillation to torsional oscillation should be given by

$$N_t = N \sqrt{\frac{1}{c_t\,(2\,r/b)^2 + c_c}} \ldots\ldots\ldots\ldots\ldots\ldots (84)$$

For instance, for a weight of 2,113 lb per ft of girder roadway and of 747 lb per ft of cable, $c_t = 0.74$ and $c_c = 0.26$. Using a radius of gyration ratio of $\frac{r}{0.5\,b} = \frac{2}{3}$ the numerical result becomes (in cycles per minute): $N_t = 1.305\,N = 7.95 \times 1.305 = 10.4$, whereas Eq. 21*b* would give $1.5\,N = 11.9$.

The fact that the observed frequency ($N = 12$) was somewhat higher than the frequency (10.4) determined by the more exact formula is probably explained by a smaller value of the radius of gyration r, by the torsional elastic stiffness of the stringers and the concrete of the roadway, and by the transverse force components of the hangers.

The author's analysis of partly stable vertical oscillations due to the negative range of the lift characteristic of the cross section and his recommendation that such faulty cross sections be investigated and avoided (Part 2) deserve the full attention of bridge designers. On the other hand, his ideas and explanations concerning the generation of destabilizing phase differences by means of a phase factor β and by a disturbance or an impulse traveling across the width of the roadway are not clear.

In principle the problem of the origin of bridge oscillations, which accumulate energy out of a uniform wind flow, is very hard to handle owing to the rugged and diversified shape of the cross sections. The rational derivation of a flow pattern around these aerodynamically irregular sections, when producing a phase difference of negative damping, appears extremely difficult. The writer may mention that even the so-called flutter theory of the potential flow around perfectly streamlined airfoils governing the rhythm of the circulation by their sharp trailing edges is considered as one of the most intricate problems of aerodynamics. This makes it very doubtful that a valid analysis can be deduced from the mere geometric concept of a phase factor.

The University of Washington in Seattle and the California Institute of Technology have made pertinent experiments[53, 54] on models supported on

---

[53] "Failure of the Tacoma Narrows Bridge: Report of the Special Committee of the Board of Direction," *Proceedings*, Am. Soc. C. E., December, 1943, p. 1578.

[54] "The Failure of the Tacoma Narrows Bridge," a report to the Hon. John M. Carmody, Administrator of the Federal Works Agency, Washington, D. C., March 28, 1941, by a board of engineers consisting of O. H. Ammann, Theodor von Kármán, and Glenn B. Woodruff, Chapter IV, p. 96.

springs in such a way that the effect of aerodynamic damping could be observed separately from that of structural damping. These experiments were made for such a wide variety of cases and with such careful attention to the theory of similarity that one may be justified in using them as the only available and reliable basis for a semi-empirical, semi-analytical formula. An expression for the logarithmic decrement, δ_a, as presented in the Carmody Report,[3,53,54] can be written in any arbitrary consistent units in the form,

$$\delta_a \frac{w}{\rho\, g\, b^2} \left(\frac{r}{b}\right)^2 = -\,2.05 \left(\frac{V}{b\,\omega} - 0.958\right) \ldots\ldots\ldots\ldots\ldots (85)$$

in which $\omega = N \times 2\,\pi$. From Eqs. 84 and 85, it follows that the critical velocity V_a (without structural damping) is given by

$$V_a = 0.958\, b\, \omega = 0.958\, \pi\, b \sqrt{\frac{g}{2\,f \left[c_t \left(\frac{2\,r}{b}\right)^2 + c_c\right]}} \ldots\ldots (86)$$

For critical velocities greater or less than that expressed by Eq. 86, the logarithmic decrement becomes

$$\delta_a = 2.05\, \frac{\rho\, g\, b}{w\, \omega} \left(\frac{b}{r}\right)^2 \times (V_a - V) \ldots\ldots\ldots\ldots (87)$$

Eq. 87 is a simple, dimensionally accurate expression which has been confirmed experimentally. Until the development of a completely rational analysis leading to the derivation of the logarithmic decrement, designers must be content with it.

From Eq. 86, it follows that, for the case of aerodynamic damping alone, the only way to increase the critical velocity is to increase the product of the width of the bridge floor and the natural frequency. As the practical frequency variation is very small, the critical velocity can be raised only by increasing the width of the floor, b. The relation between this width and the aerodynamic critical velocity is demonstrated by Table 9. The low value of b and of the critical velocity for the Tacoma Narrows Bridge is particularly significant. For the conditions assumed in Eq. 84, c_t was found equal to 0.74. The writer has assumed the value of 0.75 in Table 9 except in the case of the George Washington Bridge, which has four cables and no stiffening girders.

TABLE 9.—CRITICAL WIND VELOCITY (NO STRUCTURAL DAMPING, SEE EQ. 86)

Bridge	Width b (ft)	Height h (ft)	Distribution of mass	CRITICAL VELOCITY	
				Ft per sec	Miles per hr
Golden Gate	90	475	0.75	60.1	41.0
George Washington	106	325	0.64	98.5	67.1
Tacoma Narrows	39	232	0.75	37.2	25.3
Bronx-Whitestone	74	200	0.75	76.2	52.0

Mr. Steinman seems to distinguish between two kinds of self-excited torsional oscillations, one as treated by the Carmody Report (defined by Eq. 87 and Table 9) and the other as defined by his torque coefficient, $C_t\,\alpha$, and the phase factor β. On the other hand, the Carmody Report[3,55,56] states that curves like those in Fig. 6 represent a stable torque diagram such as might be derived by observations on an ordinary wind vane. A positive torque for a positive angle occurs only when the cross section is streamlined. Such a cross section may be called statically unstable. No self-excited oscillations appear with it but only an inclined equilibrium position which, with insufficient elastic resistance, may lead to overturning.

The Carmody Report[3] was the first to reveal the fact that in suspension bridges it is the structural damping rather than the structural elastic stiffness that contributes to dynamic stability. This is a contribution to a necessary new treatment. To maintain its economic and esthetic advantages, the suspension bridge must necessarily be much more flexible than other forms of truss frame bridges—that is, it must have a lower natural frequency. Therefore, its margin of safety over that furnished by aerodynamic stability must be provided by its internal frictional resistance. The utilization of this important knowledge, however, is impeded by the wide variation in frictional properties of materials and structures.

Experiments tend to show that the logarithmic decrement does not change with frequency but with amplitude. Eq. 35 incorporates this fact although Mr. Steinman does not discuss how this logarithmic decrement conforms with the equation of motion; nor does he cite the experiments on which it is based. Information about damping coefficients or logarithmic decrements of bridge structures—in terms of stiffness $E\,I$, depth d, span l, or stress σ—is certainly scarce if not nonexistent. For reasons of dimensional consistency, the author introduces the square root of the amplitude, thus giving an infinite slope of increase of the decrement toward zero amplitude and a steep slope for small amplitude. The writer doubts the correctness of this assumption. All published material available to the writer indicates that the decrement increases slowly with corresponding increases in stress up to the elastic limit. In fact, such an expression can be derived by starting from the concept of a quadratic velocity damping for which R. Grammel[57] in a specially simple case could show that the logarithmic decrement for small oscillations becomes independent of the frequency and proportional to the amplitude.

To linearize this procedure which is necessary to overcome the mathematical difficulties and justified for small oscillations the structural damping factor d_s may be assumed to be proportional to the average velocity in the form,

$$d_s = \frac{k}{g}\,a\,\omega \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (88)$$

in which a is the maximal amplitude of the girder, g the acceleration of gravity, and k is a dimensionless constant which expresses the functional characteristics of the members and joints of the structure, and the changes of amplitude along the length of the span.

---

[55] "The Failure of the Tacoma Narrows Bridge," a report to the Hon. John M. Carmody, Administrator of the Federal Works Agency, Washington, D. C., March 28, 1941, by a board of engineers consisting of O. H. Ammann, Theodor von Kármán, and Glenn B. Woodruff, p. 129.

[56] *Ibid.*, Appendix VIII, p. 23.

[57] "Neuere Versuche über elastische Hysterese," by R. Grammel, *Zeitschrift des Vereines Deutscher Ingenieure*, Vol. 58, 1914, p. 1600.

The combination of aerodynamic and structural damping as formulated in Eq. 89 following will lead to the interpretation of a as the amplitude which is not increasing any more. Such an effect of structural damping has also been stated by Louis G. Dunn.[54]

In 1942[51] the writer evaluated the available observations on aerodynamically critical velocities V_a and the total wind velocity V_c (condensed in Eq. 85 and in the actual observations of the critical velocity of the Tacoma Bridge) by means of the equations of motion. For this purpose constant viscous damping coefficients were used—that is, it was assumed that both decrements were inversely proportional to the frequency, which is correct only for aerodynamic damping. This assumption leads to approximate values of V_c only when applied to bridges with natural frequencies not too different from the frequency of the Tacoma Bridge. This same objection can be raised against the representation, sometimes used, of friction by an additional elastic force with an imaginary factor accounting for the phase difference in an energy-consuming resistance. Furthermore, such a method does not seem rational because it cannot be transformed into expressions involving functions of real quantities.

There seems to be no reason why the viscous damping factor, although constant for given dimensions of a system, cannot be made dependent on the frequency and the amplitude in such a way as to satisfy experimental determinations of logarithmic decrements.[58]

Neglecting the horizontal inertia forces and the cable slope, the equation of motion in its usual form is as follows:

$$\frac{w}{g}\psi\frac{\partial^2\eta}{\partial t^2} - H\frac{\partial^2\eta}{\partial x^2} + E\,I\,n_t\frac{\partial^4\eta}{\partial x^4} + \frac{\partial}{\partial t}\left(d_a\cdot V\,\eta + d_s\,E\,I\,n_t\frac{\partial^4\eta}{\partial x^4}\right) = 0 \,..(89)$$

In Eq. 89, in addition to the notation of the paper, n_t is a factor indicating an eventual torsional stiffness of the wind bracing (for a tubular cross section) and of the bridge floor; d_a is a coefficient of aerodynamic damping; d_s is a coefficient of structural damping (see Eqs. 85 and 88); and

$$\frac{w}{g}\psi = m_1 = m_{\text{girder}}\left(\frac{2\,r}{b}\right)^2 + m_{\text{cable}} \ldots\ldots\ldots\ldots\ldots\ldots(90)$$

In the last term of Eq. 89 the structural damping moment is assumed to be proportional to the time rate of change of the elastic counter forces,

$$\frac{\partial}{\partial t}\left(E\,I\,n_t\frac{\partial^4\eta}{\partial x^4}\right)b \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(91)$$

Solving Eq. 89 in the usual manner and observing Eq. 87, the logarithmic decrement becomes

$$\delta_a + \delta_s = 2.05\,\frac{\rho\,g\,b}{w\,\omega}\left(\frac{b}{r}\right)^2(V_a - V) + k\,a\,\frac{E\,I\,n_t}{w\,\psi\,l^4} \ldots\ldots\ldots(92)$$

The condition for zero decrement now becomes

$$V_c = V_a + k\,\frac{a}{b}\,\frac{E\,I\,n_t}{\psi\,l^4}\,\frac{\omega}{\rho\,g\left(\frac{b}{r}\right)^2} \ldots\ldots\ldots\ldots\ldots\ldots(93)$$

---

[58] "Damping Formulas and Experimental Values of Damping in Flutter Models," by R. P. Coleman, *Technical Notes No. 751*, National Advisory Committee for Aeronautics, February, 1941.

The only observations of critical wind velocities available with all necessary dimensions and weight data are those in connection with the Tacoma Narrows Bridge.[59] Using these observations one can discuss the significance of Eq. 93 by inserting the observed simultaneous values of $V_e = 62$ ft per sec, of the circular frequency $\omega = \frac{2\,\pi\,n}{60} = 1.25$, and the observed model value of $V_a = 37.2$ ft per sec from Table 9 into Eq. 93. Eq. 93 contains the product of the friction coefficient k and the ratio $\frac{a}{b}$ which latter is a measure of about half the maximum angle of twist, at which the bridge by the structural damping increasing with amplitude reaches a state of steady oscillation—that is, provided that the stresses in this state are not at the breaking limit as in the case of the Tacoma Bridge.

Solving for this dimensionless quantity $\frac{k\,a}{b}$ one obtains (compare Eq. 93):

$$\frac{k\,a}{b} = (V_e - V_a)\frac{l^4}{E\,I\,n_t\,\omega}\rho\,g\,\psi\left(\frac{b}{r}\right)^2$$

$$= 24.8\,\frac{2{,}800^4 \times 0.00238 \times 32.2 \times 0.59 \times 9}{3.46 \times 10^{10} \times 1.25} = 1.435 \times 10^4 \ldots\ldots(94)$$

With this value the following examples may be computed:

(1) For the Tacoma Bridge what increase of road width b and girder stiffness $E\,I$ would be necessary to raise the critical wind speed from 62 ft per sec to 150 ft per sec (for the same angle of twist)?

Choosing, as suggested by the Tacoma committee, $b = 52$ ft (instead of 39) and doubling the girder depth with the same effective flange area one obtains from Eq. 94: $V_e = 37.2 \times 1.3 + 24.8 \times 4 = 147.5$ ft per sec. If it is required that the tangent of the twisting angle for the steady state is only one fourth of the value observed at the Tacoma Bridge the allowable critical velocity would be $V_e = 48.3 + 24.8 = 73.1$ ft per sec.

(2) What is the critical velocity for the Golden Gate Bridge with the value of critical twisting angle of the Tacoma Bridge? From Table 9 and from the report of the Board of Direction,[60] the following values are used:

$$V_a = 60.1 \text{ ft per sec};\quad E\,I = 118.9 \times 10^{10} \text{ lb ft}^2;\quad n_t = 1,$$

$$\omega = 0.773 \text{ sec}^{-1};\quad \psi = 0.59;\quad l = 4{,}200 \text{ ft};\quad b = 90 \text{ ft};\quad \frac{b}{r} = 3.$$

Eq. 94 gives $V_e = 60.1 + 109.9 = 170$ ft per sec $= 116.5$ miles per hr. If only a quarter of the original value of $\frac{a}{b}$ is allowed, then $V_e = 60.1 + 27.5 = 87.6$ ft per sec $= 60$ miles per hr. It may be mentioned that the highest wind velocity of 110 ft per sec, acting on the Golden Gate Bridge was observed by R. G. Cone, M. Am. Soc. C. E., on February 9, 1938,[61] and that the bridge attained steady deflections of which the magnitude could not be measured.

---

[59] "The Failure of the Tacoma Narrows Bridge," a report to the Hon. John M. Carmody, Administrator of the Federal Works Agency, Washington, D. C., March 28, 1941, by a board of engineers consisting of O. H. Ammann, Theodor von Kármán, and Glenn B. Woodruff, pp. 21–27.

[60] "Failure of the Tacoma Narrows Bridge: Report of the Special Committee of the Board of Direction," *Proceedings*, Am. Soc. C. E., December, 1943, p. 1566, Table 1.

(3) Another opportunity for checking Eq. 94 is afforded by the Bronx-Whitestone Bridge. Here the data in feet and pounds are:

$$E\,I\,n_t = 8.5 \times 10^{10}; \quad \omega = 1.19; \quad \psi = 0.59;$$

$$l = 2{,}300; \quad b = 74; \quad \text{and} \quad \frac{b}{r} = 3.$$

With the value of $V_a = 76.2$ from Table 9, Eq. 94 yields $V_c = 76.2 + 100.0 = 176.2$ ft per sec $= 121$ miles per hr and with one quarter of the twisting angle $\frac{a}{b}$ $V_c = 76.2 + 25 = 101.2$ ft per sec.

Concerning the aim to increase the structural stiffness and friction (n_t in Eq. 89 and k in Eq. 88), Mr. Steinman's suggestion in Fig. 9 seems very appropriate. Geometrically rigid cross frames are used, particularly at the quarter points of the spans, running the entire way from and between the cables to the lower truss chords and the transverse roadway girders. In fact, such transverse bracings would force the horizontal wind bracing to resist the twisting of the bridge by means of the bending stiffness and the bending friction in its horizontal plane.

A combination of this device with diagonal stays running from the top points of the cross frames and in the planes of the cables and hangers to the piers at the bases of the pylons, and equipped with vibration absorbers, should be very efficient against all kinds of oscillations with a minimum of redundant members. An indication of a high damping effect of such stays has been found by the experiments of F. B. Farquharson,[53] M. Am. Soc. C. E.

Blair Birdsall,[62] Assoc. M. Am. Soc. C. E.—The profession is indebted to the author for his presentation of the results of an exhaustive study of the problem arising from the failure of the Tacoma Narrows Bridge and the more or less unstable behavior of several other structures. Many interesting and helpful new tools are offered for the use of the designer. Although the validity of these formulas is strikingly confirmed by comparison with observed oscillations, it is undoubtedly true, as stated by the author, that many gaps remain to be filled and that the empirical deductions require more thorough consideration.

For instance, a minimum limit of 1:100 for the ratio of depth of truss or girder to span may be more conservative than necessary. This is evident in the case of the Golden Gate Bridge. A decrease in cable sag from 11.1% to 10% of span would have increased K per cable well above the minimum value of 120 selected by the author and in this case the ratio of truss depth to span is 1:168.

[62] Asst. Chf. Engr., Bridge Div., John A. Roebling's Sons Co., Trenton, N. J.

Thus, it is to be hoped that this paper will be the beginning of a series of discussions and additional papers through which the Society will receive the benefit of the vast amount of research and investigation in progress on this subject.

The writer wishes to offer a few remarks on the "spring constant" or "coefficient of rigidity," designated by the author as K. From the derivation of K, it appears perfectly proper to consider this constant as a measure of the resistance of the span to deformations caused by loads applied uniformly along segments of the span: K per cable is a measure of resistance to loads that have a uniform intensity per foot of horizontal cable span; and K per foot is a measure of the resistance to loads that have a uniform intensity per square foot. However, since the present problem involves the aerodynamic behavior of suspension bridges, an attempt should be made to find a constant which will be a measure of the resistance of a particular structure to loads imposed by commonly occurring wind velocities. Obviously, wind of a given velocity will not have the same effect on two bridges that are identical in all respects except for the stiffening member, which is a truss in the one case and a girder in the other. Furthermore, the writer believes that vertical forces resulting from wind action are not uniform per square foot of floor area and that the total vertical wind force is not proportional to width of roadway on two structures that are identical except for width.

[a] Denotes construction with solid-web stiffening girders.

The writer suggests that an attempt be made to modify K so as to include some measure of the effect of wind action. Perhaps such a modification can be obtained from a study of the lift graph for the bridge cross section. In this way it may be possible to classify K-values for existing bridges in the order of their observed behavior. The writer has taken a step in this direction by means of the following simple device.

In Part 4, the author states that the limiting value of K per cable should be 300 for bridges with stiffening girders and 120 for bridges with stiffening trusses. By dividing all the author's values of K per cable for girder-stiffened bridges by 300/120 or 2.5, the writer has obtained a rearrangement of the order of stiffness of the bridges in Table 2 (see Table 10).

Undoubtedly this is not the correct order; nor are the values truly representative, but this arrangement does appear to conform more nearly to the observed behavior of these bridges and indicates that very satisfactory results might be obtained from a more scientific modification of K per cable.

HARDY CROSS,[63] M. AM. SOC. C. E.—The author of this paper deserves thanks for effective condensation and clear presentation. The evidence presented is chiefly analytical; this is useful, but it is hoped that, in the closure, it will be supplemented by evidence from the author's extended practice.

Structural design is based on evidence from several sources; few problems illustrate this better than that of the stability of suspension bridges. Analysis furnishes evidence, but analysis is of necessity based on assumptions. It is important to note that model experiments are merely short cuts in analysis and are also based on assumptions. Experiments seriously attempt to avoid assumptions, but they rarely do so because of differences of useful scale. Full-scale experiments are scarcely practicable for suspension bridges, although it may be possible to make them with airplanes. Experience presents results of full-scale experiment; but the experiment is not planned and the results are fragmentary and often cannot be dependably correlated. Common sense—intuitive qualitative perception of relations—also furnishes evidence; but this evidence alone is not always dependable.

Evidence from no one of these sources is inherently more dependable than that from another; all may mislead—and often do so—and all sources supply valuable evidence. Because engineers are not too wise in the ways of nature, they are not often able to reconcile what seem to be conflicting data from the various sources; the current problem illustrates the point clearly.

Suspension bridges may begin to move in a wind and these movements can build up. "Autoresonance" from wind action is indicated and is generally accepted as an explanation. If autoresonance occurs, the strains in the structure will increase to failure unless the driving force dies out or reverses, or unless damping, either frictional or internal, absorbs the energy as fast as it is supplied, or unless the vibration characteristics of the structure change, as would occur with slack ties.

The first of these phenomena may occur because the wind dies out or because it is gusty. The author thinks that the lift relations change as the vibration builds up; this may be the explanation, or an explanation. The hypothesis is an interesting contribution to speculation and it deserves investigation even though this may be difficult.

Much information is not available on friction damping. Perhaps engineers try too hard to eliminate it in structures; but to absorb by friction the energy of a vibrating suspension bridge is itself a major problem. Even less is known of internal damping, but the writer has not yet seen data to indicate that it is an important factor in this problem.

Changeable vibration characteristics seem to be nature's solution of the resonance problem and perhaps the late John Roebling, M. Am. Soc. C. E., saw their value intuitively. The writer does not know how far this field of thought has been explored but he has reason to think that the author of the paper has studied it and hopes that he will comment on it.

The author feels sure that it is better to eliminate the cause of instability than to provide a cure. Whether this is true depends on the certainty of the diagnosis of cause and the dependability of the recommended cure; good engineering depends on evaluation of insurance risks against probable occurrence and possible consequence. If the engineer can find out when—for what proportions and spans—these bridges are unstable, he may not care so much about why; certainly this is the case in many engineering problems. Usually the designer makes some observations on "when"; then he speculates as to "why"; and finally he revises and successively revises to approach dependability. The author has here contributed to the "why"; it is to be hoped that in his closure he will contribute data from his broad experience as to the "when."

Frederick C. Smith[64] and Hermann Friedlaender,[65] Assoc. Members, Am. Soc. C. E., and George S. Vincent,[66] M. Am. Soc. C. E.—In association with F. B. Farquharson, M. Am. Soc. C. E., the writers have been working on the development of equations which will express adequately the behavior of suspension bridges under vibration. Model studies of the Tacoma Narrows Bridge, one of the structures analyzed by the author, have been undertaken by the University of Washington, at Seattle, and the Washington (State) Toll Bridge Authority with the cooperation of the Public Roads Administration. These studies also involve certain supplemental tests recommended by the Advisory Committee on the Investigation of Long-Span Suspension Bridges.[67] As a part of the supplemental tests the original model was modified to represent a bridge with unloaded backstays.

The author's equations and those developed by the writers, in common with most engineering formulas, are not precise. The engineer starts with certain assumptions, makes a series of approximations of varying degree, and attempts to develop equations that will predict with fair precision the performance of the designed structure. The test of the equations is their reliability for such prediction. For this purpose, complex formulas are not justified except for limited comparative study if simpler formulas give precision equivalent to that of the observations. In the case of suspension bridge vibration due to wind, perhaps the best data for comparison with the results of equations are the observations on the Tacoma Narrows Bridge and its fifty-scale full model in the wind tunnel. The model duplicated with rather startling accuracy the behavior of the bridge in all movements covered by field observations, and provided, in addition, the opportunity to observe movements which had not been adequately observed in the field. The supplemental tests provided observations, not elsewhere available, for checking certain of the equations. It is proposed to discuss the basic assumptions made and the resulting equations, to compare the author's equations with some of the writers' equations, and to test both against observations made on the model.

[65] With U. S. Army; formerly, Engr., Webster-Brinckley Co., Seattle, Wash.

[66] Highway Bridge Engr., Public Roads Administration, Structural Research Laboratory, Univ. of Washington, Seattle, Wash.

[67] *Civil Engineering*, October, 1943, p. 503.

Assumptions.—The basic assumptions by Messrs. Steinman and Rannie[3] agree in that:

(1) The suspenders are inextensible under inertial loads;
(2) The cable stresses due to inertial load are small compared to dead-load stresses;
(3) The tower stiffness against horizontal forces applied at the top is negligible;
(4) The moment of inertia of the truss, hinged at the tower, is uniform throughout the length of the bridge; and
(5) For bridges with suspended side spans, the cable is inextensible under inertial loads.

They differ in that:

(*a*) Mr. Steinman assumes that the deflection curves due to oscillation are sine curves, whereas Mr. Rannie develops the equations for the deflection curves;
(*b*) Mr. Steinman takes truss stiffness into account in all cases, whereas Mr. Rannie neglects truss stiffness in the case of the Tacoma Bridge, although he does develop more general equations which do include the effect of truss stiffness; and
(*c*) Furthermore, Mr. Steinman develops an equation for bridges with unloaded backstays in which he takes into account the extensibility of the cable under inertial loads, a bridge condition that Mr. Rannie did not consider.

In their studies, the writers also found it necessary to take cable extensibility into account in developing equations for the condition with unloaded backstays. Furthermore, the fact was recognized that the backstays carry their own weight and, therefore, are not straight. They are actually loaded equilibrium polygons subject to elastic distortion and, accordingly, were treated as loaded side spans but with unit loading different from that on the main span and correspondingly modified sag (the cable weight on the Tacoma Bridge was about 25% of the total weight).

Equations.—The author simplifies the derivation of many expressions by the use of approximations which, for the most part, appear to be permissible. However there are apparently certain errors in Eqs. 11*c* and 14. Consider first Eq. 11*c*. If, as is suggested by the author, the integration of Eqs. 2 and 4 is extended over the three spans the following equation is obtained:

$$K = \frac{\left[\frac{\pi^2 n^2}{l^2} + \frac{2\,(a_1)^2\,l_1}{a^2\,l}\frac{\pi^2\,(n_1)^2}{(l_1)^2}\right] H + \left[\frac{\pi^4 n^4}{l^4} + \frac{2\,(a_1)^2\,l_1}{a^2\,l}\frac{\pi^4\,(n_1)^4}{(l_1)^4}\right] E\,I}{1 + \frac{2\,(a_1)^2\,l_1}{a^2\,l}} \quad \text{..(95)}$$

If the term, $\frac{2\,(a_1)^2\,l_1}{a^2\,l}$ were equal to q of Eq. 11*c*, Eq. 95 would be identical with Eq. 11*b*, but $\frac{2\,(a_1)^2\,l_1}{a^2\,l}$ is approximately equal to $\frac{(n_1)^2}{2\,n^2}\frac{l}{l_1}\,(\sec^4 \gamma_1)^2$ and not $\frac{(n_1)^2}{2\,n^2}\frac{l}{l_1}\sec^4 \gamma_1$, which the author gives as the value for q. It seems to the writers that $(\sec^4 \gamma_1)^2$ is more nearly correct for the secant term than is $\sec^4 \gamma_1$ for the following reasons:

After developing Eq. 9 (in the development of which the author assumes no tower-top movement), Mr. Steinman states: "The resulting value of Δl_c or Δl will be the algebraic sum of the component values." The writers understand this to mean that, assuming that the tower tops do move, Δl caused by the multiple segment wave represented by the equation,

$$\eta = a \sin \pi n \frac{x}{l} (\sin 2 \pi N t) \qquad (96a)$$

will be the same as Δl caused by a single segment wave represented by the equation,

$$\eta = \frac{a}{n} \sin \pi \frac{x}{l} (\sin 2 \pi N t) \qquad (96b)$$

An approximate formula[68] for the change in length of the span, Δl, when there is a small change in the sag, Δf, is given by the formula,

$$\Delta l = \left\{ \frac{\frac{16 f}{l} \left[5 - 24 \left(\frac{f}{l} \right)^2 \right]}{15 - 40 \left(\frac{f}{l} \right)^2 + 288 \left(\frac{f}{l} \right)^4} \right\} \Delta f \qquad (97)$$

An approximate formula[69] for the length of the side span cable commonly used is

$$L_1 = l_1 \left(\sec \gamma_1 + \frac{8}{3} \frac{(f_1)^2}{(l_1)^2 \sec^3 \gamma_1} \right) \qquad (98)$$

where l_1 is length of side span and γ_1 is the angle the chord of the side span makes with the horizontal.

If this expression is differentiated first in respect to f_1 and then in respect to l_1 and the resulting expressions equaled, the following expression is derived

$$\Delta l_1 = \frac{\frac{16}{3} \frac{f_1}{l_1}}{\sec^4 \gamma_1 - \frac{8}{3} \frac{(f_1)^2}{(l_1)^2}} \Delta f_1 \qquad (99)$$

Neglecting all terms but the first in both the numerator and denominator and substituting $\frac{a}{n}$ for Δf and $\frac{a_1}{n_1}$ for Δf_1 the following approximate formulas are obtained:

$$\Delta l \approx \frac{16}{3} \frac{f}{l} \frac{a}{n} \qquad (100a)$$

and

$$\Delta l_1 \approx \frac{16}{3} \frac{f_1}{l_1} \frac{a_1}{n_1} \frac{1}{\sec^4 \gamma_1} \qquad (100b)$$

---

[68] "The Theory and Practice of Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, John Wiley & Sons, Inc., New York, N. Y., 1917, p. 199.

[69] "Suspension Bridges," by D. B. Steinman in "Movable and Long-Span Steel Bridges," by George A. Hool and W. S. Kinne, McGraw-Hill Book Co., Inc., New York, N. Y., 1923, p. 292.

(For the Tacoma Bridge this approximation introduces an error of less than 2% in the value of Δl and less than 1% in Δl_1.) In Eqs. 100, Δl must be equal to 2 Δl_1; therefore,

$$a_1 = \frac{1}{2}\frac{f}{f_1}\frac{l_1}{l}\frac{n_1}{n}\, a \sec^4 \gamma_1 \ldots\ldots\ldots\ldots\ldots\ldots (101)$$

Substituting this value of a_1 in the expression, $\frac{2\,(a_1)^2\, l_1}{a^2\, l}$ of Eq. 95 and remembering that $\frac{f_1}{(l_1)^2} = \frac{f}{l^2}$ gives:

$$q = \frac{(n_1)^2\, l}{2\, n^2\, l_1}(\sec^4 \gamma_1)^2 \ldots\ldots\ldots\ldots\ldots\ldots (102)$$

A somewhat more precise expression for L_1 is[70]

$$L_1 = l_1 \left[\, 1 + \frac{8}{3}\frac{(f_1)^2}{(l_1)^2} + \frac{1}{2}\tan^2 \gamma_1 \right] \ldots\ldots\ldots\ldots\ldots (103)$$

By a similar derivation this gives

$$\Delta l_1 = \frac{\frac{16}{3}\frac{f_1}{l_1}}{\frac{1}{2}(1 + \sec^2 \gamma_1)}\, \Delta f_1 \ldots\ldots\ldots\ldots\ldots\ldots (104)$$

and

$$q = \frac{(n_1)^2\, l}{8\, n^2\, l_1}(1 + \sec^2 \gamma_1)^2 \ldots\ldots\ldots\ldots\ldots\ldots (105)$$

These changes make very little difference in the value of K. In fact, for practical purposes, the secant term could be neglected entirely as its effect on the value of K is small.

If this correction is accepted, not only should Eq. 11c be modified as described, but Eq. 14 which is derived from the same assumptions should also be modified.

The fundamental equilibrium equation, as it pertains to suspension bridges, may be stated as:

$$w + \Delta w = -\,(H + \Delta H)\left(\frac{d^2y}{dx^2} + \frac{d^2\eta}{dx^2}\right) + E\, I\left(\frac{d^4\eta}{dx^4}\right) \ldots\ldots (106)$$

The quantity Δw, being the inertial load per foot per cable, may be written:

$$\Delta w = \frac{w\, a}{g} = -\,\frac{w}{g}\,\omega^2\, \eta_x \sin \omega\, t \ldots\ldots\ldots\ldots\ldots\ldots (107)$$

Eq. 106 recognizes that the curve of the deflected cable is proportional to the moment diagram of the loading carried by the cable, and therefore the load on the cable is proportional to the second derivative of the cable curve. It recognizes also that the load carried by the deflected girder is proportional to the fourth derivative of the deflection curve of the girder. Eq. 107 recognizes that the inertial load in vibration is proportional to the second derivative of the deflection with respect to time. The quantity ΔH, being the result of the inertial loads, also contains the factor, sin ωt, so that the fundamental equation can be written in the form:[71]

---

[70] "The Theory and Practice of Modern Planned Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, John Wiley & Sons, Inc., New York, N. Y., 1917, p. 195.

$$-\frac{E\,I}{H}\frac{d^4\eta}{dx^4}+\frac{d^2\eta}{dx^2}+\frac{w}{H\,g}\,\omega^2\,\eta=\frac{\Delta H\,w}{H^2}\ldots\ldots\ldots\ldots\ldots(108)$$

If, instead of the unknown frequency, ω, the dimensionless quantity

$$\mu=\sqrt{\frac{w}{H\,g}}\,\frac{l\,\omega}{2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(109)$$

is used, the following equation results:

$$-\frac{E\,I}{H}\frac{d^4\eta}{dx^4}+\frac{d^2\eta}{dx^2}+\left(\frac{2\,\mu}{l}\right)^2\eta=\frac{8\,f}{l^2}\frac{\Delta H}{H}\ldots\ldots\ldots\ldots(110)$$

Letting $\frac{H}{E\,I}=k^2\left(\frac{2}{l}\right)^2$:

$$\frac{d^4\eta}{dx^4}-\left(\frac{2\,k}{l}\right)^2\frac{d^2\eta}{dx^2}-\left(\frac{4\,\mu\,k}{l^2}\right)^2\eta=-\frac{8\,f}{l^2}\frac{\Delta H}{H}\left(\frac{2\,k}{l}\right)^2\ldots\ldots(111)$$

Eq. 111 is a standard differential equation, the special solution of which is[72]

$$\eta=C_1e^{2k_2\frac{x}{l}}+C_2e^{-2k_2\frac{x}{l}}+C_3e^{2i\mu_2\frac{x}{l}}+C_4e^{-2i\mu_2\frac{x}{l}}+\frac{2f\Delta H}{H\mu_2}\ldots\ldots(112)$$

in which $i=\sqrt{-1}$

$$(k_2)^2=k^2\left[\sqrt{\left(\frac{\mu}{k}\right)^2+\frac{1}{4}}+\frac{1}{2}\right]\ldots\ldots\ldots\ldots\ldots(113a)$$

and

$$(\mu_2)^2=k^2\left[\sqrt{\left(\frac{\mu}{k}\right)^2+\frac{1}{4}}-\frac{1}{2}\right]\ldots\ldots\ldots\ldots\ldots(113b)$$

For the symmetric modes, η has the same value for $+x$ as it has for the corresponding $-x$. When this fact is used the first two quantities on the right side of Eq. 112 combine as a hyperbolic function and a single constant. The terms involving i may be written as trigonometric functions and there results the equation

$$\eta=Y\cosh\frac{2\,k_2\,x}{l}+A\cos\frac{2\,\mu_2\,x}{l}+\frac{2\,f\,\Delta H}{H\,\mu^2}\ldots\ldots\ldots\ldots(114)$$

The general relation between deflection and moment in the stiffening truss is

$$\frac{d^2\eta}{dx^2}=-\frac{M}{E\,I}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(115)$$

Making use of this relationship, the following equation is obtained from Eq. 112:

$$\eta=\frac{2\,f\,\Delta H}{H\,\mu^2}\left[1-\frac{(k_2)^2}{(\mu_2)^2+(k_2)^2}\,\frac{\cos\frac{2\,\mu_2\,x}{l}}{\cos\mu_2}-\frac{(\mu_2)^2}{(\mu_2)^2+(k_2)^2}\,\frac{\cosh\frac{2\,k_2\,x}{l}}{\cosh k_2}\right].(116a)$$

---

[71] "The Failure of the Tacoma Narrows Bridge," a report to the Hon. John M. Carmody, Administrator of the Federal Works Agency, Washington, D. C., March 28, 1941, by a board of engineers consisting of O. H. Ammann, Theodor von Kármán, and Glenn B. Woodruff, Appendix VI, p. 15, Eq. 10.

[72] "Elements of the Differential and Integral Calculus," by W. A. Granville, P. F. Smith and W. R. Longley, Revised Ed., Ginn & Co., 1934, p. 403.

Eq. 116*a* holds between the limits of $x = \pm \frac{l}{2}$. For the side spans in which x varies between $\pm \left(\frac{l}{2} + l_1\right)$, the following equation may be derived:

$$\eta = \frac{2 f \Delta H}{H \mu^2} \left[1 - \frac{(k_2)^2}{(\mu_2)^2 + (k_2)^2} \frac{\cos \mu_2 \left(1 + \alpha - \frac{2x}{l}\right)}{\cos \alpha \mu_2} - \frac{(\mu_2)^2}{(\mu_2)^2 + (k_2)^2} \frac{\cosh k_2 \left(1 + \alpha - \frac{2x}{l}\right)}{\cosh \alpha k_2} \right] \ldots\ldots\ldots\ldots (116b)$$

in which $\alpha = \frac{l_1}{l}$.

To this point the foregoing development follows that of Mr. Rannie quite closely, differing only in that a more exact term for truss stiffness is used by the writers. The writers' development differs further from that by Mr. Rannie in that cable extensibility is taken fully into account.

The extension of the entire cable from anchorage to anchorage, $L - L_0$, can be expressed as $\frac{\Delta H}{A\ E} \int_{-0.5\ l - l_1}^{0.5\ l + l_1} \frac{ds^2}{dx}$. The term, $\int \frac{ds^2}{dx}$, is often referred to simply as L_T, and was evaluated by Mr. Steinman in a previous paper.[73] The foregoing relationship may be expressed as

$$L - L_0 = \frac{\Delta H}{A\ E} L_T \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (117a)$$

With a fair degree of approximation the value of $L - L_0$ can be obtained from the geometry of the cable and stated as follows:

$$L - L_0 \approx \frac{8 f}{l^2} \int_{-0.5\ l - l_1}^{0.5\ l + l_1} \eta\, dx \ldots\ldots\ldots\ldots\ldots\ldots (117b)$$

Substituting in Eq. 117*b* the expressions for η in Eqs. 116, integrating over the entire length of the bridge, and then equating Eqs. 117 results in the expression:

$$\tan \mu_2 + 2 \tan \alpha \mu_2 = (1 + 2 \alpha) \mu_2 - \left(\frac{\mu_2}{k_2}\right)^3 (\tanh k_2 + 2 \tanh \alpha k_2) + (1 + 2 \alpha) \frac{(\mu_2)^3}{(k_2)^2} - C (\mu_2)^3 \left[\frac{(\mu_2)^2 + (k_2)^2}{k^2}\right] \ldots\ldots\ldots (118)$$

in which $C = \frac{L_T H_w l}{16 f^2 A E}$ and μ, μ_2, k, and k_2 have the values indicated in connection with Eqs. 112 and 113.

In the development of Eq. 117*b* the approximation is made that $\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{1.5} = 1$. If this approximation is not used the more rigorous solution gives the same equations as the foregoing except that $L_T = \int \frac{ds^2}{dx}$ is replaced by $\int \frac{ds^3}{dx^2}$, sometimes referred to as L_S. This solution satisfies the requirement that the sum of the kinetic energy, elastic energy, and energy of position must be constant for a given frequency and amplitude. The difference between L_S and L_T, however, is not significant.

---

[73] "A Generalized Deflection Theory for Suspension Bridges," by D. B. Steinman, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1145.

If the dead load of the side span varies from that of the main span in the ratio of $w_1/w = \beta$, Eq. 116*b* becomes

$$\eta = 2f \frac{\Delta H}{H \mu^2} \left[1 - \frac{(k_s)^2}{(\mu_s)^2 + (k_s)^2} \frac{\cos \mu_s \left(1 + \alpha - \frac{2x}{l}\right)}{\cos \alpha \mu_s} - \frac{(\mu_s)^2}{(\mu_s)^2 + (k_s)^2} \frac{\cosh k_s \left(1 + \alpha - \frac{2x}{l}\right)}{\cosh \alpha k_s} \right] \qquad (119)$$

in which

$$(k_s)^2 = k^2 \left[\sqrt{\beta \left(\frac{\mu}{k}\right)^2 + \frac{1}{4}} + \frac{1}{2} \right] \qquad (120a)$$

and

$$(\mu_s)^2 = k^2 \left[\sqrt{\beta \left(\frac{\mu}{k}\right)^2 + \frac{1}{4}} - \frac{1}{2} \right] \qquad (120b)$$

Similarly, Eq· 118 becomes

$$\tan \mu_2 + 2\phi\beta \left(\frac{\mu_2}{\mu_s}\right)^3 \tan \alpha \mu_s = (1 + 2\alpha)\mu_2 - \left(\frac{\mu_2}{k_2}\right)^3 \tanh k_2 - \frac{2\phi}{\sqrt{\beta}} \left(\frac{\mu_s}{k_2}\right)^3 \tanh \alpha \sqrt{\beta} \frac{\mu_2}{\mu_s} k_2 + (1 + 2\alpha) \frac{(\mu_2)^3}{(k_2)^2} - C (\mu_2)^3 \left[\frac{(\mu_2)^2 + (k_2)^2}{k^2} \right] \qquad (121)$$

in which $\phi = \dfrac{2 (\mu_2)^2 + k^2}{2 (\mu_s)^2 + k^2}$.

In Eq. 118, μ_2 must be determined by trial. This may be facilitated by plotting each side of the equation against μ_2 and noting the intersections of the curves that give the successive values of μ_2 which satisfy the equation.

Fig. 19 shows the general forms of these curves. Curves (1) show the left side of the equation, curve (2) shows the right side, and curve (3) shows the right side if the last term (which includes the effect of cable extension) is omitted. It will be noted that cable extensibility may have a quite marked effect on the frequency of a lower mode but has relatively little effect on that of the higher modes. With or without this factor the intersections for higher values of μ_2 approach odd multiples of $\frac{\pi}{2}$ or of $\frac{\pi}{2\alpha}$. It should be noted, furthermore, that C is the only term in Eq. 118 that is affected by the dead load. The expression for C contains H_w and, therefore, is directly proportional to w.

Comparison with Observations.—Tests made on the model of the original Tacoma Bridge indicated that the frequency of oscillation of both the asymmetric and symmetric modes can be predicted with about the same degree of precision by either Mr. Steinman's, Mr. Rannie's, or the writers' equations. The author's equations have the advantage of simplicity, at least for the symmetric modes (n is odd).

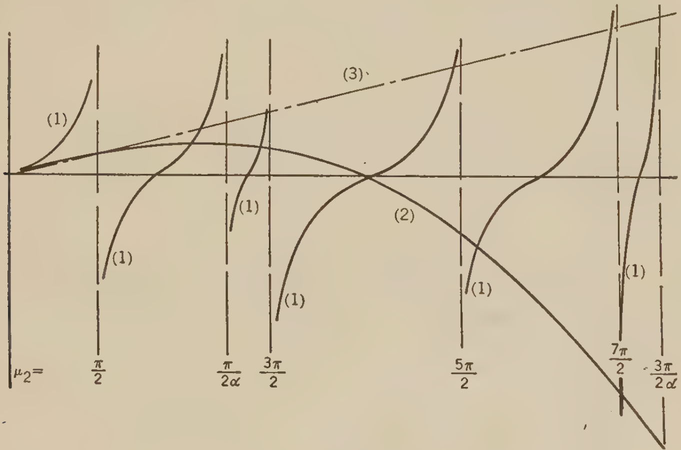

FIG. 19.—SOLUTION OF EQ. 118

When in the supplemental tests unloaded backstays were substituted for the loaded side spans, it was found that, for the asymmetric modes (but not for the symmetric ones), both the author's and the writers' equations had equal validity.

The symmetric modes with unloaded backstays (curves IV, V, and VI, Fig. 20), however, are greatly distorted as compared with the waves on the original bridge (curves I, II, and III, Fig. 20). No fundamental mode could be produced on the model, either by wind action or manually, but two distinct two-node (three-wave) movements developed readily under wind action. One had a very long middle wave and the other a very short one. A four-node (five-wave) movement of nearly equal wave segments also developed readily. Eq. 15 gives values for frequency which usually miss the observed values by plus or minus 10% or more. Although the results of the writers' equations do not check observed values as closely as in the case of the original bridge, they are much more consistent with observations than are the results of Mr. Steinman's equations. It appears probable that the weight and vertical movement of the backstays, neglected in the derivation of the author's equation, should be taken into account.

Table 11 shows prototype conditions with unloaded backstays tested on the model, with a comparison of observed and computed frequencies. The span lengths and main-span sag are the same as for the original Tacoma Bridge. The weight per foot of the main span is varied. The weight of the cable is constant throughout. Blanks in Table 11 indicate modes for which the equation or observation involved gives no value—that is, the equation does not indicate the mode or (in the "observed" column) the mode did not occur.

The wave forms (as distinct from the frequencies) of the asymmetric modes obtained from the different formulas are substantially similar, both for the original bridge and for the bridge with unloaded backstays.

4	5	20.8	20.4	21.9	20.9	20.7	20.5	20.4	19.8	21.0

However, for the symmetric modes (n is an odd number), the various formulas give wave forms that differ significantly, as can be seen by referring to the typical charts in Fig. 20. Curves I, II, and III are typical of the original bridge; and curves IV, V, and VI of the original bridge with unloaded backstays with the dead load per foot on the main span increased 32%.

It will be seen that all the equations are reasonably precise for the conditions in which the observed wave segments are about equal. The differences in amplitude, shown best in condition I, Fig. 20, arise principally from two sources:

(1) The curves in Fig. 20, calculated from Mr. Steinman's equations for the main span and side span, are assumed to be sine waves correlated by the required ratio of their amplitudes, $\frac{a}{a_1} = \frac{2\, l_1}{l\, n_1} \frac{n}{\sec^4 \gamma_1}$, whereas those by Mr. Rannie are not true sine curves but are represented by a modified trigonometric equation similar to Eq. 116*a* but with the hyperbolic term omitted. Because of Mr. Rannie's basic assumptions the negative and positive areas under his curves must balance. This difference is most evident in the form of the main-span wave (see Fig. 20, curve I).

(2) The curves in Fig. 20 calculated from the writer's equations differ from both of the others because the extension of the cable recognized in the writers' formulas permits a given downward deflection of the main span to take place without being fully balanced by the upward deflection of the side span. The effect of this factor is shown also in condition III, Fig. 20, in which the writers' side-span deflection is actually reversed from the direction required to balance the waves. A more striking example of this effect is found on the model of the proposed new design for the Tacoma Bridge. No vertical oscillations have been produced by wind action on this model but several modes have been produced manually. Among these is one of the form shown in Fig. 21. This is reproduced faithfully by the writers' Eqs. 116. Of course, this form of wave can occur only if the length of the cable changes during oscillation.

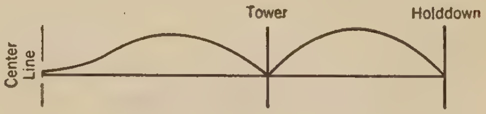

FIG. 21

In cases where the observed lengths are quite unequal, as in conditions IV and V (unloaded backstays), Fig. 20, the writers' equations give very satisfactory results. It is obvious that Eq. 15, based upon wave segments of equal length, cannot represent these conditions adequately.

Eqs. 21*a* and 21*b* properly relate torsional rigidity to vertical rigidity when the torsional stiffness of the suspended structure is neglected. Investigations to date seem to indicate that the torsional stiffness of the suspended structure as usually designed may be neglected without appreciable error. However, the writers' studies indicate that the effect of torsional stiffness does become significant if top and bottom lateral systems are provided.

The author presents, in simple form, equations which adequately predict a large proportion of the movements of a suspension bridge. However, the writers believe that the equations they have derived following Mr. Rannie's basic method have some advantages over those of the paper because, as has been shown by tests on the model, not only can these equations be used to predict performance with results equal in validity to those obtained from the author's equations in those cases in which the author's equations apply, but can also be used to make reliable predictions in those cases in which the author's equations would lead to erroneous conclusions. However, it seems reasonable to anticipate that the author will be able to modify his equations to give them more general and rigorous application.

Louis Balog,[74] Esq.—The basic formula of this paper is Eq. 6, representing the stiffness of suspension bridges by the summation of expressions that characterize the stiffness of the component parts—cable and girder—of the center span. The cable is assumed to be a string under tension, rigidly held at its ends; the girder, to be a simple beam of uniform section. The accuracy of this approximation when determining the frequencies of a practically unstiffened bridge is well indicated by the agreement between the calculated and observed values for the Tacoma Narrows Bridge. However, the equations given for the condition of three spans coupled do not define the values of n_1 corresponding to values of n in Table 1. For bridges with stiffening girders of small rigidity, the exceedingly simple Eq. 17, which was presented by Joseph Melan in 1906,[75] gives useful results. The frequencies of the Tacoma Narrows Bridge differed by only 6% up to the observed $n = 9$, from those obtained by Eq. 17.

The K-values of Eq. 6 are characteristic of deformation when the algebraic sum of the areas of the two segments below and above the initial condition of the cable equals zero, or when the deformation occurs without change in H, without stretch of cable, without movements of the towers, and without involving the side spans. For these reasons, Eqs. 16 and 22 cannot reliably be

---

[74] Cons. Engr., New York, N. Y.

[75] "Handbuch der Ingenieurwissenschaften," by Joseph Melan, Vol. 5, 3d Ed., Leipzig, 1906, pp. 208–214.

used for estimating live-load deflections and rotations which, besides being influenced by the enumerated changes, are also affected by the ratio of live load to dead load. The close agreement in Example 2 and Example 4 between the results obtained from these equations and those obtained from the deflection theory is accidental as shown in Table 12.

The application of Eqs. 16 and 22 to a number of bridges in addition to those in Table 12 resulted in deviations, up to a maximum of 48%, from the values obtained by the deflection theory. These deviations also prove that the author's physical interpretation of the $\frac{2K}{b}$-values (as the loading from tower to midspan in pounds per square foot which produces a 1-ft quarter-point deflection of stiffened suspension bridges) is incorrect. The percentages given are indicative of the accuracy of this interpretation.

The basic cable term of Eq. 6, $\frac{l^2}{H} = \frac{8f}{w}$, however, can be used for the calculation of quarter-point deflections of the unstiffened cable, due to the loading mentioned, if it is considered to be inextensible and fixed at the towers. For this condition, $\eta_{0.25} = f\left(4 + \frac{8w}{p}\right)^{-1}$. For $p = 100$, considering the prevailing dead loads, $\frac{w}{p}$ is between 12 and 150 and, even in the extreme case, the average value, $\eta_{0.25} = 1.525\,\frac{l^2}{H}$, is a close approximation ($\pm$ 2%) of the correct values.

To connect the stiffness and aerodynamic behavior of suspension bridges, the author evaluates Eq. 6 for twenty bridges, divides these values by the width, and lists the bridges in order of the magnitude of these values (Table 2). From experience the author states that stability requires these K per foot values to be not less than 15 for bridges stiffened by plate girders and not less than 6 for truss-stiffened bridges. In this manner, an empirical connection is established between the $\frac{2K}{b}$-values and the aerodynamic oscillations of suspension bridges.

The use of the basic terms of Eq. 6 to express the stiffness of a suspension bridge cable and its stiffening girder has been practicable in suspension bridge design. The concept of extending these terms by the corresponding first harmonic coefficients and dividing their sum by the width of the bridge is new; as is the significance ascribed to the resulting values by the author.

The practical meaning of the author's requirements for the minimum values of $\frac{2K}{b}$, for the $\frac{l}{d}$-ratio of 100, and for the minimum values for K and R can best be discussed by the application of these rules to several suspension bridges representing the span range of structures actually built.

Table 13 demonstrates that, for spans longer than 1,000 ft, the requirements result in plate girders of impractical dimensions. For the Golden Gate Bridge, trusses would be required which would nearly double the cost of the structure. This bridge has been exposed for seven years to the most unfavorable wind conditions experienced by any of the large suspension bridges and has exhibited dynamic stiffness sufficient for its use and safety. Observed oscillations for winds of from 60 miles per hr to 78 miles per hr were quickly damped out when the wind velocity decreased. Therefore, the Golden Gate Bridge may be assumed to represent the limit of satisfactory dynamic behavior, contradicting the general validity of the author's dynamic stability criteria.

TABLE 13.—APPLICATION OF THE AUTHOR'S MINIMUM REQUIREMENTS FOR $\frac{2\,K}{b}$-VALUES AND $\frac{l}{d}$-VALUES TO VARIOUS BRIDGES

Bridge	Type	Center span (ft)	(a) GIRDER AS BUILT			(b) MINIMUM REQUIREMENTS				
			Depth (ft)	I (in.^{2}-ft^2)	K (Eq. 6)	Depth (ft)	I (in.^{2}-ft^2)	K (Eq. 6)	$\frac{d}{b}$	Increase in cable area (%)
Golden Gate.....	Truss	4,200	25.0	44,000	116	42.0	520,000	270	0.47	75
Tacoma Narrows.	Plate girder	2.800	8.0	1,000	62	28.0	165,000	300	0.72	157
	Truss	2,800	....	....	..		50,000	120		33

	Truss	2,300	....	....	..		38,000	222		18
Deer Isle.........	Plate girder	1,080	6.5	424	69	10.8	6,000	300	0.46	75
	Truss	1,080	....	....	..		1,860	120		4
Thousand Islands.	Plate girder	800	6.0	252	127	8.0	1,600	300	0.26	21
	Truss	800	....	....	..		330	145		0

The requirement that plate-girder stiffened bridges be 150% stiffer than truss-stiffened bridges eliminates their use. The requirement that $\frac{l}{d} = 100$ has the same effect because it is destructive to advantageous $\frac{d}{b}$-ratios. Nor could plate girders be used for spans longer than 1,000 ft if $\frac{l}{d} = 100$ and an H-section had to be maintained. Nevertheless, the author concentrates on the investigation of this section which, in view of experience and his recommendations, has lost its practical importance.

The author's analysis of the aerodynamic excitation of vertical and torsional oscillations is based on the characteristic drag, lift, and torque curves obtained on section models of the Tacoma Narrows Bridge. By idealizing the laboratory results, the author obtains a family of lift graphs corrected for drag (Fig. 5). The introduction of the K-values into the frequency, as well as into the energy, relations of vertical and torsional oscillations has the effect of establishing the connection between s' (the slope of the corrected lift graph) or s_t (the slope of the torque graph)—both for $\alpha = 0$—K, V, β, and the aerodynamic amplification ratio δ. The arbitrary function, β, of the phase difference across the section is also introduced for vertical oscillations to explain the behavior of the Tacoma Narrows Bridge in the low-velocity range. The values of δ_s, derived from the moment of inertia of the girders equated with δ, result in Eqs. 44 to 46 for the critical velocities of vertical oscillations and in Eqs. 62 to 64 for the critical velocities of torsional oscillations.

The author proves the validity of these equations by examples which give values corresponding to the observations on the Tacoma Narrows Bridge. Applying the equations to other bridges, however, the results are not convincing. For the Thousand Islands (across the St. Lawrence River), Bronx-Whitestone, and Golden Gate bridges $\left(\frac{0.5\,d}{b} = 0.139\right)$, Eq. 45*b* with $n = 9$ yields 48, 85, and 70 miles per hr, and Eq. 46*b* with $n = 2$ yields 5, 1.7, and 2 miles per hr, respectively. The Tacoma Narrows Bridge subjected to a wind velocity of 42 miles per hr changed from a vertical oscillation with $n = 9$ to a violent torsional oscillation with $n = 2$. The maximum critical velocities determined by the author's equations were experienced by the enumerated bridges without any such effects. For this reason, the practical meaning of Eqs. 45 and 46 is not apparent.

Eqs. 62, 63, and 64, which show increasing safety from torsional oscillations, with decreasing width, also do not give results consistent with the behavior of actual structures. For more than five years the Bronx-Whitestone Bridge was exposed to wind velocities as great as 95 miles per hr, but at no wind velocity did torsional oscillations occur. Using Eq. 62*a*, the critical velocity of torsional oscillations of this bridge is 18.2 miles per hr; and, using Eq. 64*a*, 18.5 miles per hr. Assuming that everything is unchanged except that the bridge is narrowed to half of its width, then, for $\frac{b^2}{w} = 0.25$, Eq. 62*a* results in a critical velocity of 20.8 miles per hr, and Eq. 64*a* yields a critical velocity of 21.6 miles per hr. Such a drastic variation in the $\frac{b^2}{w}$-value did not change the critical velocities appreciably.

The evaluation of observations on the Tacoma Narrows Bridge and on its section models failed to give generally valid relations even for the solid H-section. The author's analysis is more interesting from the point of view of procedure than of practical applicability to design. This fact is apparent from "Part 4.—Methods of Securing Rigidity and Aerodynamic Stability," in which the proposed measures do not follow from the application of the results of the presented analysis. The condition $\delta - \delta_s = 0$ is a basic relation in the critical velocity equations (see heading, "Part 2.—Aerodynamic Excitation of Vertical Oscillations: Structural Damping") where δ_s is essentially a function of R, the proportion of K due to I (the moment of inertia of the girder sections). In building up the resistance of the structure to aerodynamic action with stay ropes, the author assigns a new meaning to δ_s by explaining (see heading, "Part 4.—Methods of Securing Rigidity and Aerodynamic Stability: Use of Longitudinal Stays") the mechanical interference of stays with oscillations; and then writes (but without derivation) Eq. 65 for the amount that K is augmented by the stays. Eq. 65 is similar to the cable term, and not to the girder term, of Eq. 6, S being a function of a unit stress and the initial stay rope sag. Hence, the addition of this quantity to the girder term in the equation for K, to show a desired degree of increase in R is not warranted by the author's explanations or by the fact that pre-stressed stay ropes stiffen a suspension bridge to a certain extent. With the recommended minimum $K = 300$, the cost of the Tacoma Narrows Bridge, stiffened by plate girders, would be more than doubled (see Table 13); whereas by application of 16 sq in. of wire rope strand, in the form of longitudinal diagonal stays, the K-value of the bridge that failed would be raised to 332 and R would be increased to 0.816. In other words, a structural damping well above that of the Williamsburg Bridge would be secured at insignificant expense. This result, which is of great economic importance, demands a more thorough proof than the explanations in the paper. Experience with stays and reference to the Brooklyn Bridge, which was stiffened by six trusses, without stays, having values of $K = 190$ and $R = 0.22$, do not prove the author's claims.

The author's reference to the interference of transverse diagonal stays and top struts, with the out-of-phase movement of the cables, does not prove that Eq. 66*a* represents quantitatively the dynamical effectiveness of this arrangement (Fig. 9). The makeshift appearance of this detail (which has been used on ore-transport suspension bridges) does not befit the permanent and monumental character of a vehicular bridge structure.

The author's statement that the aerodynamic forces causing the vertical and torsional oscillations of the H-section can be eliminated or reduced to negligible proportions by leaving open spaces near the girders or by open-floor construction (see heading, "Part 4.—Methods of Securing Rigidity and Aerodynamic Stability: Use of Open-Floor Construction") is contradicted by experience and wind-tunnel tests. The Bronx-Whitestone Bridge was constructed in the following stages:[76]

(1) All steel, including reinforcing grid with floor plates attached, was erected and sidewalk areas were open, leaving two lateral vents with a total width of 13 ft $\sim \left(\frac{3\,b}{16}\right)$. At this stage, $\frac{b^2}{w} = 1.41$.

(2) Roadway concrete was poured and sidewalk areas were still open. At this stage, $\frac{b^2}{w} = 1.10$.

(3) Sidewalk concrete was poured and the vents in stage (1) were closed. At this stage, $\frac{b^2}{w} = 1.0$.

In none of these stages, nor during the following five years, did the bridge have any torsional oscillations. Its largest vertical oscillations occurred, however, during stage (1) when, according to Eq. 60, the aerodynamic lift was reduced 60%, and, in addition, the multiplier β was reduced 40%.

Homer M. Hadley, Assoc. M. Am. Soc. C. E., describing experiments with the 100-ft scale models of the Tacoma Narrows Bridge, states:[77]

> "The steelwork of the original deck was reproduced to scale—8 ft. marginal stiffening girders, floor beams, stringers and wind trusses—but the floor slab and sidewalks were omitted. This model lacked 20 percent of the stabilizing weight of the prototype $\left[\frac{b^2}{w} = 0.67\right]$ * * *. It was tested with and without midspan diagonal stays. Without stays * * * it quite closely reproduced the vertical undulations of the prototype and torsional movements as well."

---

[76] *Construction Methods*, Vol. 21, June, 1939, p. 46.

[77] *Engineering News-Record*, November 4, 1943, p. 80.

Neither closing nor opening the horizontal member of the solid H-section altered the aerodynamic behavior of the section as Eqs. 43 and 60 indicate; and the dimensional ratio $\frac{b^2}{w}$ cannot be offered as a measure of sensitiveness to torsional aerodynamic instability.

The structural arrangements, recommended by the author as methods for securing aerodynamic stability, have been used on actual bridges and in proposed designs for many years. It is not proper to call the H-section "conventional." Many existing suspension bridges have shallow, deck plate-girder, suspended structures, and it is purely accidental that long-span bridges using this form have not been built. Such suspended structures were proposed for the 3,000-ft Wilmington Bridge, in Delaware, and also for the 4,700-ft Battery-Brooklyn Bridge in New York, N. Y., in 1939, because this design satisfied the requirements of those bridges better than the H-section. All stay systems (center, longitudinal, and transverse, Figs. 8 and 9) discussed by the author were suggested by others, or were tested in practice long ago, and then as now they have proved themselves mostly inefficient. In 1926, open sidewalk spaces were used in the design of the proposed bridge over the First Narrows, Vancouver, B. C., Canada, by Henry C. Tammen, M. Am. Soc. C. E. Also, the 1,050-ft Otto Beit Bridge, built in 1938, over the Zambezi River in Rhodesia, Africa, is provided with lateral vents of width $\frac{3\,b}{16} \sim 6$ ft. Outside sidewalks have been used on bridges too numerous to list. Static or structural considerations suggested all these arrangements. Their effectiveness for securing aerodynamic stability is not supported by experience or experimental evidence.

Simple relations derived from the rigidity characteristics of a basic structure actually constructed seem to gage the sufficiency of stiffening trusses for aerodynamic stability. To establish such empirical relations, the dimensional properties of the bridges will be expressed by the cable and girder stiffness parameters: $\pi_1 = \frac{l^2}{H} = \frac{8\,f}{w}$ and $\pi_2 = \frac{l^4}{E\,I}$, and, by their ratios, the dimensionless parameters: $\pi_3 = \frac{\pi_2}{\pi_1} = \frac{H\,l^2}{E\,I}$ and $\pi_4 = \frac{\pi_2}{\pi_{1B}}$. The parameter π_{1B} refers to the basic structure. The writer utilized these parameters by equating the π_3-values of the Golden Gate and Bronx-Whitestone bridges, thus deriving the value of I required to stiffen the latter structure in 1941. At a conference on November 3, 1941, Shortridge Hardesty, M. Am. Soc. C. E., who was asked to pass on the sufficiency of the design, outlined a dependable deflection method on which he based his recommendations. For two basic structures, Golden Gate and Lions' Gate, the two methods gave identical results. General utilization of these parameters will be effected by means of a representation in which the π_3 and π_4 values of the bridges are referred to parabolic curves obtained by assuming the span length to be variable in the following expression of the π_3-value of the basic structure:

$$\pi_{3x} = \pi_{4x} = \left(\frac{H}{E\,I}\right)_B (l_x)^2 \ldots\ldots\ldots\ldots\ldots\ldots (122)$$

Eq. 122 contains the aerodynamic and structural damping characteristics of the basic structure and indicates, for another structure of similar aerodynamic characteristics, the corresponding amount of structural damping that will assure stability, in the form of a requirement for the moment of inertia of the girders. For the reasons stated in connection with Table 13, the Golden Gate Bridge was selected as the basic structure. Introducing its $\frac{H}{E\,I}$-value into Eq. 122, a criterion of satisfactory dynamic behavior is obtained as follows:

$$\pi_{3x} \gtreqless \pi_{4x} \gtreqless 0.3872 \times 10^{-4}\,(l_x)^2 \ldots\ldots\ldots\ldots\ldots\ldots \quad (123)$$

and the required moment of inertia of the stiffening trusses becomes:

By considering π_{3x} and solving Eq. 123 for I_x—

$$I_x = \left(\frac{I}{H}\right)_B H_x = 0.00089\,H_x\ (\text{in.}^2\text{-ft}^2) \sim 0.0009\,H_x\ (\text{in.}^2\text{-ft}^2) \,..\,(124a)$$

by considering π_{4x} and solving Eq. 123 for I_x—

$$I_x = \left(\frac{I}{l^2}\right)_B (l_x)^2 = 0.00499\,(l_x)^2\ (\text{in.}^2\text{-ft}^2) \sim 0.005\,(l_x)^2\ (\text{in.}^2\text{-ft}^2) \,..\,(124b)$$

[a] All bridges are truss type except those numbered 2, 4, 8, 18, and 21 which are plate-girder types. Item 19 combines both types. [b] Estimated from insufficient data. [c] Data supplied by Glenn B. Woodruff, M. Am. Soc. C. E.

Table 14 contains the numerical values of parameters π_1, π_2, π_3, and π_4 for twenty-four suspension bridges.

The π_1-values are plotted in Fig. 22. A circle is placed around the plots of the bridges that moved. Fig. 22 indicates that oscillations occurred in the full range of cable stiffness variation of bridges actually built. It shows that cable stiffness does not govern dynamic stability and demonstrates that weight is not only the most expensive but also is ineffective in controlling aerodynamic oscillations.

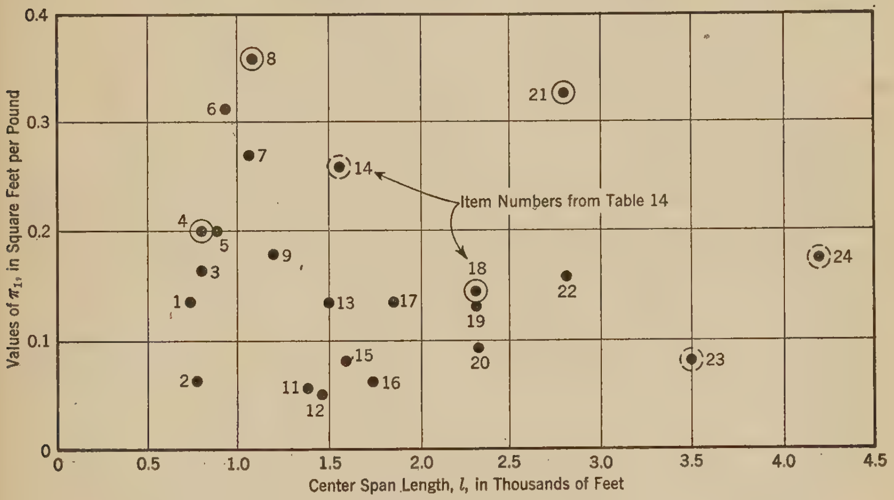

FIG. 22.—CABLE STIFFNESS OF SUSPENSION BRIDGES, AS MEASURED BY PARAMETER π_1 (Full Circle Denotes Objectionable, Dotted Circle Denotes Not Objectionable Movements)

Eq. 123 is represented by a curve passing through the ($\pi_3 = \pi_4$)-value of the Golden Gate Bridge in Fig. 23. The plotted points in Fig. 23(*a*) correspond to the first interpretation of the criterional parabola (Eq. 124*a*), representing the π_3-values. In Fig. 23(*b*) they correspond to the second interpretation (Eq. 124*b*), representing the π_4-values. The plots of those bridges with satisfactory resistance to aerodynamic action are near or below, and the plots of those with objectionable movement are considerably above, the curve, the divergence being nearly proportional to the character of the oscillations. When the distances of the plots are measured with the corresponding ordinates of the parabola, the deficiency or excess stiffness is indicated as compared with that required by Eqs. 124.

Table 15 lists the bridges in the sequence of their dynamic stiffness, as determined by the foregoing simple relations and the ratios of the required moment of inertia of the stiffening girders to the moments of inertia in the actual structures. Examination of Table 15 indicates some evident inconsistencies in both Eqs. 124*a* and 124*b*. However, the behavior of the actual structure is the integrated result of action and resistance since neither the acting forces nor the damping effects are shown quantitatively by the behavior. For this reason a consistent arrangement of the bridges in the order of their dynamic stiffness is unknown. Nevertheless, Fig. 23 disproves visibly "the high consistency and validity" of the stability criteria presented in the paper. For the Bronx-Whitestone Bridge, the author's minimum requirements (Table 13) result in trusses of 140% larger moment of inertia than is sufficient for stability; contrariwise for the Deer Isle and Thousand Islands bridges they result in

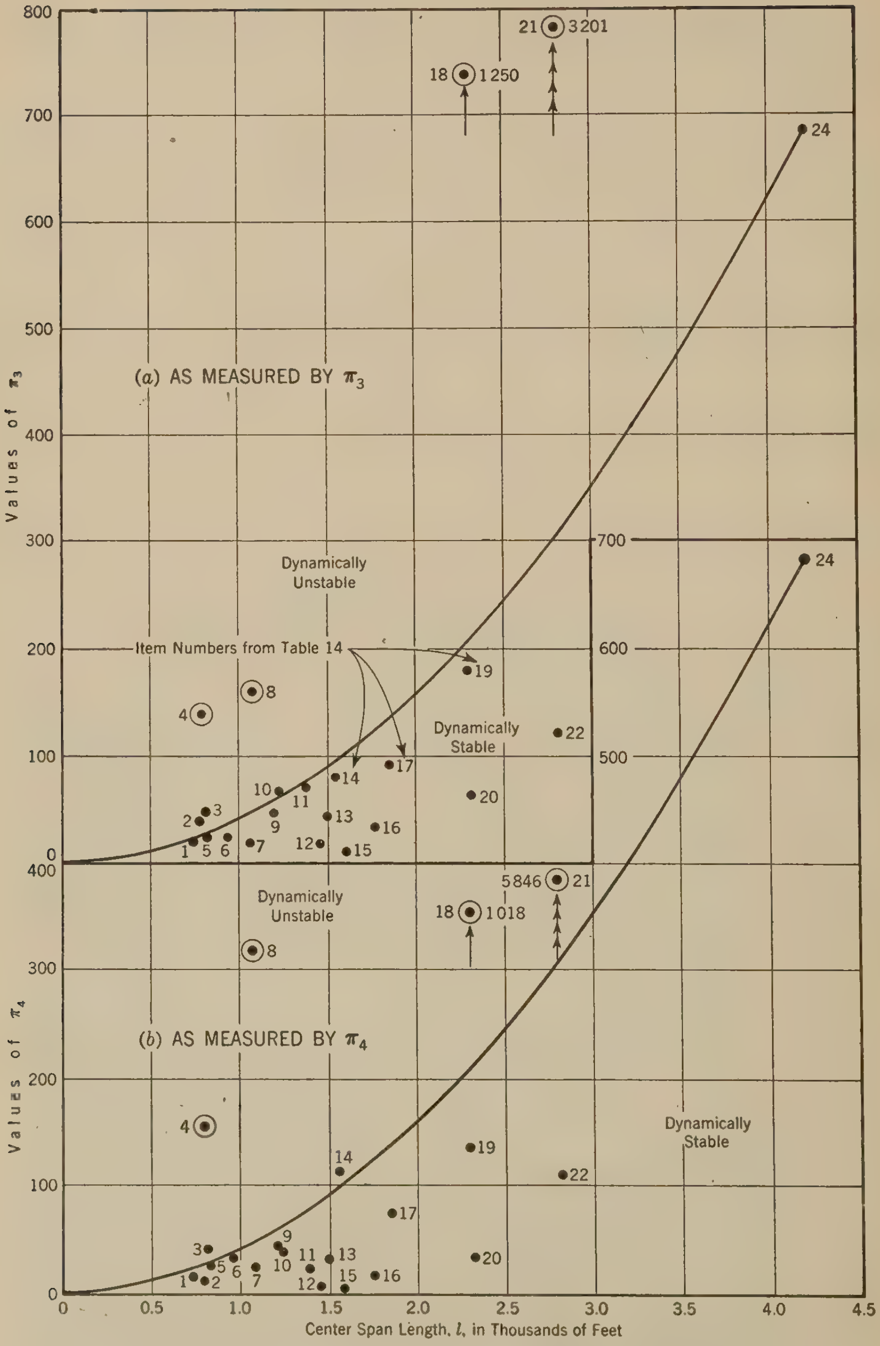

FIG. 23.—DYNAMIC STIFFNESS OF SUSPENSION BRIDGES, AS MEASURED BY DIMENSIONLESS PARAMETERS π_3 AND π_4

trusses, the moments of inertia of which are deficient 60% and 380%, respectively, as indicated by Fig. 23. (Bridges that are stable without satisfying this criterion have been discussed by the writer elsewhere.[78]) Any attempt, however, to derive aerodynamic stability from purely empirical considerations should be regarded as a temporary expedient for estimating purposes and should not take the place of specific experimental research for each structure to be designed.

TABLE 15.—Ratios of Required Moment of Inertia and Moment of Inertia in Actual Structure

Because the weight of the various characteristics affecting economical design for aerodynamic stability is not apparent from the results reported in the paper, the importance of the variation of the characteristics of the suspension bridge system as they influence aerodynamic stability will be examined. This examination reveals the following:

(1) Cable sag ($\sqrt{f}$) determines the fundamental frequency; hence the actual frequency variation is very small and its effect on stability irrelevant.

(2) Cable stiffness, predominately, determines the structural elastic stiffness. Consequently the requirements of static stiffness can often be met fully without trusses. Fig. 22 shows that within the limits of its practical variation, cable stiffness cannot assure aerodynamic stability.

(3) Trusses, within economically practical limits, contribute little to the structural elastic stiffness but they can be the principal contributors to structural damping. They represent, however, neither a progressive, nor always an economical, solution in the design for aerodynamic stability.

(4) Stay systems may be developed into efficient contributors to structural damping. Dynamic models overestimate the damping efficiency of stay

---

[78] *Engineering News-Record*, December 16, 1943, pp. 74–75.

systems grossly. The Bronx-Whitestone model indicated high damping effect for stays which, installed on the prototype, have been found insignificant. Wind-tunnel models equipped with stays should supply basic data for the development of efficient stay systems. Stay systems will then gain importance in the economical design for aerodynamic stability.

(5) Suspended structures which are aerodynamically stable, with or without efficiently provided additional structural damping, constitute the economical solution of the design problem of aerodynamic stability. In other words, the structure whose satisfactory static rigidity has been achieved the most economically will also be aerodynamically stable, or can be made so the most economically.

The author's equations are useless for the solution of the practical design problem, because neither the variation of aerodynamic damping with arbitrary modification of the shape of the suspended structure, nor the variation of structural damping resulting from any practical arrangement, can be calculated by them. In fact, they give inconsistent results even for shapes similar to the one from which they were derived, as proved by the behavior of existing bridges.

The author's conclusions recommending that stability be secured by increasing weight and depth must be rejected. The fundamental design principle of structural efficiency, expressed by lowering the ratio of the weight of metal in the structure to the live load the structure is able to carry, should never be abandoned, especially because weight, within any reasonable limit, does not assure dynamic stability. Analysis of the cost items of long-span suspension bridges clearly indicates the great economic significance of the reduction of weight. Deep girders also affect the cost unfavorably. The determination of stability, therefore, is primarily the task of aerodynamic research which should be connected directly with the design of suspension bridges until the experiments permit a clear theoretical interpretation.

D. B. Steinman,[79] M. Am. Soc. C. E.—To those engineers who have contributed discussions, challenging, confirming, or supplementing the material presented in this paper, the profession is indebted. A careful study of the data in the discussions reveals nothing that contradicts the writer's predictions and much that confirms his recorded conclusions. The writer welcomes the opportunity afforded by this closing discussion to answer the questions that have been raised, so that this study of a critical problem, enriched by the discussions, may be brought closer to complete solution and practical application.

Definitions.—For those who have been puzzled by the seemingly paradoxical conclusions of this paper, certain clarifying definitions may be helpful. Misconception has been caused by failure to perceive the distinction drawn by the writer between basic aerodynamic stability of the section and aerodynamic stability of the structure.

An "aerodynamically stable section" is one having a positive lift (or torque) graph. (Examples: A circular section, a half-round section with convex face toward the wind, a T-section with stem toward the wind, a conventional airfoil, a horizontal flat plate, and an H-section with $d/b < 0.24$.) The defining condition is s' (or s_t) > 0.

---

[79] Cons. Engr. (Robinson & Steinman), New York, N. Y.

An "aerodynamically unstable section" is one having a negative lift (or torque) graph. (Examples: A half-round section with flat face toward the wind, a T-section with head toward the wind, a vertical flat plate, and an H-section with $d/b > 0.24$.) The defining condition is s' (or s_t) < 0.

An "aerodynamically stable structure" is one in which no aerodynamic amplification of oscillations can occur. The defining condition is $\delta_s > \delta$.

An "aerodynamically unstable structure" is one in which aerodynamic amplification of oscillations can occur. The defining condition is $\delta_s < \delta$. (There are at least eight such bridges.)

On account of the phase-difference effect across the width of a section, aerodynamic instability of a structure may be produced with either stable or unstable sections. The basic aerodynamic stability or instability of the section influences the degree and the range of potential instability of the structure. If the section is aerodynamically stable, any instability of the structure is more limited in wind-velocity range and in amplitudes, and is more easily prevented or cured.

The Problem and Its Logical Solution.—The primary purpose of the paper was not to explain past events but rather to provide a basis for future practical application. Any reference to past or present structures is merely incidental, as a test of validity.

The practical problem of the bridge engineer must be kept in mind. The bridge engineer cannot, as a rule, afford elaborate wind-tunnel tests, scale models, and tests on oscillating section models for every bridge he has to analyze or design or for each successive preliminary design for a project. Rarely will time or financial limitations permit extensive investigations of such character. The governing relations must be reduced to scientific, mathematical form and then to guiding specifications to permit direct application in design.

For these reasons, the writer has endeavored to reduce the problem to four separate steps:

1. The simple determination of the rigidity characteristics of the structure, represented by the coefficient of rigidity K, enabling the frequency N to be computed accurately for any mode of oscillation;
2. The determination of the aerodynamic amplification characteristics of the structure, represented by the logarithmic increment δ, as a function of the cross section;
3. The determination of the potential instability, or amplification characteristics, at different wind velocities, represented by the variation of δ with $V/(N\,b)$ (supplied by the writer in the form of the β-function, which has a quantitative rational basis in the concept of the phase-difference effect); and
4. The evaluation of the positive damping characteristics of the structure, represented by the logarithmic decrement δ_s (tentatively covered by the writer's semi-empirical formulas for δ_s, in the form indicated by rational considerations and with coefficients and exponents written to fit available data and known behavior of actual structures).

These four steps, when combined, offer a complete solution for any structure. Their separation, for research and analysis, permits a logical and scientific attack. Without such clarification, much experimentation may become mere groping and mystification.

Rigidity of Suspension Bridges.—Table 2 was not presented as a proposed grading of the relative aerodynamic susceptibility of different bridges. It was merely an attempt, by the statistical method, to find the dividing line below which aerodynamic instability may be anticipated unless prevented.

The coefficient of rigidity K, or its quotient $2\ K/b$, constitutes a simple and convenient measure of rigidity. It epitomizes all that needs to be known about the structure from the viewpoint of elastic resistance to oscillations; it represents the combination of the theory of suspension bridges with the theory of mechanical vibrations—the remainder of the problem is concerned with aerodynamics and structural or mechanical damping. If K can be computed, there is little or no need for building costly scale models of the structure. All the aerodynamic questions can be answered better by small section models.

In emphasizing the significance of the quotient $2\ K/b$, the writer was endeavoring to correct the insistence by others that K, the rigidity per cable, is the sole criterion. Both $2\ K/b$ and K need to be considered, in conjunction with other factors. That K alone does not tell the entire story is indicated by the fact that the George Washington Bridge, with $K = 244$, despite its low value of d/b, is admitted to be subject to aerodynamic oscillations, whereas the Ambassador Bridge (between Detroit, Mich., and Windsor, Canada), the Grand Mère Bridge (in Quebec Province, Canada), the Mount Hope Bridge (in Rhode Island), and the Waldo-Hancock Bridge (in Maine), all with lower values of K, have been immune. The Canadian suspension span of the Thousand Islands Bridge and the Bronx-Whitestone Bridge have identical values of $K = 141$; yet the former, with a few light cable stays added, has had no reported oscillations, whereas the latter has had quite a different history. The Lions' Gate Bridge, with $K = 112$ and $2\ K/b = 5.62$, has not had the large oscillations that have been observed on the Golden Gate Bridge, with $K = 116$ but with $2\ K/b = 2.56$. The Tacoma Bridge, with $K = 62$, was destroyed within four months by the first 42-mile wind, whereas the narrower Deer Isle Bridge, with $K = 63$, plus a few light stays added, in a more exposed coastal location, has for five years repeatedly withstood storms of from 70 to 80 miles per hr. In these comparisons, if $2\ K/b$ is used instead of K and if the girder and truss bridges are segregated, the differences in behavior are understandable.

Besides the rigidity coefficients K and $2\ K/b$, other factors affecting the aerodynamic stability are truss or girder construction, the camber, the location and exposure, the cross section of the bridge, side-span and tower rigidity (in some modes), torsional bracing, the ratio d/b determining the aerodynamic constants, the structural damping δ_s (including any artificial damping devices), the ratio R helping to determine the structural damping, and the width factor b^2/w. Some of these governing numerical ratios, directly or indirectly, are represented as a composite function in the slenderness ratio, d/l. Practically all known suspension bridges with d/l less than 1/100 have shown aerodynamic instability. An exception is the Ronosfoss Bridge in Norway; its reported immunity (with $K = 62.5$ and $2\ K/b = 6.36$) is explained by an extremely low value of d/b, almost a flat plate, yielding very low aerodynamic lift and only positive (stabilizing) torque. The George Washington Bridge would have similar immunity, except for a low value of $2\,K/b$ ($= 4.60$) and the floor opening in the wrong place. The opening reduces passive atmospheric damping although it affects little reduction in the laterally concentrated lift pressures. The Grand Mère Bridge, with K only 188, is aerodynamically stable because the high value of $2\,K/b$ for a truss bridge represents high rigidity and the exceptionally high value of $R = 0.66$ creates very high structural damping. The Bronx-Whitestone Bridge, because of its width, has an abnormally high value of b^2/w (in fact, twice the normal value), which practically doubles the instability by doubling the value of δ to which the bridge is subjected.

Generalized K-Formula for Any Harmonic Modes.—The simple K-formulas originally presented (Eqs. 2 to 15) suffice to cover all modes of span oscillation previously recorded. To cover other possible combinations of spans, modes, and superimposed harmonics, a generalized formula for K may be written:

$$K = \frac{\pi^2 \Sigma\left(\frac{n^2\,a^2}{l}\right) H + \pi^4\,\Sigma\left(\frac{n^4\,a^2}{l^3}\right) E\,I + \frac{512}{\pi^2}\,\frac{E_c\,A_c}{L_s}\left[\Sigma'\left(\frac{a\,f}{n\,l}\right)\right]^2}{\frac{1}{w}\,\Sigma(w\,a^2\,l) + \frac{2}{w}\,\Sigma(w\,e^2\,l)} \quad ..(125a)$$

in which a is the vertical amplitude of any component mode in any span, e is the amplitude of longitudinal oscillation of any span; and L_s is a cable-length constant[73,80,81] given by

$$L_s = E_c\,A_c\,\Sigma \int_0^l \frac{1}{E_c\,A_c}\,\frac{ds^3}{dx^2} \approx E_c\,A_c\,\Sigma \frac{1}{E_c\,A_c}\left(l + 8\,\frac{f^2}{l}\right) \sec^3\gamma \quad ..(125b)$$

In Eqs. 125 and those that follow, Σ denotes summations covering all similar expressions in all spans, and Σ' denotes a summation covering only the odd values of n in the several spans.

In Eq. 125*a* and the following equations, and in all similar formulas involving summations of functions of the amplitudes, it is not necessary to know the absolute magnitudes of the several concurrent amplitudes (a and e) but merely the relative magnitudes.

Eq. 125*a* is completely general for any number of spans of any respective lengths, simple or continuous, with any respective cable sags, including straight or unloaded backstays, for any combinations of values of n and a in simple or superimposed harmonic oscillations in the different spans, with any concomitant longitudinal oscillations in any spans, with different values of w, H, $E\,I$, and $E_c\,A_c$ in different spans, and with any value of ΔH producing cable stretch.

The general formula for K, Eq. 125*a*, may be rewritten in a single compact expression of equal generality:

$$K = \frac{\Sigma(K\,a^2\,l)}{\frac{1}{w}\,\Sigma(w\,a^2\,l) + \frac{2}{w}\,\Sigma(w\,e^2\,l)} \quad \ldots\ldots\ldots\ldots\ldots\ldots(126a)$$

---

[80] "A Practical Treatise on Suspension Bridges, Their Design, Construction and Erection," by D. B. Steinman, 2d Revised Ed., John Wiley & Sons, Inc., New York, N. Y., 1929, p. 37 and pp. 250–251.

[81] "On the Deflection Theory of Suspension Bridges," by S. O. Asplund, Upsala (Stockholm), Sweden, 1943, p. 27.

in which K for each span or for each component mode has been computed separately by any of the pertinent formulas in this paper, including Eq. 125a or any reduced form of Eq. 125a.

With w equal in all spans, and with $e = 0$, Eq. 126a takes the simpler form:

$$K = \frac{\Sigma(K\, a^2\, l)}{\Sigma(a^2\, l)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(126}b\text{)}$$

which may also be written directly from the energy relation of Eq. 28b.

The last term in the numerator of Eq. 125a represents the effect of ΔH. It is ordinarily either zero (in antisymmetric modes) or of relatively minor magnitude. There will be no cable stretch between anchorages ($\Delta H = 0$) if

$$\Sigma'\left(\frac{a\, f}{n\, l}\right) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(127}a\text{)}$$

over all spans, or if

$$\Sigma'(a/n) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(127}b\text{)}$$

in each span—also, of course, for antisymmetric modes. (If the cable is anchored at midspan, as by center stays, and longitudinal oscillation of the span is prevented, Eq. 127a is applied over the half span and side span, or from the point of fixation to either anchorage, using the obviously modified values of n, f, and l.)

A simple short cut for estimating the value of K is to assume that $\Delta H = 0$. Consistent relative amplitudes are then given by Eq. 127a, and their substitution in Eq. 125a or 126b yields K with sufficient accuracy for all practical purposes (see Table 1).

Determination of K and Relative Amplitudes for Composite Modes.—A simple or primary mode is one represented by a single sinusoidal curve—hence, single values of n and of a, as in Eq. 5. The term "composite mode" is used herein to denote oscillations comprising a plurality (superimposed or coupled, or both) of simple modes, as in Eqs. 9 to 12.

For each symmetric component mode, the general formula for K is

$$K = \left(\frac{\pi^2\, n^2}{l^2} H + \frac{\pi^4\, n^4}{l^4} E\, I\right) + \left(\frac{512}{\pi^2}\, \frac{f}{l^2}\, \frac{E_c\, A_c}{L_s}\right) \frac{1}{n\, a}\, \Sigma'\left(\frac{a\, f}{n\, l}\right) \ldots \text{(128)}$$

This is a reduced and simplified form of the composite formula, Eq. 125a. It may be derived independently (compare Eq. 6), or it may be written by applying the mathematical condition for a minimum (or a maximum) to Eq. 125a.

In Eq. 128, the first two terms are identical with the basic Eq. 6, and the third term represents the correction for ΔH. Denoting the first two terms by K_n (defined by Eq. 6), and the constant dimensional factor in the third term by C, Eq. 128 may be written in convenient, compact form:

$$K = K_n + C\, \frac{1}{n\, a}\, \Sigma'\left(\frac{a\, f}{n\, l}\right) \ldots\ldots\ldots\ldots\ldots\ldots \text{(129)}$$

This is a basic equation in the theory that follows. For antisymmetric modes, K is simply equal to K_n.

For symmetric modes (necessarily composite), Eq. 129 is valid for each component mode; and, with the consistent (normal) relative amplitudes substituted, it must yield the same value of K (and, hence, the same frequency) for each component mode. To satisfy this condition, Eq. 129 yields two simple governing relations between K and the respective values of n, a, and K_n of the component modes:

$$\Sigma'\left(\frac{1}{n^2}\,\frac{C\,f/l}{K - K_n}\right) = 1 \qquad (130)$$

and

$$n\,a \propto \frac{1}{K - K_n} \qquad (131)$$

Eq. 130 yields the desired value of K for the normal (balanced) composite mode, and Eq. 131 gives the relative amplitudes of the component modes.

In practical application, the largest number of component modes necessary to be considered and substituted in Eq. 130 is three, and that is the case of the lowest symmetric mode ($n = 1$, $n = 3$, and $n_1 = 1$). In the higher symmetric modes, the superimposed harmonics prove negligible, and only two primary K_n-values need to be substituted, one for each span (example: $n = 3$ and $n_1 = 1$). Accordingly, Eq. 130 is in reality a quadratic, or cubic, equation for K. Each real root of this equation will represent a normal composite mode with a mathematically and physically consistent set of relative amplitudes.

In practical application, Eq. 130 lends itself to a simplified numerical solution by an expedited method of trial substitution. It is the sum of two or three fractions equated to unity, with the sole unknown, K, in each denominator. If the mode represented by the first fraction is dominant, substitute an approximate trial value of K in the other term or terms, and solve the first fraction for K. The first or second trial will generally suffice. Similarly, the one or two other roots are obtained by treating the other fraction or fractions, respectively, as dominant.

Example 7: Computation of Symmetric Composite Modes for a Three-Span Bridge.—For the dimensions of the Tacoma Bridge, $K_0 = 15$, $K_1 = 100$, and $K_3 = 140$ (see Table 1); and $C = 1{,}420$. Substituting in Eqs. 130 and 131,

$$\frac{a_1}{a} = \frac{K - 15}{K - 100} \qquad (132a)$$

$$\frac{3\,a_3}{a} = \frac{K - 15}{K - 140} \qquad (132b)$$

and

$$\frac{117.7}{K - 15} + \frac{13.1}{K - 140} + \frac{92.6}{K - 100} = 1 \qquad (132c)$$

The three solutions of this equation (for $n = 1$, $n = 3$, and $n_1 = 1$, as the dominant modes, respectively) are $K = 53$, $K = 135$, and $K = 290$ ($N = 7.5$, 11.8, and 17.3 per min), each corresponding to a normal mode repeatedly observed in the actual structure. With each value of K, the corresponding values of a_1/a and a_3/a are determined.

For the mode $n = 5$ and $n_1 = 1$, Eq. 130 yields $K = 415$ for a_5 dominant, or $N = 20.7$, as compared with $N = 20.8$ observed in the actual structure (see Table 1).

Example 8: Calculation of Modes with Straight Backstays.—For the lowest symmetric modes $n = 1$ and $n = 3$, the respective values of K_n (see Table 1) are 15 and 140. With $Cf/l = 118$, the composite value of K is given very simply by

$$\frac{118}{K - 15} + \frac{118/9}{K - 140} = 1 \quad\ldots\ldots\ldots\ldots\ldots\ldots (133)$$

Eq. 133 yields $K = 102$ and $K = 184$; hence $N = 10.2$ and 13.8 per min (versus 10.5 and 13.8 observed; see Table 11). The amplitude relation is $\frac{a_3}{a_1} = 1/3\, \frac{K - 15}{K - 140} = -0.76$ and $+1.28$. The node points are defined by

$$\frac{\sin x/l}{\sin 3\, x/l} = -\frac{a_3}{a_1} \quad\ldots\ldots\ldots\ldots\ldots\ldots (134)$$

yielding $x/l = 0.22$ and 0.42 (versus 0.22 and 0.41 observed). In the first case the end segments are shortened; in the second case they are lengthened. In the same mode type, the two cases represent, respectively, a minimum and a maximum value for K; yet both are normal (balanced) modes. Because two nodes appeared in the model tests, this mode type was wrongly classified as a higher mode with two unexplained variations, and the investigators vainly sought the missing lower mode (see Table 11).

Instead of designating mode types by the number of nodes, it is more informative and scientifically more consistent to designate them by the number of segments—that is, by the n-value or values.

The fact, revealed by the writer's analysis, that a normal mode is produced by a maximum value of K (or N), as well as by a minimum value, appears to be a new discovery, previously unnoted in vibration analysis.

Application to Unloaded Backstays with Cable Sag Considered.—In Eqs. 128 to 131, the usual relation of equal unit dead loads in main and side spans ($w_1 = w$) was assumed. If w_1 is not equal to w, the sole change is to replace K_{n1} for any side-span component by $\frac{w}{w_1} K_{n1}$, in Eqs. 129, 130, and 131.

Example 9: Calculation of Modes with Unloaded (Sagging) Backstays.—Modifying Example 8 by considering sag in the unloaded backstays, with $w_1/w = 1/4$ (hence, $f_1 = 9$) and using $C = 1{,}425$, as before, the key equations for the lowest composite mode ($n = 1$, $n = 3$, and $n_1 = 1$) are

$$\frac{3\, a_3}{a} = \frac{K - 15}{K - 140} \quad\ldots\ldots\ldots\ldots\ldots\ldots (135a)$$

$$\frac{a_1}{a} = \frac{K - 15}{K - 4\,(98)} \quad\ldots\ldots\ldots\ldots\ldots\ldots (135b)$$

and

$$\frac{118}{K - 15} + \frac{13.1}{K - 140} + \frac{23.2}{K - 4\,(98)} = 1 \quad\ldots\ldots\ldots\ldots (135c)$$

The three solutions of Eq. 135c (with a, a_3, and a_1 dominant, respectively) are $K = 99$, $K = 175$, and $K = 427$. With the maximum value of K, all amplitudes are in the same direction, producing maximum cusps at the towers. This checks and explains Fig. 21.

Effectiveness of Inclined Stays.—A confirmation of the writer's theory for calculating the effectiveness of inclined stays is afforded by observations on the Deer Isle Bridge. For the initial stays placed on the structure in 1939, the calculated increase in rigidity by Eq. 65 is $\Delta K = 98$. The actual increase, computed from the observed values of N, is from $K = 63$ to $K = 165$, or $\Delta K = 102$, which is almost identical with the value given by the formula. With the concomitant increase in the value of R, yielding a fourfold increase in structural damping, the critical velocity was thereby materially raised.

Effect of Center of Suspension.—The effective center of suspension of a suspension bridge cross section in torsional oscillation is the midpoint of the line joining the two points of connection of the suspenders to the outside girders. The torsional stability of the section is increased by raising this center of suspension relative to the center of gravity of the suspended section. This is confirmed by simple model tests. The spring constant K_t is augmented by a torque of gravity restitution; a gravity pendulum effect is added to the torsional spring constant.

If h is the vertical height of the center of suspension above the center of gravity of the suspended section, the value of K_t given by Eq. 21a is augmented to

$$K_t = \frac{b^2}{2} K + 2\,h\,(w - w_c) \qquad (136)$$

in which w_c is the cable dead load. The total energy W required for any angular amplitude is increased in the same proportion, and consequently the aerodynamic instability, measured by the rate of amplification δ, is correspondingly reduced.

Instead of increasing h by raising the points of suspender connection, as by deeper girders or by brackets, the same improvement may be accomplished by lowering the center of gravity of the suspended section. Accordingly, torsional rigidity and stability may be improved by changing from deck or half-through construction to through construction. The writer has confirmed this conclusion by model tests. A deck truss section mentioned by Professor Farquharson as unstable becomes aerodynamically stable when simply inverted.

Calculation of R and Energy Distribution in Composite Modes.—Any formula for K may be written

$$K = K_H + K_I + K_{\Delta H} \qquad (137)$$

which is the sum of three terms representing, respectively, the contributions of cable displacement, girder bending, and cable stretch. The same three terms also represent the respective relative distribution of the total oscillation energy stored in the structure at any time (see Eq. 28b). Since the K_H-portion represents merely gravitational potential energy (a raising of the center of gravity of the total suspended dead load), it does not contribute directly to hysteresis damping. The remaining fraction of the total energy is elastic energy, subject to hysteresis damping, and is represented by

$$R = \frac{K_I + K_{\Delta H}}{K} \qquad (138)$$

In antisymmetric modes, and in most other cases, ΔH is zero or negligible, so that R is simply K_I/K (see Table 2). This may be written (for each span),

$$R = \frac{\pi^2 n^2 S^2}{1 + \pi^2 n^2 S^2} \qquad (139a)$$

in which S is the familiar stiffness factor of suspension bridges,[82]

$$S = \frac{1}{l}\sqrt{\frac{E I}{H}} \qquad (139b)$$

(See also Mr. Gronquist's discussion.)

In any composite mode (including coupled modes and superimposed harmonics), the basic relation of the general Eq. 126b for K also applies to the three parts, K_H, K_I, and $K_{\Delta H}$. Consequently,

$$R = \frac{\Sigma(R\,K\,a^2\,l)}{\Sigma(K\,a^2\,l)} = \frac{\Sigma(R\,K\,a^2\,l)}{K\,\Sigma(a^2\,l)} \qquad (140)$$

Eq. 140 gives R for the composite mode as a weighted mean of the individual values of R, defined by Eq. 138, for each component mode.

If the determined rates of hysteresis loss in cable and girder are different R may be separated into R_I and $R_{\Delta H}$, defined by K_I/K and $K_{\Delta H}/K$, respectively. One may also write, for the nonelastic contribution, $R_H = K_H/K$. The fundamental relation of Eq. 140 may then be applied to R_H, R_I, and $R_{\Delta H}$, separately, to obtain their values for the composite mode.

By Eq. 28b, the total energy stored in cable displacement, girder bending, and cable stretch, respectively, is

$$W_H = \tfrac{1}{2}\,R_H\,K\,\Sigma(a^2\,l) \qquad (141a)$$

$$W_I = \tfrac{1}{2}\,R_I\,K\,\Sigma(a^2\,l) \qquad (141b)$$

and

$$W_{\Delta H} = \tfrac{1}{2}\,R_{\Delta H}\,K\,\Sigma(a^2\,l) \qquad (141c)$$

If the logarithmic decrements $\Delta W/(2\,W)$, corresponding to hysteresis (and friction) loss in girder bending and cable stretch, are denoted by δ_I and $\delta_{\Delta H}$, respectively, the combined logarithmic decrement representing these two contributions will be

$$\delta_s = R_I\,\delta_I + R_{\Delta H}\,\delta_{\Delta H} \qquad (142a)$$

or, in general, for all conditions,

$$\delta_s = \Sigma(R\,\delta_s) \qquad (142b)$$

in which R represents the fraction of the total energy for each element in the structure. If all elements are included, $\Sigma R = 1$.

Logarithmic Increment.—In Eqs. 29a and 30, the writer introduced δ as the rate of amplification $\left(\frac{\Delta a}{a}\right)$ per cycle. Normally δ may be taken as equal to the logarithmic increment. If δ (or δ_s) is defined as the logarithmic increment or decrement, the exact relation is

---

[82] "A Practical Treatise on Suspension Bridges, Their Design, Construction and Erection," by D. B. Steinman, 2d Revised Ed., John Wiley & Sons, Inc., New York, N. Y., 1929, p. 277.

$$\delta = \tfrac{1}{2} \log \left(1 + \frac{\Delta W}{W} \right) = \log \left(1 + \frac{\Delta a}{a} \right) \qquad (143a)$$

Utilizing the writer's empirical short cut[83] for logarithmic relations,

$$\delta \approx \frac{\Delta W/(2\,W)}{1 + 0.45\,\Delta W/W} \approx \frac{\Delta a/a}{1 + 0.45\,\Delta a/a} \qquad (143b)$$

Eqs. 143 will be found more convenient to apply than Eq. 76 given by Professor Robertson. Eqs. 143 indicate plainly that for small values of δ the amplification ratio is closely equal to the logarithmic increment.

Use of K for Estimating Deflections.—Eqs. 16 and 22 for estimating live-load deflections directly from K and K_t were not a part of the aerodynamic analysis but were introduced as items of interest merely to emphasize the picture of the physical meaning of K as the "coefficient of rigidity." By using the words "estimating" and "approximate," and the sign for "approximately equal," the writer endeavored to make it clear that those two short-cut formulas were presented as approximate. Nevertheless, he believes that, as a rule, those formulas will yield better estimates of the indicated live-load deflections than any other formulas of comparable simplicity.

Mr. Balog's criticism of Eqs. 16 and 22 is therefore inappropriate. It is easy to show that any approximate formula is only approximate, especially if the numerical values used as standards of comparison are themselves erratic. The formulas that Mr. Balog offers for calculating quarter-point deflections are derived from inconsistent and inadmissible assumptions and would yield greater discrepancies. For the Tacoma Bridge the calculated deflections by his formula would be 38% too low; for the Maumee River Bridge (in Toledo, Ohio) the calculated deflections by his formula would be 48% too high; and the error would be still higher for more highly stiffened bridges.

In supplying and then criticizing a definition which he improperly ascribes to the writer, Mr. Balog has misinterpreted the physical meaning of $2\,K/b$. Actually, $2\,K/b$ is the loading increment Δw, in pounds per square foot, required to produce a 1-ft deflection, in which Δw is not a uniform load limited to the half span but is a sine-curve loading proportional to the displacements η, changing sign at midspan or at any node point. The basic relation (see definition of K and Eq. 6) is $K = \Delta w/\eta$. It is only by virtue of the convenient "accidental" relation of Eqs. 16 and 22 (and subject to the same degree of approximation) that a uniform half-span load may be substituted for the nonuniform reversing full-span load in the foregoing definition.

In criteria for aerodynamic stability, the use of calculated quarter-point deflections under uniform half-span load is a crude substitute; it cannot be as scientifically accurate and consistent as the use of K, given simply and directly by Eq. 6. In aerodynamic oscillations, the loading is not a uniform half-span load; the correct loading is represented by K; the correct frequencies are given by K; and all relations involve K. The evasive replacement of K by an arbitrary, and sometimes erratic, substitute serves no useful purpose and is patently unscientific.

---

[83] "Mathematical Short-Cuts for Engineers," by D. B. Steinman, *Engineering News-Record*, May 20, 1943, pp. 79–81.

The Vortex Theory.—A number of considerations prompted the writer's decision to omit the study based on the vortex theory. The theory predicated on the von Kármán vortex trail, in which aerodynamic frequency is normally a fixed function of the wind velocity and of the sectional dimensions instead of being automatically resonant with the frequency of the structure, appears to be inconsistent with many known facts, such as (1) instability over wide ranges of wind velocities (extending in some cases to infinity); (2) instability over a plurality of ranges that are not related as simple harmonics; (3) ranges of vertical instability alternating, instead of coinciding, with ranges of torsional instability; and (4) a contrary or reversed relationship in some bridges. The burden of explaining these inconsistencies rests with the proponents of the theory.

The most pressing reason for the omission was the fact that the vortex theory is far from being in a form to yield the quantitative constants and relations necessary to compute the excitation and amplification of vertical and torsional oscillations, aerodynamic forces and moments, lift and torque response graphs for the oscillating section, energy relations, positive and negative damping effects, critical wind velocities, critical angles of attack, rates of amplification, limiting amplitudes, effect of change of section, and criteria for predicting stability and instability. If the vortex theory is not directly applicable to these problems, it is not helpful to the bridge engineer.

The Theory of Self-Excited Oscillations.—The writer employed and developed the theory of self-excited oscillations because this theory offered the most useful quantitative results. The theory utilizes the familiar static lift and torque graphs to furnish the basic quantitative magnitudes of L and T. The fundamental concept, as applied to vertical oscillations of ice-coated transmission lines, was originated by J. P. Den Hartog. The writer developed the Den Hartog concept as a working theory for bridge spans and extended it to torsional oscillations. Furthermore, by introducing the β-concept, the writer showed how instability may be identified with, and calculated from, lift and torque graphs of positive slope.

The theory of self-excited oscillations is valid for either positive or negative slopes of the stationary lift or torque graph. It is not dependent upon any reversal of slope in the lift or torque graph. The writer's calculation of the limiting amplitudes of vertical oscillations on the Tacoma span (with results identical with the recorded values of the limiting amplitudes) was based on the actual lift graph of positive slope. The limitation of amplitudes is produced by the structural damping increasing with amplitude in accordance with Eq. 35. This maximum limiting amplitude, occurring at a maximum ordinate δ in a critical range of $V/(N\,b)$, is not increased by an increase in the wind velocity V. A substantial increase in wind velocity V takes $V/(N\,b)$ out of the critical range for the existing mode and ends the oscillation.

In the case of torsional oscillations in bridges of the Tacoma type, with the upper critical range of $V/(N\,b)$ extending to infinity, there is no maximum ordinate in the δ-graph—that is, there is no limit to the value of δ given by Eq. 51. Moreover, the value of δ may be several times higher than the value of δ for vertical oscillations. If δ_s is small as compared with δ, the effective limit for amplitudes is that provided by the reversal in the slope of the torque graph (Eqs. 54 and 55 and Fig. 7). Amplitudes close to this limit are rapidly attained, lowering the value of δ to the value of δ_s, and any subsequent increase in wind velocity merely overcomes δ_s to squeeze the already high amplitude closer to the limit.

It is important to note that a lift graph with negative slope may produce the same intensified amplification characteristics for vertical oscillations as described herein for torsional oscillations. Some lift graphs (those for sections with d/b greater than 0.24) have a negative slope. This would tend to make vertical oscillations catastrophic. The Deer Isle section belongs to this category; and the writer is convinced that the few light cable stays installed for restraint should be credited with saving the bridge from catastrophe in the severe storms and hurricanes to which it has been subjected since its completion in 1939.

The theory of self-excited oscillations, as extended and developed, appears adequate to explain the known behavior of actual structures and all experimental results known to the writer. Moreover, it provides a complete and consistent analysis yielding a quantitative solution and a prediction of all the data a bridge engineer needs, including aerodynamic forces and moments, critical wind velocities, critical angles of attack, rates of amplification, limiting amplitudes, criteria for stability, evaluation of methods of prevention, specifications for design limitations, and guides for design to assure stability.

Velocity Relations.—Stability or instability of a section, in sign and in intensity, is a function of wind velocity V. All formulas for δ, whether positive or negative, contain the basic factor $V/(N\,b)$ as well as the modifying factor β which is also a function of $V/(N\,b)$.

The governing velocity ratio $V/(N\,b)$ is nondimensional. It is known in aerodynamic analysis as the "reduced velocity." The writer prefers to call it the "velocity ratio." It is the ratio of the wind velocity V to the related constants $N\,b$ of the oscillating section. It is the ratio of the spacing or "wave length" (V/N) of the aerodynamic disturbance to the corresponding dimension (b) of the section. Thus, $V/(N\,b) = 3$ is the velocity ratio of a wind traveling three widths per cycle, or traversing the section in one third of a cycle. The reciprocal of $V/(N\,b)$ is, accordingly, the total phase difference (in fractions of a cycle) encountered across the width of the oscillating section.

The elementary expression for energy input by the aerodynamic action in an element of time on an element of surface requires three-way integration: (1) Over the cycle, (2) over the width of the section, and (3) over the length of the span. The integration over the width of the section, taking into account the varying phase differences encountered in the traverse of the section, yields the important modifying factor β as a function of $V/(N\,b)$. Because β changes sign as well as magnitude with variation in $V/(N\,b)$, potential stability and instability undergo reversal as well as variation in intensity with variation in $V/(N\,b)$.

For differentiation of aerodynamic response, the total range of wind velociy from zero to infinity is divided into a low-velocity range and a high-velocity range. The division point is V_p, the critical velocity due to phase difference. This critical velocity V_p is not a constant; but, for a given section and a given type of oscillation (vertical or torsional), the critical velocity ratio $V_p/(N\ b)$ is a constant for all modes and all rigidities. Hence, higher modes are represented by higher critical velocities V_p. (Compare this statement with Professor Farquharson's discussion, based on his misinterpretation of this point.)

Sections with negative slope of lift or torque graphs, herein termed "unstable sections," are potentially unstable (against the respective type of oscillations) in the high-velocity range. Instability of a structure in the high-velocity range is dangerous and may prove catastrophic. Such instability is not limited, for any mode, to a narrow range of wind velocity but increases indefinitely with V. The Tacoma Bridge, with a negative torque graph, was destroyed by torsional oscillations in the high-velocity range. The Deer Isle Bridge, with a negative lift graph, has inherent vertical instability in the high-velocity range. This bridge was critically tested by vertical oscillations in a wind of 72 miles per hr on the night of December 2, 1942. (The mode was $n = 1$, and the observed vertical amplitude was 12.5 ft, compared with a vertical amplitude of 12.4 ft calculated for this wind velocity by the writer's formulas. The light cable stays initially installed prevented the development of the more natural mode, $n = 2$. The additional stays subsequently installed have apparently proved effective in making the structure safe against all modes of oscillation, despite the severe storms in the exposed coastal location.)

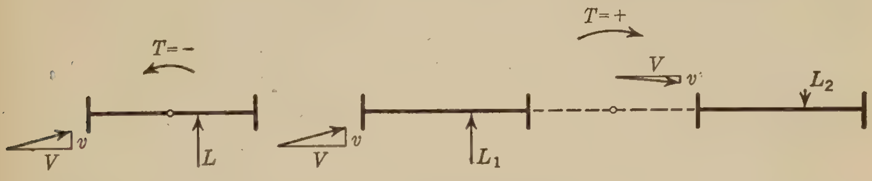
Conversely, sections with positive slope of lift or torque graphs are stable in the high-velocity range. Their potential instability is limited to the low-velocity range. The Tacoma Bridge, with a positive lift graph, had its vertical oscillations (in all modes) limited to the low-velocity range—that is, below the respective values of V_p.

"Unstable" sections (negative slope) also have potential instability in the low-velocity range. The high-velocity range is a single critical range extending from V_p to infinity. The low-velocity range is composed of a series of alternating critical ranges, represented by an oscillating graph converging from V_p down to a zero value of V. If this instability response graph is plotted on $V/(N\ b)$ instead of on V, the same graph will be valid for all modes. The alternate critical ranges belong to "stable" and "unstable" sections, respectively. These relations apply to torsional oscillations, as well as to vertical oscillations. Instability in the low-velocity range is limited, and is more easily prevented or cured.

The foregoing conclusions, derived by analysis, may be subject to minor qualifications; but, in their essential features, they have received multiple confirmation by both experiment on models and experience on actual structures.

Stable Sections.—That aerodynamic stability or instability of a section is a function of the form and proportions of the section and may be controlled by the provision of suitably located and proportioned openings in the horizontal width of the section is a demonstrable fact. Bridge cross sections can be devised or modified to produce assured aerodynamic stability. Tests made by

Prof. J. Ackeret at Zürich, Switzerland, in 1941 proved absolute torsional stability, at the highest wind velocities ($V/(N\,b)$ = from 43 to 175), for a section consisting of two H-sections with the roadway between them removed. With this gap closed, the section was violently unstable, self-starting under wind, and attained angular amplitudes of more than 90° in a few seconds. With the gap open, no applied wind could make the section oscillate, and any applied amplitude was almost instantaneously damped by the wind At the highest wind velocities, an applied amplitude of 70° was brought to rest in two seconds. These results have been confirmed independently in similar model tests by the writer. The aerodynamic stability of this section is easily explained by the writer's theory (see Fig. 24).



(a) UNSTABLE SECTION (T=−)

(b) STABLE SECTION (T=+)

FIG. 24.—AERODYNAMIC STABILITY OF A SECTION SUBJECT TO TORSION

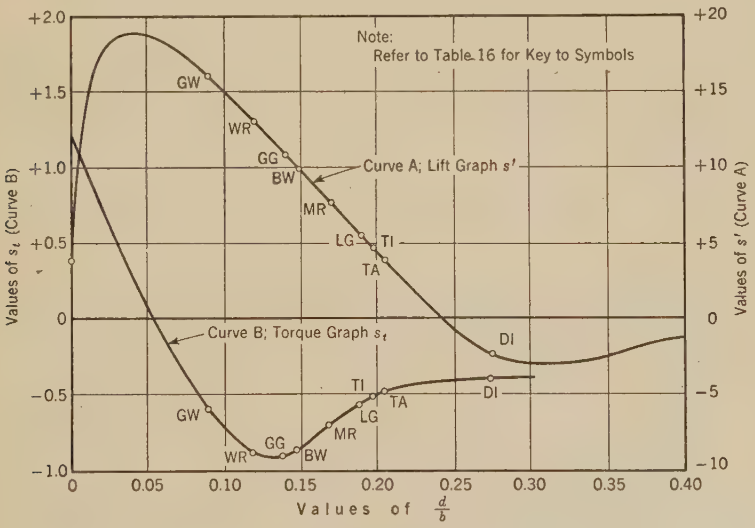


FIG. 25.—VARIATIONS OF SLOPES OF LIFT GRAPHS s' AND TORQUE GRAPHS s_t FOR DIFFERENT SECTION RATIOS d/b

Slopes of Static Lift and Torque Graphs.—By plotting the coefficient of α from Eq. 47, curve A in Fig. 25 is obtained, giving the governing slopes (s') of static lift graphs for different section ratios. Identified points correspond to specific known suspension bridges, using $d/2$ instead of d in the case of truss bridges. Nearly all the bridges marked on the graph fall in the range of positive s', representing vertically "stable sections." Those having the highest positive s' will have the highest potential vertical instability in the low-velocity range. The Deer Isle section is identified in the range of negative slope, representing vertical instability in the high-velocity range. At $d/b \approx 0.24$, the graph crosses the axis, representing zero s' and therefore minimum vertical instability. At $d/b = 0$, the graph comes down to the value for a flat plate.

Curve B in Fig. 25 is the corresponding graph for the governing slopes s_t of static torque graphs. With more direct experimental determination, these curves can be confirmed or perfected.

Modification of the section in the direction of reducing drag, by providing or enlarging openings in the vertical projection or by streamlining, will reduce the effective d/b. The consequent shift of the ordinate toward the left in Fig. 25 may or may not improve aerodynamic stability, depending upon the resulting augmentation or reduction of the ordinate and any change in sign. In some cases, as indicated by the graphs, aerodynamic stability may be improved by limited increases in the vertical projection of the section so as to change the effective d/b to a more stable ratio.

Confirmation by Model Tests.—The model tests (1942–1944) at Seattle, Wash., and at the California Institute of Technology offer confirmation of the theory and analysis developed and presented by the writer. In particular, the experiments confirm the validity and usefulness of the following conclusions which had previously been missed or unsuspected:

1. For vertical aerodynamic oscillations of bridges of the Tacoma type (positive lift graph), the critical wind velocity V_p for any mode is an upper limit, and no material vertical instability in that mode can occur at any higher wind velocity ratio. (This is exactly the reverse of the relation that had been generally assumed.)

2. Data on vertical aerodynamic oscillations of different modes at different wind velocities will fall into a consistent and orderly arrangement if reduced to a $V/(N\,b)$ basis.

3. The possible vertical aerodynamic oscillations of bridges of the Tacoma type, for all modes, fall into a mathematically related series of ranges of $V/(N\,b)$, all below $V_p/(N\,b)$. The maximum potential amplitudes occur approximately at the middle of each range. The second critical range occurs approximately at 0.45 of the mean value of $V/(N\,b)$ for the highest critical range. For all values of $V/(N\,b)$ in the intervals between the critical ranges, sections of the Tacoma type are aerodynamically stable.

4. Only the crests of those critical ranges overtopping a horizontal secant representing δ_s will be effective in producing aerodynamic instability. If δ_s is reduced, the effective critical ranges are widened and lower critical ranges may be brought into play.

5. In bridges of the Tacoma type (with negative torque graph), there are potential critical ranges in torsion below V_p as well as in the known catastrophic range above V_p. (This fact, missed in the tests for the official report on the Tacoma failure, is predicted by Eq. 60*b*.)

6. The aerodynamic behavior of a section in vertical and torsional oscillations can be predicted from the characteristics of the static lift and torque graphs, respectively.

Open Sidewalks.—Questioning the efficacy of the writer's proposal of open sidewalks, Professor Farquharson gives some fragmentary information on unreported model tests he made on such construction as applied to the Tacoma section. Correspondence has elicited the information that the tests were made hurriedly and under difficult conditions, and the further significant fact that, for the sole observed vertical mode ($n = 4$), the critical velocity (prototype scale) was increased from 17 miles per hr for the closed deck and 13 miles per hr for the section with open roadway to 38 miles per hr for the section with open sidewalks. It would have required a large amount of additional stiffening by stays or trusses to produce this 120% augmentation of critical velocity. For the sole observed torsional mode ($n = 2$), the critical velocity (prototype scale) was increased from 15 miles per hr for the closed deck and 10 miles per hr for the section with open roadway to 18 miles per hr for the section with open sidewalks. The results indicate that the aerodynamic instability of the section, measured by the net aerodynamic amplification ($\delta - \delta_a$), was reduced at least 32% in torsion and more than 84% in vertical instability by the mere opening of the narrow sidewalk areas. In the section with open roadway but with closed sidewalks, the reduction in atmospheric damping δ_a outweighed the reduction in negative damping δ; but, in the reverse condition (sidewalks open), the reduction in δ was so great that it far outweighed the reduction in atmospheric damping.

The maximum amplitudes attainable are not a measure of the instability, but depend upon other conditions, including curvature (or lack of curvature) of the lift and torque graphs. A section of lower instability may attain the same amplitudes, but the rate of amplification will be slower, and hours of sustained wind velocity (represented by minutes in the model) may be required to reach the given amplitudes. Obviously, such lower instability can be cured more easily.

Unfortunately, Professor Farquharson omitted any measurements of the rate of amplification, and no static lift or torque graphs of the section with open sidewalks were secured. The opening of the sidewalks increased the critical velocity ratio $V/(N\,b)$ for vertical oscillations from 2.30 to the abnormally high value of 6.60. If the lift graph was thereby reversed in slope (bringing the critical $V/(N\,b)$-ratio into the high-velocity range), some intermediate degree of opening in the sidewalks might give a lift graph of zero slope (s'), yielding zero (or negligible) amplification. As an alternative, a somewhat greater width of "sidewalk" opening might yield zero amplification in lift or in torsion, or both. All these points need further exploration.

Critical Ranges in Vertical Oscillations.—In the large-scale model of the Tacoma Bridge at the University of Washington in Seattle, the structural damping was about thirteen times as high as it appears to have been in the original structure. This explains why only one "subharmonic" range could be evoked for vertical oscillations in the model, as compared with at least five critical ranges recorded in the actual structure. Obviously, the inability of the model to show the lower critical ranges does not disprove the recorded fact of the occurrence and observation of lower critical ranges in the original bridge. The lowest velocity at which vertical oscillations could be produced in the model was (translated to the scale of the prototype) 6.7 miles per hr. In the actual bridge, vertical oscillations were measured and recorded at 1 mile per hr or, adding the 50% calibration correction, at 1.5 miles per hr. By the writer's formulas, the minimum critical velocity (see Example 5) was 1.3 miles per hr. These comparisons answer Professor Farquharson's criticism. The model is in error—not the bridge nor the writer's formulas.

Critical Ranges in Torsion.—A plurality of critical ranges of torsional instability is indicated by the trigonometric formulas for the β-function in torsion. By Eq. 60*b*, the critical ranges of $V/(N\ b)$ are: From ∞ to 3.13; from 1.35 to 0.80; from 0.57 to 0.44; and from 0.36 to 0.31; etc. The graph of $\beta\ V/(N\ b)$, plotted from Eq. 60*b*, showing these critical ranges, is recorded in Fig. 26. The results thus predicted by the writer's analysis have been confirmed by experiment (see Professor Farquharson's discussion). The writer's assumption—that a persistent correlation exists between the stationary lift and torque graphs and the aerodynamic behavior of the oscillating section—thus derives added corroboration.

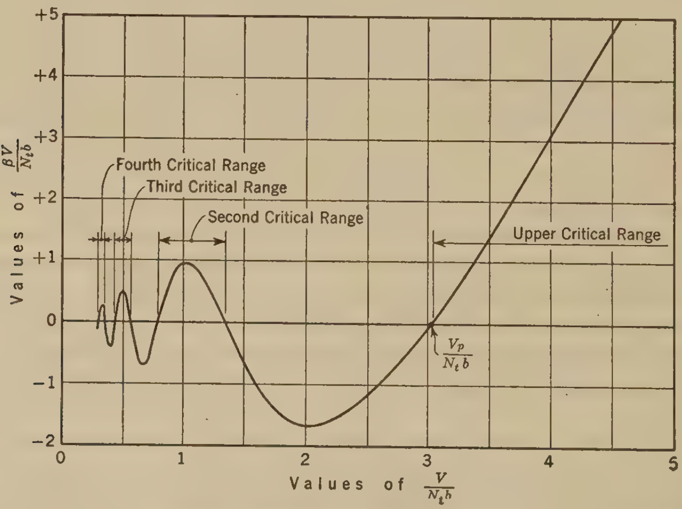

FIG. 26.—GRAPH OF CRITICAL RANGES FOR TORSIONAL INSTABILITY (BY EQ. 60*b*)

Structural Damping.—In writing his tentative formula for structural damping, Eq. 35, based on limited data, the writer assumed that the logarithmic decrement δ_s increases with amplitude and that it is a function of a fractional power of the amplitude. His assumptions have been confirmed by additional data. The experiments of O. Föppl,[31,84,85] J. Schmidt,[86] A. Appenrodt,[87] H. Sonnemann,[88] M. Hempel,[89] B. J. Lazan,[36] and A. J. Yorgiadis and A. U. Kutzay[90]—all confirm the increase of hysteresis damping (expressed as a logarithmic decrement) with stress, strain, or amplitude. From the data obtained by various procedures and presented in different forms, the writer has calculated the corresponding values of δ_s and the law of the variation of δ_s with strain. Professor Föppl's data on mild steel in torsional shear yield values of δ_s increasing from 0.02 to 0.10 with increase in amplitude or strain; and the law of variation is found to be represented by an exponent having a mean value of 1.5. For duralumin in torsion, Mr. Lazan's data yield values of δ_s increasing from 0.02 to 0.08, with the exponent of the amplitude averaging 1.5 for higher stresses. The two metals, mild steel and duralumin, show parallel hysteresis characteristics (in the range of δ_s and the exponential relation of δ_s) when both are tested in torsion. For duralumin in repeated reversals of longitudinal stress, Mr. Lazan's test results yield values of δ_s increasing with amplitude or strain, with 0.55 as a mean value of the exponent. From the foregoing comparisons, steel in reversing longitudinal stress may be expected to yield closely parallel results. Hence, the writer's assumption that δ_s is a function of $a^{0.50}$ is given increased validity. The experimental results also confirm the writer's conclusion that the function expressing δ_s is not zero at zero amplitude.

Professor Sonnemann's tests on solid and riveted flat bars in bending, using steel with a tensile strength of 50,000 lb per sq in., seem to show that riveted joints increase δ_s by a constant amount of 0.015.

In the welcome discussion by Professor Robertson, convincing and consistent data are presented (Fig. 14) confirming the increase of hysteresis damping with strain and yielding a uniform exponent of unity for the law of variation. Of particular interest is the fact that tests on steel in direct stress (as distinguished from shear or torsion) are included. Messrs. Robertson and Yorgiadis have verified this conclusion by tests on two steels, in addition to tests on a variety of other materials.

For application to actual structures, the aggregate of positive damping includes not only hysteresis loss in the solid metal but also energy absorption in pin connections and riveted joints, bearings, foundations, etc., in addition to atmospheric damping. The elements of friction damping yield a logarithmic decrement varying inversely with the amplitude. Atmospheric damping theoretically yields an exponent of unity, but experiments show a fractional exponent. All these additional elements tend to reduce the exponent of unity

yielded by pure hysteresis damping, so that the total resultant positive damping will be represented by a fractional exponent of the amplitude. Professor Robertson states (in correspondence) that he believes the fractional exponent would be nearer zero than unity, and that such fractional exponents were obtained when extraneous losses at the supports were not eliminated from his experiments (and from prior experiments by others).

The writer's prior conclusion that structural damping increases with the amplitude and that it may be taken as varying with the one-half power of the amplitude thus appears to be justified. Moreover, Eq. 35 for structural damping of riveted girder suspension bridges checks the known behavior of actual structures.

Atmospheric Damping.—Contrary to opinions expressed in the discussions, atmospheric damping as a factor in the aerodynamic problem is real and may be significant. As an illustration of the range of information obtainable by simple means, the following conclusions from some tests using a small-scale model of the Tacoma section and taking but a few hours of office time are recorded:

(1) With the wooden section model replaced by a small steel plummet of equal weight hung from the same spring suspension, so as to make atmospheric damping negligible, the number of oscillations required for 50% decay of amplitude was increased from 16 to 231. The respective calculated logarithmic decrements were 0.045 and 0.003, indicating that in this section model the atmospheric damping ($\delta_a = 0.042$) amounted to fourteen times the net structural (hysteresis) damping ($\delta_s = 0.003$).

(2) With the floor fully open (roadway and sidewalks removed), the mean δ_a (after subtracting the constant mean $\delta_s = 0.003$) was reduced from 0.042 to 0.010, a reduction of 76%.

(3) With the roadway removed and the sidewalks in place, the mean δ_a was reduced from 0.042 to 0.020, a reduction of 52%.

(4) With the sidewalks open and the roadway closed, the mean δ_a was reduced from 0.042 to 0.040, a reduction of only 5%.

(5) Per square foot, the roadway area was five times as effective as the sidewalk area in contributing atmospheric damping in vertical oscillations.

(6) In all cases, the positive damping (δ_s or δ_a) clearly increased with the amplitude. The indicated formulas are: For case 0 (streamlined plummet)—

$$\delta_s = 0.005\, a^{0.21} \qquad (144a)$$

for case 1 (model, floor fully closed)—

$$\delta_a = 0.070\, \frac{b'}{w}\, a^{0.42} \qquad (144b)$$

for case 2 (sidewalk open)—

$$\delta_a = 0.160\, \frac{b'}{w}\, a^{0.67} \qquad (144c)$$

for case 3 (roadway open)—

$$\delta_a = 0.126\, \frac{b'}{w}\, a^{0.71} \qquad (144d)$$

and, for case 4 (floor fully open)—

$$\delta_a = 0.034 \frac{b'}{w} a^{1.23} \qquad (144e)$$

in which b' is the net solid width of the section, after deducting the width of all floor openings. Case 2 (sidewalk open) gave the highest atmospheric damping per square foot of net horizontal area. (In all tests, the total suspended weight was kept constant by adding dead load to compensate for the weight of flooring removed.)

(7) In Eqs. 144, the augmenting exponents of the amplitude as the floor area is progressively removed indicate that the component of δ_a due to air friction and disturbance along the vertical faces of the girders increases with an exponent of unity or higher power of the amplitude, whereas the component of δ_a due to reaction of the horizontal area of the section increases with the one-half power or lower exponent of the amplitude.

(8) With the sidewalks open, the mean δ_a per square foot of horizontal area was actually increased from 0.022 to 0.027. This increase may be attributed to the increased air friction on the inner vertical faces of the girders.

(9) Adopting an exponent of 0.50 for the power of the amplitude, the foregoing tests yielded, for the normal cross section with the floor fully closed,

$$\delta_a = 0.086 \frac{b}{w} a^{0.50} \qquad (145a)$$

or, with an exponent of unity,

$$\delta_a = 0.30 \frac{b}{w} a \qquad (145b)$$

The mean of the results for all the sections, open and closed, yielded

$$\delta_a = 0.097 \frac{b'}{w} a^{0.76} \qquad (145c)$$

These empirical results may be compared with the theoretical formula for atmospheric damping based on uniform velocity:

$$\delta_a = 0.087 \frac{b}{w} a \qquad (145d)$$

The correction for acceleration appears to be an increase in the coefficient or a reduction in the exponent, or both.

(10) Using the indicated differentiation between the contributions of girder friction and normal floor resistance, the foregoing tests would yield for an **H**-section with closed floor:

$$\delta_a = 0.075 \frac{b}{w} a^{0.50} + 0.030 \frac{d}{w} a \qquad (146a)$$

and, for an **H**-section with open sidewalk areas:

$$\delta_a = 0.075 \frac{b'}{w} a^{0.50} + 0.060 \frac{d}{w} a \qquad (146b)$$

(11) With weight and springs constant, the frequency of oscillation increased slightly, from 78 and 79 (per min) in the closed model to 81 and 82 in the open models, and to 83 when the streamlined plummet was substituted, apparently because the mass of air to be moved by the oscillating model was reduced.

(12) Under transverse wind, at a velocity contributing aerodynamic stability, an active aerodynamic damping (δ) was consistently added to the passive atmospheric damping in all cases and at all amplitudes.

(13) Under transverse wind, opening the sidewalks (21% of the total area) reduced the superimposed aerodynamic δ by 81%; opening the roadway (45% of the total area) reduced the aerodynamic δ by 82%. Hence, the sidewalk area was more than twice as effective per square foot in producing aerodynamic δ.

(14) Under transverse wind, the aerodynamic δ consistently diminished when the amplitude was increased, as predicted from the curvature of the lift graph. Doubling the amplitude (at 1 in. in the model) reduced δ by 20%.

Atmospheric Damping in Torsional Oscillations.—With the same section model in angular oscillations, a continuation of the foregoing office experiments yielded the following results:

1. In torsional oscillations, the values for atmospheric damping averaged 69% of the corresponding values in vertical oscillations.
2. The mean values of the atmospheric damping in torsion were as follows: Full section, $\delta_a = 0.0288$; roadway removed, $\delta_a = 0.0185$; sidewalk removed, $\delta_a = 0.0158$; and both roadway and sidewalk removed, $\delta_a = 0.0158$.
3. In torsional oscillations, in all cases, δ_a increased with increasing amplitude. The mean rate of variation for the complete section corresponded to $a^{0.84}$. It was somewhat lower ($a^{0.78}$) when the roadway was removed and higher ($a^{1.05}$) when the roadway was restored and the sidewalk removed, indicating (as in the case of vertical oscillations) that air friction on the vertical faces of the girders contributed the higher exponent. Removal of the sidewalks concentrated a relative vertical air flow against the inner faces of the girders.
4. With an exponent of unity, the formula yielded by the test results for the normal section (with floor fully closed) was

$$\delta_a = 0.20 \frac{b}{w} a \qquad (147a)$$

or two thirds of the corresponding value in vertical oscillations, as given by Eq. 145*b*. The mean of the results for all the sections, open and closed, yielded

$$\delta_a = 0.22 \frac{b'}{w} a^{0.89} \qquad (147b)$$

5. Using the indicated differentiation between the contributions of girder friction and normal floor resistance, the foregoing tests in torsional oscillations yielded, for an H-section with closed floor:

$$\delta_a = 0.050 \frac{b}{w} a^{0.50} + 0.030 \frac{d}{w} a \qquad (148a)$$

and, for an H-section with open sidewalk areas:

$$\delta_a = 0.050 \frac{b'}{w} a^{0.50} + 0.060 \frac{d}{w} a \ldots\ldots\ldots\ldots\ldots (148b)$$

(Compare Eqs. 148 with Eqs. 146.)

6. With a light transverse wind blowing across the oscillating section, positive aerodynamic damping was added at small amplitudes (below 1 in. in the model) which changed to negative aerodynamic damping at higher amplitudes. By opening the sidewalks, the positive aerodynamic damping was increased (from 0.0024 to 0.0060), and the negative aerodynamic damping (at the higher amplitudes) was reduced (from 0.0077 to 0.0028). With the roadway removed, or with the entire floor open, the aerodynamic damping δ was negative (tending to produce instability) even at zero amplitude. The most stable combination (against torsional oscillations) was the section with the sidewalks open.

7. The results with transverse wind on the torsionally oscillating section model were consistent with experimental findings by others that in some cases a certain minimum amplitude must be reached before aerodynamic damping becomes negative (δ becomes positive). This critical amplitude in the model was 0.87 in. for the solid section and 1.19 in. for the section with open sidewalks (3.2 ft and 4.4 ft in the prototype), or 37% higher for the section with open sidewalks. Instability was not produced, because the atmospheric damping δ_a far outweighed δ and was increasing far more rapidly.

Structural and Atmospheric Damping.—It appears desirable to separate the atmospheric damping from the structural damping in the formula for the combined positive damping. Such modification of Eq. 35 would be

$$\delta_s = (0.001 + 0.06\,R)\left(1 + 50\,\frac{n}{l}\,\sqrt{a_m\,d}\right) + \delta_a \ldots\ldots\ldots (149)$$

in which the δ_a-term at the end of the expression may be separately formulated and evaluated.

If the amplifying ratio δ is determined from oscillating model experiments as a net logarithmic increment, without separation of active aerodynamic and passive atmospheric effects, it will automatically include a reduction by δ_a; in such case, the δ_a-term in Eq. 149 would be redundant.

Expressions for the atmospheric damping δ_a may be formulated from theoretical considerations and then modified in numerical parameters by experimental determination.

Starting with the elementary formula for air resistance to steady motion of a flat plate, the resulting expression for energy loss ΔW in a cycle of oscillation yields the following formula for atmospheric damping on a flat bridge floor of a span with vertical oscillations:

$$\delta_a = 0.087 \frac{b}{w} a_m \ldots\ldots\ldots\ldots\ldots\ldots\ldots (150a)$$

Accordingly, this contribution to δ_s would vary directly with the amplitude.

The relation given for the simple theoretical case by Eq. 150*a* is modified by the accelerated motion of the oscillating section, and is augmented by the H-form of the cross section and by the side friction of the relative vertical air flow on the vertical faces of the girders. The writer's experiments (see Eqs. 145 to 148) indicate a substantial increase in the numerical coefficient of Eq. 150*a*, together with a reduction in the exponent of the amplitude for the component due to direct pressure on horizontal areas, but with an exponent of unity or higher for the component due to air friction on vertical areas. Provisionally, as a simple and convenient formula to cover the mean effect of all contributions to atmospheric damping, an indicated expression is

$$\delta_a = 0.36 \frac{b}{w} a_m \quad \text{(150}b\text{)}$$

For greater refinement, or for special cases such as partly open floors, Eq. 150*b* may be modified by dividing it into two components as suggested by Eqs. 146.

For torsional oscillations, the same elementary derivation as represented by Eq. 150*a* yields

$$\delta_a = 0.0054 \frac{b}{w} \left(\frac{b}{r}\right)^2 a_m \quad \text{(151}a\text{)}$$

or, with $b^2/r^2 \approx 8$, one half of the value for vertical oscillations. A probable concentration of the air pressure toward the corners of the oscillating section would increase this ratio; and the cable and side friction contributions would tend to make the ratio equal to unity. With the augmented coefficient suggested by the writer's experiments, and pending further test results, the indicated composite formula for atmospheric damping in torsional oscillations is

$$\delta_a = 0.03 \left(\frac{b}{r}\right)^2 \frac{b}{w} a_m \approx 0.24 \frac{b}{w} a_m \quad \text{(151}b\text{)}$$

or two thirds of the value in vertical oscillations.

Failure to separate the passive decrement δ_a, or δ_s (including δ_a), from the active aerodynamic factor δ in tests on oscillating models impairs the consistency, clarity, and generality of the results.

Structural Damping by Diagonal Stays.—For the augmentation of structural damping contributed by diagonal stays, the fundamental energy relations yield the simple formula

$$\Delta\delta_s = \frac{\Delta K}{K} \delta_{st} \quad \text{(152)}$$

in which δ_{st} is the hysteresis damping factor of the material of the stays, and ΔK is the augmentation of K contributed by the stays (see Eqs. 65 and 66). For wire rope ("bridge cable") use $\delta_{st} = 0.025$, and for wire rope strand ("bridge strand") use $\delta_{st} = 0.009$.

For the Tacoma Bridge, by Eq. 152, the single system of inclined stays assumed in Example 6 would have increased δ_s from 0.002 to 0.041, and the double system would have increased δ_s to 0.080, a fortyfold increase.

For the Deer Isle Bridge, by Eq. 152, the initial installation of a few inclined cable stays of wire rope, adding $\Delta K = 102$ to the rigidity, increased δ_s from 0.013 to 0.053, a fourfold increase.

The relationship expressed in Eq. 152 is basic. It may be written in general form:

$$\delta_s \text{ (total)} = \frac{\Sigma(K\,\delta_s)}{\Sigma K} + \delta_a \qquad (153)$$

in which the summations cover all component contributions to K (cables, girders, stays, etc.) and the respective damping factors.

Evaluation of Friction Damping.—If a rope stay, instead of being rigidly secured at both ends, is passed through or around a friction damping device at one end and is kept taut by counterweighting or by connection to another stay of equal and opposite change of length, the resulting contribution of friction damping, expressed as a logarithmic decrement, is

$$\delta_f = 2\,F\left(\frac{a_2 - a_1}{a_m}\right)\sin\psi\,\frac{1}{K\,l\,a_m} \qquad (154)$$

in which F is the constant friction force developed by the friction device. Note, by Eq. 154, that the effectiveness of any friction damping device diminishes with increase of K, l, and a_m. The last is significant; apparently friction damping is the only type of damping that diminishes as the amplitude increases. It is infinite at zero amplitude. It prevents amplification until a certain minimum amplitude is initiated.

For the Tacoma span, with $n = 2$, by Eq. 154, a single 45° floor stay or cable stay between the tower and the quarter point of the span, with a friction clamp developing a friction force of 2,000 lb in the stay, would contribute a positive damping of $\delta_f = 0.016/a_m$. This value would be multiplied by the number of such stays.

The effectiveness of friction brakes installed at the ends of the main span may be similarly determined. For $n = 2, 6, 10, \cdots$ (vertical oscillations, with center stays and no side-span participation) the positive damping contributed by such brakes at the two ends of the span would be

$$\delta_f = 4\,F\left(\frac{16}{3\,n}\,\frac{f}{l}\right)\frac{1}{K\,l\,a_m} \qquad (155)$$

The effectiveness is greatly reduced in the higher modes, since δ_f varies inversely with K and n. The effectiveness also diminishes as the amplitude increases. The value of δ_f in Eq. 155 is diminished by the percentage of side-span participation.

For $n = 1, 3, 5, \cdots$, Eq. 155 may be used upon substituting the span camber f_c for the cable sag f. In these modes, end friction brakes are ineffective if the camber is small.

For the installation on the Bronx-Whitestone Bridge, for $n = 1$ and $n_1 = 1$, Eq. 155 yields $\delta_f = 0.069/a_m$ (neglecting the increase in K by floor stays, which would reduce δ_f).

For the modes $n = 4, 8, 12, \cdots$, the end friction brakes are of zero effectiveness.

With friction brakes installed at the two ends of the span, the longitudinal reaction to be resisted by center stays is augmented by $2F$.

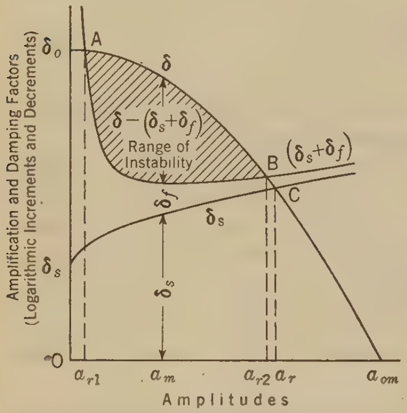

FIG. 27.—GRAPHIC DETERMINATION OF LIMITING AMPLITUDES

Graphic Determination of Limiting Amplitudes.—The relations between the logarithmic amplification and damping factors and the resulting limiting amplitudes are represented graphically in Fig. 27.

The graph of δ, the logarithmic increment, starts at the initial value of δ_0 at zero amplitude. By Eq. 38, it is a parabola, intersecting the amplitude axis at the theoretical limiting amplitude, a_{om}. The reduction of δ with amplitude is due to the curvature of the lift (or torque) graph. By the same assumed correlation, a straight lift (or torque) graph would yield a constant δ, and a lift (or torque) graph curving away from the α-axis would yield a varying δ increasing with amplitude.

The graph of δ_s, representing structural plus atmospheric damping, records the increase with amplitude, as given by Eq. 35 or Eq. 149. The intersection of the ascending δ_s-graph with the descending δ-graph at point C determines the limiting amplitude a_r, terminating amplification.

If friction damping is provided, the ordinates δ_f, varying inversely with amplitude, are added to the ordinates δ_s to give the graph of total positive damping, $\delta_s + \delta_f$. This new graph cuts the δ-graph at two points, A and B, yielding the minimum and maximum limiting amplitudes (for amplification), a_{r1} and a_{r2}. Although δ_f is large at small amplitudes (infinite at zero amplitude), the resulting reduction in the range of instability (from a_r to a_{r2} and from zero to a_{r1}) may be relatively small.

By increasing $\delta_s + \delta_f$ to exceed δ, the range of instability is eliminated.

Oscillating Lift Graphs in the High-Velocity Range.—Vertical amplitude response curves obtained for the writer by Prof. Harold A. Thomas, M. Am. Soc. C. E., are presented in Fig. 28. A wind stream of variable but controlled and measured velocity was applied to the section models which were free to oscillate vertically. The frequency of oscillation was controlled by varying the elastic restraint. The amplitudes were measured on an automatically recorded graph of the oscillations, and are plotted (as corresponding amplitudes in the prototypes) for various velocity ratios, $V/(N\,b)$. For comparison, two different sections were used—the Tacoma section with $d/b = 0.205$, and the Deer Isle section with $d/b = 0.276$. The dimensional difference was so slight that, to the unaided eye, the two models appeared identical. However, the marked difference in aerodynamic behavior of the two sections was "astonishing"; the writer's theory and predictions thus received striking confirmation.

As predicted by the writer's analysis, the Deer Isle section, with $d/b > 0.24$, is vertically unstable in the high-velocity range. The maximum amplitudes increase rapidly with the wind velocity, without any top limit.

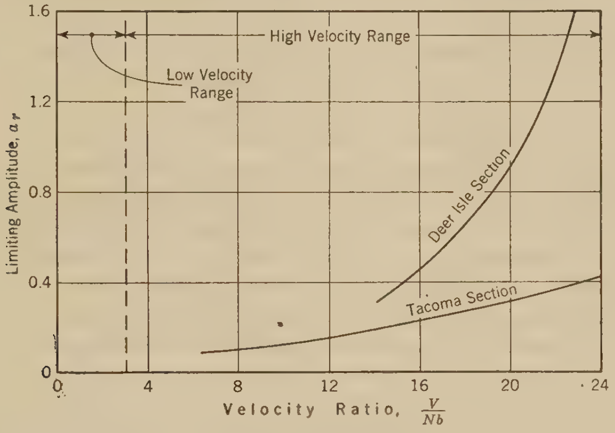

Fig. 28.—Oscillating Lift Graphs (Showing Vertical Instability in the High-Velocity Range)

In the case of the Tacoma section model, with $d/b < 0.24$, the vertical oscillations detected in the high-velocity range represent a secondary effect, little more than a "tremor." The maximum amplitudes in the model, even at velocities corresponding to hurricanes, amounted to only 1/16 in.

Oscillating Torque Graph with Friction Damping.—Fig. 29 records a torsional amplitude response curve, obtained for the writer by Professor Thomas, using a small oscillating model of the Tacoma section. The experimenters found, for each value of $V/(N_t b)$ in the unstable range, two limiting amplitudes, a minimum and a maximum. The lower amplitudes represent an unstable steady state, with stability below the line and amplification above. The upper amplitudes represent a stable steady state, terminating amplification. The region within the bounding curve represents aerodynamic instability.

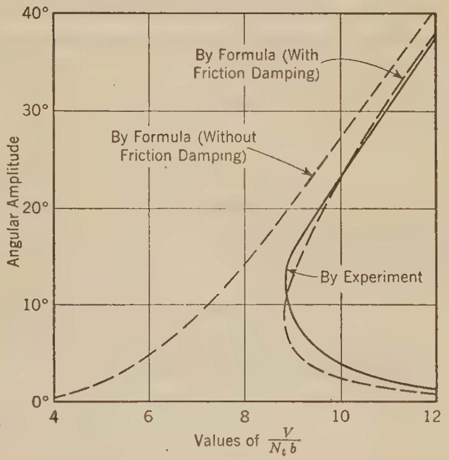

Fig. 29.—Oscillating Torque Graph (Tacoma Section)

This novel response curve is explained by the relatively high friction damping δ_f unintentionally introduced by the use of a center pivot at each end of the oscillating section model. The dotted line shows the theoretical response curve calculated by the writer's formulas without considering friction damping, and the dashed line shows the theoretical response curve calculated by the writer's formulas with friction damping included, assuming constant friction and using estimated values of the damping constants. The agreement between the calculated and observed curves, allowing for the unknown variable elements, is further confirmation of the writer's theory and formulas.

Fig. 29 clearly illustrates the substantial effect of friction damping at low amplitudes and the relatively negligible effect of friction damping at high amplitudes.

Aerodynamic Damping Due to Relative Velocities.—A frictionless pendulum swinging in still air is brought to rest by simple atmospheric damping (δ_a), produced by the velocity (v) of the pendulum. A steady wind (V) in the line of swing will bring the pendulum more quickly to rest; this additional damping is an effect of relative velocities. The pressure opposing the swing into the wind is augmented in proportion to $(V + v)^2$, and the pressure aiding the return swing is reduced in proportion to $(V - v)^2$. Whenever there is energy withdrawal, the addition of velocities augments the resisting pressure; whenever there is energy input, the subtraction of velocities reduces the effective pressure. Hence, this contribution of aerodynamic damping is always positive. It may greatly exceed the simple atmospheric damping δ_a. Because this contribution of aerodynamic damping is, in effect, an addition to δ_a but depends upon V, it is denoted subsequently by δ_{aV}.

In the pendulum analogy, the net energy input in a cycle, per unit of normal surface, is

$$\Delta W = \oint C \frac{\rho}{2} (V^2 + v^2 \pm 2\, V\, v)\, v\, dt \ldots\ldots\ldots\ldots (156a)$$

The three terms in this expression, divided by 2 W, yield, respectively, δ, δ_a, and δ_{aV}. (In this case, a pendulum under steady longitudinal wind, $\delta = 0$.)

Similarly, in the case of a vertically oscillating bridge section, the net energy input per cycle is

$$\Delta W = \int_0^l \int_0^b \oint C \frac{\rho}{2} [(V_L)^2 + v^2 \pm 2\, V_L\, v]\, v\, dt\, db\, dx \ldots\ldots (156b)$$

in which V_L, the mean effective lift component of V at any relative instant, is given by

$$V_L = V \sqrt{(C_L)'/C} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (157)$$

The integration of the first term of Eq. 156*b*, divided by 2 W, yields the negative aerodynamic damping:

$$\delta = -\frac{1}{4} \beta\, s' \left(\frac{\rho\, b^2}{2\, m}\right)\left(\frac{V}{N\, b}\right) \ldots\ldots\ldots\ldots\ldots (158a)$$

which is identical with the several expressions previously presented.

The second term, divided by 2 W, yields the simple atmospheric damping:

$$\delta_a = \frac{32}{9\,\pi} C \left(\frac{\rho\, b^2}{2\, m}\right) \frac{a_m}{b} \ldots\ldots\ldots\ldots\ldots\ldots (158b)$$

in which the aerodynamic pressure constant $C \approx 2$. (This reduces to Eq. 150*a*.) Note that δ_a is independent of N, K, and V and, hence, may be easily determined by testing a section model in still air. The increase of this damping with amplitude helps to restrict maximum amplitudes.

The third term, divided by 2 W, yields the aerodynamic damping due to relative velocities:

$$\delta_{aV} = \frac{1}{2}\left(\frac{\rho\, b^2}{2\, m}\right)\left(\frac{V}{N\, b}\right)\sqrt{\pm\, C\,(C_L)'} \tag{159a}$$

in which $(C_L)'$ denotes the mean effective value of the lift graph ordinate (disregarding sign) as it varies over the range $\alpha \pm \Delta\alpha$. If this range of the lift graph traversed during a cycle is approximately straight and lies entirely above or below the axis, $(C_L)'$ may be taken simply as the ordinate at the specified angle of attack α. However, if the involved range of the lift graph crosses the horizontal axis, so that $(C_L)'$ changes sign during the cycle, the value to be used in Eq. 159*a* is given, with sufficient accuracy, by the mean effective value—

$$(C_L)' = \frac{8}{\pi}\frac{N}{V}\, a_m\, s' \tag{159b}$$

This yields

$$\delta_{aV} = 0.8\left(\frac{\rho\, b^2}{2\, m}\right)\sqrt{\pm\, C\, s'\left(\frac{a_m}{b}\right)\left(\frac{V}{N\, b}\right)} \tag{159c}$$

As a rule, use either Eq. 159*a* or Eq. 159*c*, whichever yields the higher value of δ_{aV}. At angles of attack corresponding to large ordinates of the lift graph, Eq. 159*a* governs; at angles of attack corresponding to small intercepts $(C_L)'$, the effect of $\pm\, \Delta\alpha$ becomes important and Eq. 159*c* governs.

Since δ_{aV} is always positive, it is most conveniently grouped with the positive damping contributions (δ_s and δ_a), instead of being incorporated in the formulas as a reduction of δ.

For the Tacoma section, in the critical range for vertical oscillations, δ_{aV} by Eq. 159*c* is seven or more times as large as δ_a by Eq. 158*b*.

Note that δ_{aV} increases with increasing V and, in the more usual case (Eq. 159*c*), with increasing a, but diminishes with increasing N. This helps to explain limiting amplitudes, as well as the cutting off of a prevailing mode with increasing wind velocity. Most important, however, δ_{aV} supplies a most welcome additional safety factor—a contribution of positive damping that is most effective when it is most needed, namely, at high wind velocities, at high amplitudes, and in the lower modes. This is the only positive damping (other than $-\delta$) that increases with wind velocity.

The same reasoning applied to torsional oscillations yields a corresponding series of expressions:

$$\delta = -\frac{1}{8}\,\beta\, s_t\left(\frac{b}{r}\right)^2\left(\frac{\rho\, b^2}{2\, m}\right)\left(\frac{V}{N_t\, b}\right) \tag{160a}$$

$$\delta_a = \frac{1}{9\,\pi}\, C\left(\frac{b}{r}\right)^2\left(\frac{\rho\, b^2}{2\, m}\right)\theta_m \tag{160b}$$

and

$$\delta_{aV} = \frac{1}{14}\left(\frac{b}{r}\right)^2\left(\frac{\rho\, b^2}{2\, m}\right)\left(\frac{V}{N_t\, b}\right)\sqrt{\pm \frac{3}{2} C \left(C_T, \text{ or } \frac{4}{\pi^2}\, \theta_m\, s_t \right)} \quad \text{..(160}c\text{)}$$

in which θ_m is the angular amplitude at midsegment. In Eq. 160*c*, either the ordinate C_T or the slope term is used, whichever is larger. As a rule, the involved range of the torque graph crosses the horizontal axis; hence, in most applications, the slope term governs.

For vertical oscillations, convenient expressions for δ_{aV} may be written from Eqs. 158*a* and 159:

$$\frac{\delta_{aV}}{\delta} = \frac{\sqrt{\pm 8\, (C_L)'}}{-\beta\, s'} \quad \text{.....................(161}a\text{)}$$

or

$$\frac{\delta_{aV}}{\delta} = \frac{4.5\, \sqrt{a_m}}{-\beta\, \sqrt{\pm\, s'\, V/N}} \quad \text{...................(161}b\text{)}$$

If either of these fractions equals or exceeds unity, vertical stability is assured. Eq. 161*a* determines critical and stable angles of attack, by the ordinates $(C_L)'$ of the lift graph. Eq. 161*b* determines a limitation of amplitudes at any velocity ratio V/N.

Similarly, for torsional oscillations, from Eqs. 160*a* and 160*c*:

$$\frac{\delta_{aV}}{\delta} = \frac{\sqrt{\pm\, C_T}}{-\beta\, s_t} \quad \text{.......................(162}a\text{)}$$

or

$$\frac{\delta_{aV}}{\delta} = \frac{\sqrt{0.4\, \theta_m}}{-\beta\, \sqrt{\pm\, s_t}} \quad \text{....................(162}b\text{)}$$

If either of these fractions equals or exceeds unity, torsional stability is assured. Eq. 162*a* determines critical and stable angles of attack, by the ordinates C_T of the torque graph. Eq. 162*b* determines limitations of amplitude θ_m. These limitations of torsional amplitude are virtually independent of wind velocity and of mode in the high-velocity range. (Structural and atmospheric damping and curvature of the lift and torque graphs will contribute further restriction of critical ranges and limiting amplitudes.)

By Eq. 161*a*, the Tacoma section (using the California Institute of Technology lift graph) had maximum vertical instability at $\alpha = 0°$ and $-10°$, and was vertically stable at all angles of attack exceeding $\alpha = +9°$ and $-12°$. Eq. 161*b* yields, for the Tacoma section, limiting vertical amplitudes of 1.6 ft for all modes, without considering other damping effects.

Correction of Torque Graph for Center of Rotation.—In the static torque graph for a section, the torques represented by C_T are obtained or plotted for an assumed center of rotation. For any specified raising of the center of rotation by an amount z, the ordinates of the modified torque graph are given by

$$(C_T)' = C_T - \frac{z}{b} C_D \quad \text{.....................(163)}$$

Raising the center of rotation thus depresses the torque graph relative to the horizontal axis.

In any application in which the torque-graph ordinates are used to determine the magnitude and distribution of the vertical pressures (or vertical velocity components), the torque due to the horizontal drag forces (represented by C_D) should first be eliminated by subtraction. For this purpose, the assumed center of rotation should be lowered to the level of the center of pressure of the drag forces. With this shift of centers denoted by $-z$, the ordinates of the torque graph "corrected for drag" are given by Eq. 163.

Significant Characteristics of Static Lift Graphs and Torque Graphs.—There are three significant characteristics of static lift graphs and torque graphs that affect the stability or instability of a section—(1) slope, (2) curvature, and (3) ordinates.

(1) A positive slope yields a "stable section"; that is, one that will be essentially stable in the high-velocity range. A negative slope yields an "unstable section"; that is, one that is potentially unstable in the high-velocity range. Both types have (alternate) ranges of potential instability in the low-velocity range. Reducing the slope reduces the potential instability. Changing the angle of attack to a point of reduced slope reduces the potential instability. When the amplitudes correspond to traversal of the lift graph or the torque graph into regions of diminished or reversed slope, the intensity of amplification (δ) diminishes with increasing amplitude and a limiting amplitude is thereby determined.

(2) The curvature of the lift graph or torque graph (represented by s'/i^2 or s_t/i^2) affects or determines the limiting amplitudes by determining the reduction of mean effective slope with increasing amplitude. Curvature toward the horizontal axis has a tempering or limiting effect. Curvature away from the horizontal axis increases instability (δ) with increasing amplitude. A graph of zero initial slope curving away from the horizontal axis represents stability until certain initial amplitudes are imposed; the smaller the curvature is, the greater are the critical initial amplitudes required to start amplification.

(3) The ordinate, $(C_L)'$ or $(C_T)'$, of the lift or torque graph at any angle of attack α determines the significant positive damping contribution δ_{aV}. If the ordinate is sufficiently large, the resulting value of δ_{aV} will exceed δ (or $\delta - \delta_s$), producing stability.

It should be noted that the three parameters—slope, curvature, and ordinates—are to be measured at the abscissa α, representing the angle of attack, and that, for any material amplitude, the corresponding range of the graph is to be considered, and the mean effective value of each parameter over that range is to be used.

Confirmation by Critical Angles of Attack.—Professor Farquharson, in his discussion, mentions a section that was aerodynamically stable in horizontal wind but, unlike all sections previously tested, revealed pronounced torsional instability at certain critical positive and negative angles of attack. Those results are explained and duplicated in Fig. 30. The slope, curvature, and ordinates of the static wind-tunnel graph supply the keys for Fig. 30.

Because the section was vertically unsymmetrical, the torque graph was depressed vertically and displaced horizontally by substantial amounts. Even after correction for the moments of the drag forces about the elevated center of rotation used in the wind tunnel, the reduced negative ordinates are sufficiently large to produce stability, by Eq. 162a, at flat angles of attack.

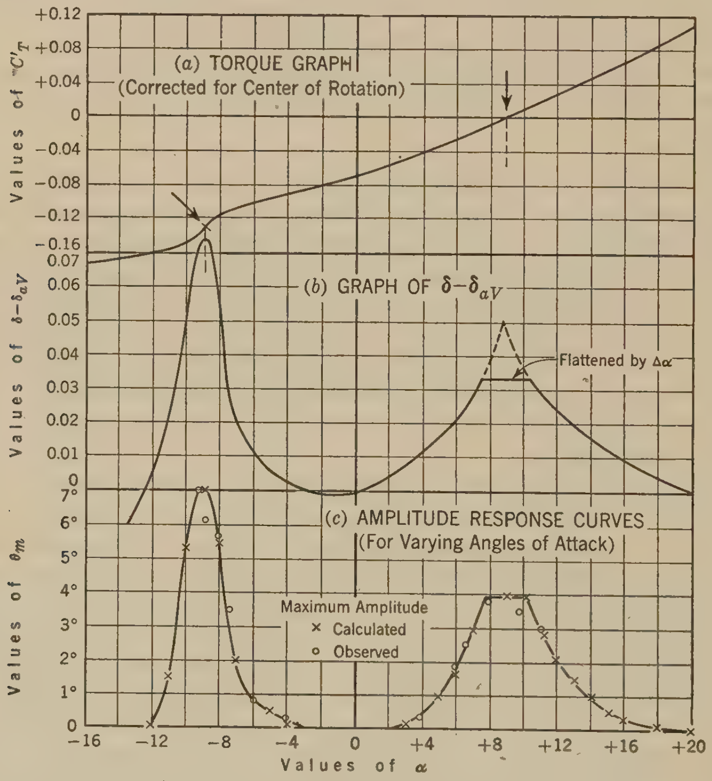

FIG. 30.—CONFIRMATION OF THEORY BY AMPLITUDE RESPONSE CURVES AT CRITICAL ANGLES OF ATTACK

The torque graph, corrected for the drag moments by Eq. 163, is plotted in Fig. 30(a). The ordinates $(C_T)'$ of this modified graph are used in calculating δ_{aV} (by Eq. 160c), and the slopes s_t of the original torque graph are used in calculating δ (by Eq. 160a). The resulting values of $(\delta - \delta_{aV})$ are plotted in Fig. 30(b). These ordinates, representing instability, are zero or negligible in the middle range (α = from $-3°$ to $+1°$), on account of the depressed torque graph yielding high values of δ_{aV}. The localized steep slope of the graph at $\alpha = -9°$ produces maximum instability at that angle of attack; and the zero intercept of the (corrected) torque graph produces a second (lower) peak of instability at $\alpha = +9°$. This latter peak is truncated, however, by the δ_{aV} produced by the amplitude (see Eq. 160*c*).

The maximum amplitudes, calculated by the writer's formulas from the values of $(\delta - \delta_{aV})$, are plotted in Fig. 30(*c*), and in the same curves are plotted the actual limiting amplitudes obtained and recorded in the Seattle model tests. The agreement, remarkable as it is, may be brought even closer to identity by minor adjustments of the assumed constants.

The extreme right-hand branches of the graphs in Figs. 30(*b*) and 30(*c*) are found, in the computations, to be highly sensitive to minor variations in the slope of the corresponding portion of the torque graph, and may become horizontal, ascending, or wavering with such slope variations. This explains why that portion of the amplitude response curve obtained in the model tests varied in range and in form with various modifications of the section, as with the application of streamlining, "spoilers," special railings, open curbs, etc.

Method of Predicting Critical Velocities.—An essential constant in predicting the aerodynamic behavior of any given section at any given wind velocity is the critical velocity ratio $V_p/(N\,b)$, constituting the line of demarcation between stability and potential instability. It has different values for vertical and for torsional oscillations, and it varies with the section ratio d/b. It is defined by the condition $\beta = 0$.

A general expression for β may be written in simple form. In vertical oscillations,

$$\beta = \frac{\int_0^b p_x \cos\phi\, dx}{\int_0^b p_x\, dx} \qquad \text{(164}a\text{)}$$

and, in torsional oscillations,

$$\beta = \frac{\int_0^b p_x \left(\frac{b}{2} - x\right) \cos\phi\, dx}{\int_0^b p_x \left(\frac{b}{2} - x\right) dx} \qquad \text{(164}b\text{)}$$

in which x is measured across the width b of the section, and p_x is the corresponding intensity of aerodynamic pressure. If the law of variation of p_x were known, all unknowns of the aerodynamic behavior of the section would be given by simple integration. The denominator of Eq. 164*a* is the static lift force L', and that of Eq. 164*b* is the static torque T. The numerator determines aerodynamic stability or instability, in both sign and intensity. Any value of ϕ' (total phase difference) that makes the numerator zero gives a critical velocity ratio $(V/(N\,b) = 2\,\pi/\phi')$.

The law of variation of p_x across an H-section, at different angles of attack, may be determined experimentally. (See G. Eiffel's classic experiments[91] on flat plates.)

---

[91] "La Resistance de l'Air," by G. Eiffel, Dunod and Pinat, Paris, 1910; see also "The Resistance of the Air and Aviation Experiments Conducted at Champ-de-Mars Laboratory," by G. Eiffel, 2d Ed., translated by Jerome C. Hunsaker, Houghton, Mifflin Co., Boston and New York, 1913.

In the case of an **H**-section, there is a region of suction or negative pressure for some distance (approximately 2 d) behind the windward girder.[91] An upward angle of attack produces a positive (upward) pressure beyond this shielded range. The fraction j of the width, representing the effective division point, may be expressed as a function of the depth ratio d/b. The resultant pressures herein considered also include the contributions (positive or negative) on the reverse face of the horizontal member.

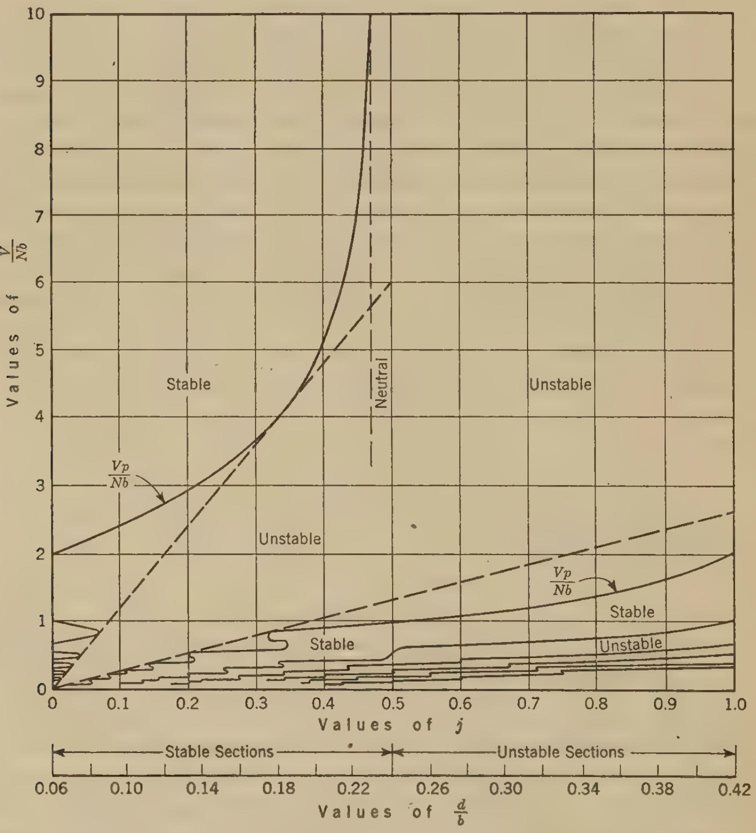

FIG. 31.—CRITICAL VELOCITY RATIOS FOR VERTICAL OSCILLATIONS

For preliminary exploration of the ranges of stability and instability, an assumed law of variation of p_x may be applied. One of the simplest assumptions, yielding reasonably consistent results, is a uniform pressure p_x, positive beyond the shielded fraction of the width and negative (downward) in the shielded range.

Substitution of this simple p_x-relation in the denominators of Eqs. 164 yields values of L' and T that follow the general variation of the known slopes of the static lift and torque graphs for different section ratios. By this matching, an indicated expression for j is

$$j = 2.8\left(\frac{d}{b} - 0.06\right) \ldots\ldots\ldots\ldots (165a)$$

An alternative expression, checking known test results even more closely, is

$$j = 10\left(\frac{d}{b}\right)^2 \ldots\ldots\ldots\ldots (165b)$$

The dividing lines between stable and unstable sections are $j = 0.50$ in lift and $j = 0$ in torsion, corresponding to $d/b = 0.238$ and $d/b = 0.06$, respectively, by Eq. 165*a*.

Substitution of the same simple relations in the numerators of Eqs. 164 yields the critical values of $V/(N\,b)$. These values, for vertical oscillations, are plotted in Fig. 31, thereby charting the critical ranges of stability and instability for varying section ratios d/b. This chart informatively presents the contrasting response of "stable" and "unstable" sections. It clearly shows that V_p is an upper limit of instability in stable sections and a lower limit of instability in unstable sections. Between the two limits is a narrow neutral band of minimum vertical instability at all wind velocities. A corresponding chart for torsional instability is similarly obtained.

Although predicated on a simplifying asumption, this preliminary illustration of a rational method of predicting critical velocities yields results that closely check recorded experimental observations. Fig. 32 shows how the graph of $V_p/(N_t\,b)$ in torsion, given by this simplified theory, agrees almost identically with experimental results obtained by Theodor von Kármán, M. Am. Soc. C. E. Mr. von Kármán's results, plotted on b/d instead of d/b, would fall almost exactly on a straight line through the origin:

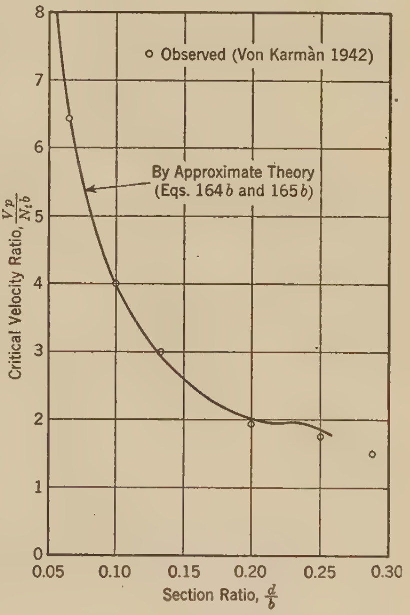

Fig. 32.—Critical Velocity Ratios for Torsional Instability for Different Section Ratios; Comparison of Theory With Recorded Observations

$$\frac{V_p}{N_t\,b} = 0.4\,\frac{b}{d} \ldots\ldots\ldots\ldots (166)$$

In other words, the critical velocities in torsion vary almost exactly inversely with d. This surprising relation, obtained in section model tests, is directly the opposite of all predictions by the vortex theory; the writer's theory supplies the explanation and the predictive foundation.

Method of Predicting Instability (δ) *at Various Wind Velocities.*—By applying Eqs. 164 for β, with the same simplified law of variation of p_x as was assumed for Fig. 31, graphs are obtained showing the variation of δ with $V/(N\,b)$ for different section ratios. The graph for vertical instability is plotted in Fig. 33. It clearly shows the governing difference between vertically "stable" and "unstable" sections. The unstable sections (with $d/b > 0.24$) have an unlimited critical range yielding unlimited increase of δ with wind velocity. The optimum section ratio ($d/b \approx 0.24$) has the lowest value of maximum δ. As the section ratio is made progressively smaller, the critical range of $V/(N\,b)$ shrinks in width but becomes steeper, reaching a maximum δ at $d/b \approx 0.17$. At still lower values of d/b, the height of the instability graph progressively diminishes, approaching a second optimum ratio at $d/b = 0$ (a flat plate).

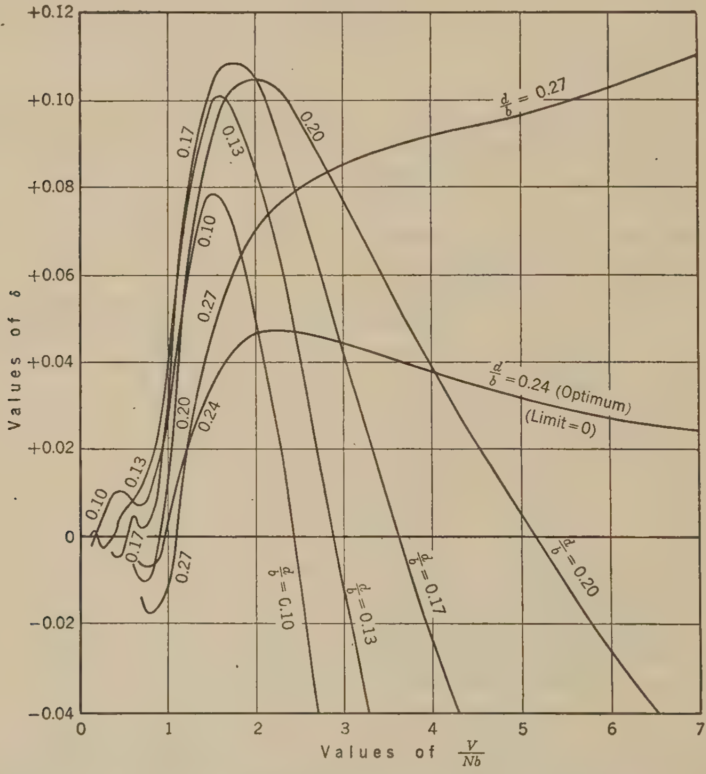

Fig. 33.—Graphs for Predicting Vertical Instability δ at Various Wind Velocities $V/(N\,b)$, for Various Section Ratios d/b (plotted for $b^2/w = 0.50$. For Other Values, Increase δ in Proportion)

Critical Velocities for Dominance of Torsional Instability.—For any given section ratio, if the δ-graphs for vertical and torsional instability are superimposed with the necessary adjustment of horizontal scale, the point of intersection of the two graphs gives the critical velocity ratio at which torsional instability becomes dominant. This is illustrated in Fig. 34 for two section ratios (using $N_t \approx 1.5\,N$). For the Tacoma section ($d/b \approx 0.20$), torsional instability becomes dominant at $V/(N_t\,b) \approx 2.9$, corresponding to $V \approx 15$ miles per hr. For the Deer Isle section ($d/b \approx 0.27$), torsional instability does not become dominant until $V/(N_t\,b) \approx 9.7$, corresponding to $V \approx 31$ miles per hr for the bridge without stays and to $V \approx 63$ miles per hr for the bridge with the present system of longitudinal stays.

The intersecting lift and torque instability graphs plotted for the Tacoma section by the theoretical formula in Fig. 34 are almost identical with the corresponding intersecting graphs of amplitude response obtained in large-scale oscillating model tests.

The Tacoma Bridge had potential torsional instability at 15 miles per hr, but torsional oscillations were prevented until the overstressed midspan stays failed. This happened to occur during a wind of 42 miles per hr. The higher wind velocity and the vertical mode $n = 9$ prevailing at the time had only an accidental relation to the appearance of torsional instability.

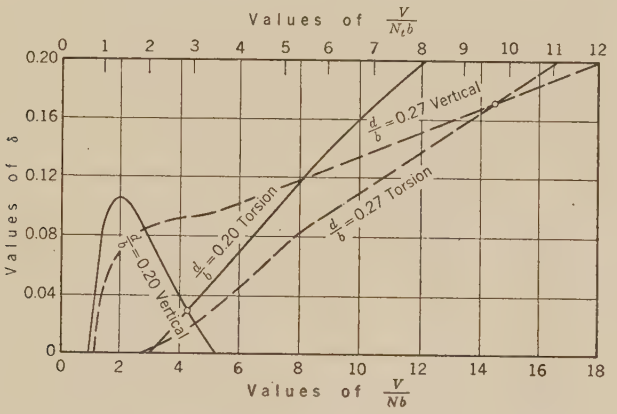

FIG. 34.—CRITICAL VELOCITIES FOR THE DOMINANCE OF TORSIONAL INSTABILITY (BY EQS. 164)

Charts for Predicting Instability at Various Wind Velocities.—Fig. 35, plotted from Eq. 164*b*, charting the values of δ in torsion in the high-velocity range, gives, and explains, results that are almost identical with results obtained experimentally in oscillating model tests. The δ-contours in Fig. 35 for torsionally "unstable" sections show steady slopes of unlimited increase of δ with wind velocity.

All these graphs (Figs. 31 to 35) are presented to illustrate governing relations, but are subject to quantitative modification by perfected analysis and more adequate test data. The graphs introduce and exemplify a method of analysis and prediction, but require further check and adjustment before they can be used for design.

Critical Velocities as Affected by Width of Section.—From the elementary relation of $V/(N\,b)$, some engineers have concluded that critical velocities are proportional to the width b of the section. The true relation is not so simple; in fact, at critical high velocities, the relation is reversed.

The general formula for potential instability in the high-velocity range may be written (see Eqs. 44, 45, 59 and Figs. 26 and 33):

$$\delta = k\,B\left(\frac{V - V_p}{N\,b}\right) \tag{167}$$

in which $B = b^2/w$ (hereinafter termed the "width factor"), and k is a coefficient times s' or s_t. Note that

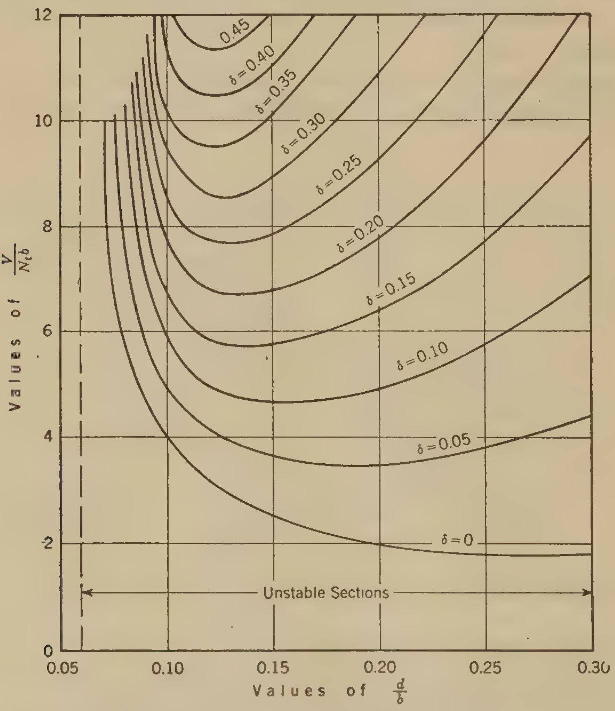

FIG. 35.—TORSIONAL INSTABILITY CURVES OF δ FOR VARIOUS SECTION RATIOS AT VARIOUS VELOCITY RATIOS

$$N\,b = 0.904\sqrt{K\,B} \tag{168}$$

From these relations, the critical velocity is given by

$$V_c = 0.904\sqrt{K}\left(\frac{V_p}{N\,b}\sqrt{B} + \frac{\delta_s}{k\sqrt{B}}\right) \tag{169}$$

in which $V_p/(N\,b)$ is a constant (independent of width) for a given section ratio. For $\delta_s = 0$, Eq. 169 yields $V_c = V_p$. The first term in the parenthesis contains $\sqrt{B}$, whereas the second term contains the reciprocal. For bridges of equal b/w, the width factor B is proportional to the width b. Hence, by Eq. 169, for a given value of K, critical velocity increases directly not with the width but with the square root of the width at zero positive damping ($V_c = V_p$), and inversely with the square root of the width at high positive damping. In other words, V_p is proportional to $\sqrt{B}$, but $(V_c - V_p)$ is proportional to $1/\sqrt{B}$. At values of V_c greater than 2 V_p, the second relation dominates. Design conditions to secure stability will usually require such a high value of $(V_c - V_p)$. Therefore, in the critical high-velocity range governing design, other factors being equal, a wider bridge will have lower critical velocities.

For aerodynamic similitude in model tests, the model must have the same value of the width factor B as the prototype. Erroneous conclusions as to critical velocities in torsion were reached in the tests for the official investigation of the Tacoma failure because all the models had lower values of B than the prototype, and consequently yielded higher critical velocities. As a result, the investigators mistakenly concluded that the critical velocity was 25 miles per hr, whereas correction for B makes the critical velocity 15 miles per hr.

Eq. 169 checks and explains the relation recorded empirically in Eqs. 57. Actually, $V_p/(N_t\, b)$ should be a constant for a given section, independent of B. A true value of $V_p/(N_t\, b)$ of approximately 2.9 for the Tacoma section, with a residual positive damping (in the models) of $\delta_s \approx 0.018$, would yield the values of $V_c/(N_t\, b)$ ranging from 3.3 to 5.1 actually observed for the models with different values of B. Hence, Eqs. 57 do not define the true V_p at zero damping but a higher V_c at a residual positive damping that was overlooked by the investigators. More recent tests on models of the Tacoma section yield values of from 2.6 to 2.8 for $V_p/(N_t\, b)$ in torsion. Other cross sections yield different values of $V_p/(N_t\, b)$, ranging from 0.75 to infinity. These results are shown both by the writer's theory and by experiment.

The conclusion that $V_p/(N_t\, b)$ is a constant for a given section but varies for different sections (see Fig. 32) supersedes Eqs. 57 and 61, and Eq. 169 supersedes Eqs. 62 and 64 and the related discussion.

Eq. 169, valid for both vertical and torsional oscillations, retains an important point—namely, that the steepness of the δ-graph is proportional to the width factor B. This affects critical velocities, amplitudes, rates of amplification, and required values of K and of structural damping. By making comparisons at small values of δ_s and, hence, at small values of $V_c - V_p$ (as Mr. Balog has done in his discussion), the effect of the relative steepness of the δ-graphs is largely lost. At high values of δ_s (or of $V - V_p$) the effect of the width factor B becomes more marked, especially in respect to amplitudes and rates of amplification.

Measures of Instability Related to Structural Proportions.—Three different measures of aerodynamic instability are: (1) Rate of amplification, (2) critical wind velocity, and (3) maximum amplitude. Simplified formulas reveal the variation of these measures of instability with governing structural factors.

The width factor $B = b^2/w$, representing in more practical form the nondimensional density-mass ratio $\rho\, b^2/(2\, m)$, appears as a factor in all formulas for aerodynamic damping, both positive and negative.

By Eqs. 1, 21, 29, and 51, a simplified formula for the rate of amplification is

$$\delta = k\, V \sqrt{B/K} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (170a)$$

in which, for vertical oscillations,

$$k = -0.0106\,\beta\,s' \qquad \text{(170}b\text{)}$$

and, for torsional oscillations,

$$k = -0.0106\,\beta\,s_t\left(\frac{b}{r}\right) \qquad \text{(170}c\text{)}$$

Similar sections at high wind velocities have like values of k. Hence, for bridges with similar cross sections or equivalent section ratios, at equal high wind velocities:

(1) Rate of Amplification is proportional to $\sqrt{B/K}$.

Critical velocity V_c is defined by applying the stable-state condition ($\delta = \delta_s$) at zero amplitude. Hence, by Eq. 170a,

$$V_c = \frac{1}{k}\,\delta_s\sqrt{\frac{K}{B}} \qquad \text{(171)}$$

in which δ_s is the positive damping at zero amplitude. Accordingly, in the high-velocity range, for bridges with similar cross sections or equivalent section ratios, with equal structural damping at zero amplitude:

(2) Critical velocities are proportional to $\sqrt{K/B}$.

Let $F(a)$ be the positive damping function of amplitude; that is,

$$F(a) = \delta_s = k_1 + k_2\,a + k_3\sqrt{a} + \frac{k_4}{a} \qquad \text{(172}a\text{)}$$

In this general expression, the successive terms represent the zero amplitude damping constant, the atmospheric damping, the hysteresis damping, and the friction damping. The hysteresis damping may also be covered by the second term. If all the terms with the exception of the second term are zero or relatively negligible, $F(a)$ is proportional to a. In general, $F(a)$ must increase with amplitude; otherwise (except for curvature of the static lift and torque graphs), there would be no limitation of amplitudes. By Eq. 170a, the maximum amplitude, defined by the steady-state condition, $\delta = \delta_s$, is given in terms of $F(a)$ by

$$F(a) = k\,V\sqrt{\frac{B}{K}} \qquad \text{(172}b\text{)}$$

Hence, for bridges of similar cross sections or equivalent section ratios, at equal high wind velocities:

(3) The maximum amplitudes, or their functions $F(a)$, are proportional to $\sqrt{B/K}$.

Each of the foregoing governing relations of proportionality (conclusions 1 to 3) contains the stiffness ratio K/B (or its reciprocal). The three measures of instability may be consolidated to read:

(1), (2), (3) Safety against aerodynamic instability is
proportional to $\sqrt{K/B}$.

Comparisons of different bridges based on K alone yield roughly satisfactory results because B is fairly constant at approximately 0.4 to 0.6 for most bridges. For wide bridges of normal or reduced weight per square foot, however, the value of B may be doubled—thus adding 41% to the instability as computed from K alone.

For bridges of equal weight per square foot, B is proportional to b. Under that limitation, K/b represents K/B and becomes an equivalent measure of stability (compare with Table 2).

Although actually the square root of the "stability factor" K/B appears in the proportionality relations, the desired objective is accomplished by specifying a minimum value of K/B. On the statistical basis of the known behavior of various structures, the indicated minimum specification is

$$\frac{K}{B} > 300 \qquad (173)$$

The formula value of K for $n = 2$ is to be used, since the mode $n = 1$ will rarely give a value materially lower. The values of K and w are for half widths.

Table 16 lists suspension bridges in the order of their stability factors K/B, and Fig. 36 presents the corresponding information graphically. With the exception of the George Washington Bridge with $K/B = 344$, no bridges with K/B greater than 300 have ever, as far as known, shown any traces of aerodynamic instability. All bridges with K/B less than 300 have evidenced aerodynamic instability, in varying degree roughly corresponding to the inverse order of the (K/B)-values.

TABLE 16.—BRIDGES LISTED IN DESCENDING ORDER OF STABILITY FACTOR, K/B

Key	Bridge	K	B	K/B	$\sqrt{K/B}$
W	Williamsburg	1,082	0.27	4,007	64
M	Manhattan	1,236	0.79	1,565	40
MR	Maumee River	648	0.53	1,218	35

GW	George Washington	244	0.71	344	18.5
GM	Grand Mère	188	0.55	339	18.5
TI	Thousand Islands	141	0.58	243	15.5
TI	Thousand Islands	127	0.58	219	15
LG	Vancouver	112	0.69	161	13
GG	Golden Gate	116	0.77	151	12
DI	Deer Isle	69	0.46	150	12
BW	Bronx-Whitestone	141	0.99	142	12
TA	Tacoma	62	0.53	117	11

Individual variations, as between the George Washington and Grand Mère bridges (the latter with higher δ_s) or between the Bronx-Whitestone and Deer Isle bridges (the latter with negative s'), are explained by differences in structural damping and in the aerodynamic characteristics of the cross sections. Eq. 173 cannot cover such differences; nor can any other generalized rule.

A more scientific specification, taking into account variations in s', s_t, and δ_s would be, from Eq. 171,

$$\delta_s \sqrt{K/B} > k\,V \qquad (174)$$

to assure a critical velocity (zero amplitude) above any specified V. It is helpful to note that

$$\sqrt{\frac{K}{B}} = 1.1\, N \left(\frac{w}{b}\right) \qquad (175)$$

Criteria for Aerodynamic Stability.—To aid in quickly checking the aerodynamic stability of a proposed bridge design, three alternate criteria, of progressively increasing scientific accuracy, are developed and presented, as follows:

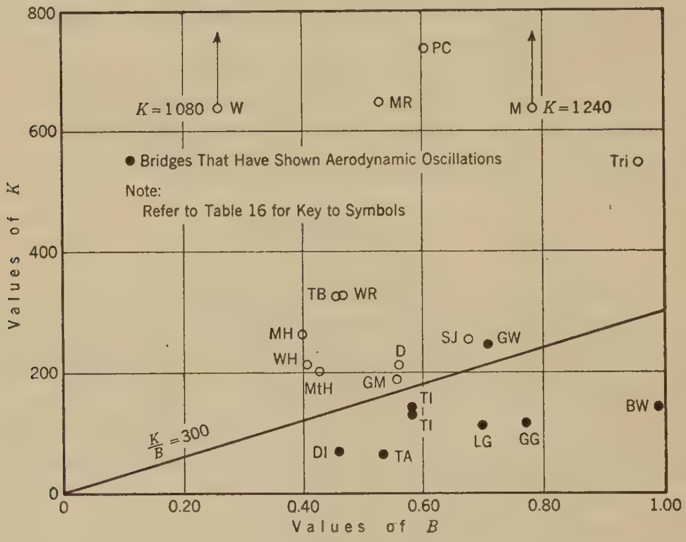

FIG. 36.—CHART OF K/B FOR VARIOUS SUSPENSION BRIDGES

1. The first criterion, recorded in Eq. 173 and illustrated in Table 16 and Fig. 36, is of simplified rational form on a statistical base. It may be simply stated:

The stiffness ratio K/B shall exceed 300.

2. The second criterion is derived from the more complete governing relation recorded in Eq. 174. Since the structural damping is essentially proportional to R, Eq. 174 yields the conclusion that the structural constant $R\sqrt{K/B}$, subsequently termed the "aerodynamic stability constant," determines the highest wind velocity of assured stability. Values of this constant for different suspension bridges are presented in Table 17. The values of $R\sqrt{K/B}$ give an order of listing that agrees with the known relative aerodynamic stability of the different bridges more consistently than any of the preceding criteria. The bridges at the bottom of the list have been the most unstable. All bridges with a value of $R\sqrt{K/B}$ less than 5 have been subject to aerodynamic oscilla-

tions. All bridges with this constant greater than 5 are in the aerodynamically stable classification. This relation yields the second criterion.

The aerodynamic stability constant $R\sqrt{K/B}$ shall exceed 5.

3. For a more completely rational criterion, the variation of potential instability with the form and proportions of the cross section must be considered. For different section ratios d/b, curves of potential torsional and vertical instability, at an assumed wind velocity of 100 miles per hr, are plotted in Fig. 37, using the computed maximum values of $\delta\sqrt{K/B}$ as ordinates. For assured stability, the structural damping δ_s must equal or exceed the maximum δ. Consequently these curves also give the required values of $\delta_s\sqrt{K/B}$. By comparison with the known behavior of these structures, the indicated appropriate values of δ_s are 0.25 R for girder bridges and 0.50 R for truss bridges. Using these coefficients, the estimated values of $\delta_s\sqrt{K/B}$ for the different bridges are given in Table 17 alongside the required values. The ratio, recorded in the final column, is the "factor of safety against aerodynamic instability." The Williamsburg Bridge has the highest ratio, 5.3, and the Tacoma Bridge has the lowest ratio, 0.02. (Multiplying by 100 miles per hr or some lower figure gives a rough idea of the wind velocity at which marked instability may appear.) All bridges for which this ratio is less than unity have been subject to aerodynamic oscillations; and, as far as known, all bridges for which this ratio is greater than unity have been aerodynamically stable. The same test is applied graphically in Fig. 37, with differentiated horizontal and vertical scales for girder and truss bridges, also using the higher ratio of $\delta_s : R$ for truss bridges. All bridges plotted below the stability graph are in the unstable category, and those above the graph are in the stable classification.

TABLE 17.—APPLICATION OF CRITERIA FOR AERODYNAMIC STABILITY

Bridge	R	$R\sqrt{K/B}$	Effective $\frac{d}{b}$	$\delta_s\sqrt{K/B}$

Degree of stability is represented by the ordinate of the plotted point divided by the corresponding ordinate of the graph. Table 17 and Fig. 37 represent the third criterion for aerodynamic stability:

> The aerodynamic stability constant $R\sqrt{K/B}$ (or the value of $\delta_s\sqrt{K/B}$ which it represents) shall exceed the required value for the section, as tabulated or as plotted in a graph for different section ratios.

Fig. 37 also shows how a horizontal line (dashed) might be used instead of the curved graph. This horizontal line would yield an apparently correct dividing line for the structures listed, but would give misleading results for any bridge designs that might fall between the horizontal line and the curved graph. The curved graph is composite, representing the criterion for torsional stability in the principal range of section ratios and the superimposed higher criterion for vertical stability for sections with effective d/b exceeding 0.25. This steeper segment of the graph explains the high instability recorded for the Deer Isle Bridge (before the present stays were installed). If the section ratio had been 0.25 instead of 0.276, the instability would have been greatly reduced, as shown in Fig. 37, and the required increase in $R\sqrt{K/B}$ would have been only 4.8 instead of 12.0.

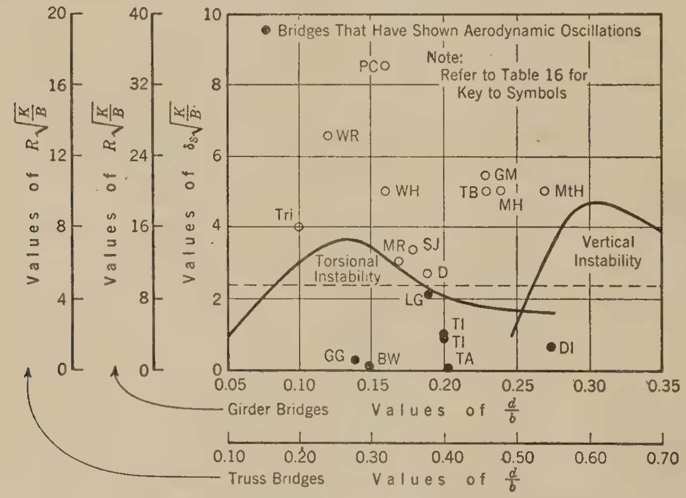

FIG. 37.—CRITERION FOR AERODYNAMIC STABILITY (REQUIRED $R\sqrt{K/B}$ FOR A CRITICAL VELOCITY OF 100 MILES PER HR)

For bridges of very low R, the comparison can be improved by taking into account the value of δ_s at $R = 0$, using a formula of the form

$$\delta_s = 0.005 + 0.25\,R \qquad (176a)$$

for girder bridges, and

$$\delta_s = 0.010 + 0.50\,R \qquad (176b)$$

for truss bridges. For bridges of high R, the first term of Eqs. 176 is relatively negligible. These values of δ_s represent the positive damping at zero amplitude, or very small amplitude, and are high because they include the damping due to friction at joints, connections, and bearings.

The scientific validity of this criterion is not dependent upon the empirically assumed values of the ratio, $\delta_s : R$. If the indicated ratio is too high, the criterion represents a critical velocity proportionately lower than 100 miles per hr.

The bridge engineer thus has his choice of three criteria, the first being the simplest and the last being the most scientific and the most accurate.

Criteria proposed by others have been based on incorrect or incomplete relations. Mr. Balog uses the ratio between the two terms of Eq. 6, represented by his parameter π_3 and by the writer's stiffness factor S (see Eqs. 139), the relation between the two being $\pi_3 = 1/S^2$. Stripped of the obscuring mathematics, all that Mr. Balog states in his criterion, Eq. 122, is that S for any bridge shall not be less than S for the Golden Gate Bridge; this is equivalent to stating that R shall not be less than 0.055. Such a criterion is inadequate, both in magnitude and in scope. From this criterion Mr. Balog derives two criteria, Eqs. 124*a* and 124*b*, the three being mutually inconsistent. Eq. 124*a* states that, for aerodynamic stability, the value of I/H for any bridge shall equal the value of I/H for the Golden Gate Bridge; and Eq. 124*b* states that I/l^2 of any bridge shall equal I/l^2 of the Golden Gate Bridge. Both these criteria, as shown by Table 15 and Fig. 23, and as stated by Mr. Balog, yield some obviously misleading results. The reason becomes clear when the two criteria are further translated: Eq. 124*a* specifies the value of $R\, l^2$ and Eq. 124*b* specifies the value of $K\, R\, l^2$, using the Golden Gate Bridge as the standard in each case. The fact that l^2 is thus arbitrarily introduced into the measure of aerodynamic stability is hidden in Mr. Balog's mathematical presentation. Thus, spurious advantage is given to long spans, and perfectly stable bridges of shorter span are made to appear unstable by the same criterion.

Required Stiffening of Suspension Bridges.—Substituting the reduced expressions for K and R as given by Eq. 6, using $n = 2$, the second criterion ($R \sqrt{K/B} > 5$) for aerodynamic stability reduces very closely to

$$E\, I > \frac{b\, l^4}{120 \sqrt{f}} \qquad \text{(177)}$$

in which I is per half width. The dead load w has disappeared from the relation by cancelation. Eq. 177 shows that augmentation of rigidity by reducing cable sag f (as was done for economy in the Tacoma Bridge) actually reduces safety against aerodynamic instability. Eq. 177 will give the same relative results as the second criterion and defines the identical dividing line between aerodynamically stable and unstable suspension bridges.

Here at last is an answer to the question that has challenged bridge engineers for a century: How much stiffening does a suspension bridge require? Any suspension bridge with a stiffening system satisfying Eq. 177 will be aerodynamically stable in the normally required range of wind velocities. The only suspension bridges that have manifested aerodynamic instability are those that have been proportioned below this requirement.

Any suspension bridge design that does not satisfy this criterion by the product $E\,I$ of the stiffening girders or trusses requires either equivalent stiffening (K and R) by other means, or special design of cross section to minimize, eliminate, or reverse any aerodynamic instability. Long-span suspension bridges will require considerably deeper stiffening girders or trusses than those of the recent past, unless the designs receive special study for aerodynamic stability.

The foregoing may be summarized in a simple practical specification:

> (a) The stiffening system of a suspension bridge shall be proportioned to yield a value $E\,I$ of not less than $b\,l^4/(120\,\sqrt{f})$; otherwise, the design shall receive special investigation for aerodynamic stability.

Required Depth of Stiffening Girders.—In normal designs by the deflection theory, for highway loading, the foregoing criterion (Eq. 177) is very closely satisfied by making

$$d > \frac{l}{120} + \left(\frac{l}{1{,}000}\right)^2 \qquad (178)$$

In other words, the required depth ratio d/l ranges from 1/120 in very short spans to 1/100 for spans between 1,000 and 2,000 ft and to 1/80 for spans longer than 4,000 ft. Matched against the second and third criteria and Eq. 177, Eq. 178 yields the same dividing line between stable and unstable bridges and an excellent correlation of ratios and orders of listing (compare Fig. 2). Thus, an even simpler, practical form of the desired specification is available:

> (b) In highway suspension bridges, the depth of stiffening girders or trusses shall be not less than $l/120 + (l/1{,}000)^2$; otherwise, the design shall receive special investigation for aerodynamic stability.

In self-anchored suspension bridges ($R = 1.00$), and in other suspension bridges proportioned by the elastic theory, a shallower depth ratio will yield the required moment of inertia I.

Methods of Securing Aerodynamic Stability.—The writer has repeatedly demonstrated by model tests that, under appropriate conditions, aerodynamic stability may be secured or materially improved by opening lateral areas. He has explained and confirmed this conclusion by supplementary tests and by analysis. He has never suggested that complete stability will be guaranteed in all cases and under all conditions. The correct answer lies in scientific investigation, not in rejection on the basis of prejudiced conclusions or fragmentary observations.

The proposal of open sidewalks must not be confused with the proposal of an open roadway. For the open roadway, the writer's model tests yielded unfavorable results.

The fact (cited by Mr. Balog) that the Bronx-Whitestone Bridge during erection, before concreting but with the floor forms in place, showed high vertical instability even with the sidewalk spaces open confirms the writer's observations and conclusions. With the low K and the high B due to small dead load, and with the low structural and friction damping due to the absence of the concrete floor, a bridge at that stage may have abnormally high aerodynamic instability, or abnormally high amplitude response, which even the open sidewalks can scarcely be expected to overcome.

Whether or not outside sidewalk brackets will contribute a stabilizing effect depends upon the proportions of the section and the category of instability. Theoretical considerations indicate a beneficial effect under some conditions. Without properly planned experiments, no categorical conclusion is justified.

The effectiveness of longitudinal and of transverse stays should be obvious, as some of the discussers have noted. The late John A. Roebling, M. Am. Soc. C. E., used floor stays and cable stays a century ago, and that was one reason why his bridges stood up while bridges built by his contemporaries were blown down by the wind.

In referring to conventional suspension bridge cross sections as H-sections, the writer uses the term in its broadest sense, so as to include flat plates, deck sections, and through sections, with either solid web or open-truss stiffening girders. After the basic relations are established for the symmetrical H-section, secondary corrections are easily determined (by experiment or analysis) for the effects of shifting the horizontal member to different heights, including the top and bottom positions, as well as for the effects of floor openings and of outside brackets. Thus, all these variations are brought into an organized relationship, instead of being left a disconnected haphazard mystery. The less common double-deck sections, and new forms like the suggested tandem H-sections, will require separate investigation.

Summary and Conclusions.—The studies represented by this paper lead to twenty-five conclusions, as follows:

1. The potential aerodynamic stability or instability of sections of various proportions for all modes of oscillation throughout the range of wind velocities can be quantitatively charted and predicted.

2. The coefficient of rigidity K, measuring the resistance to oscillation and determining the frequency of oscillation in any mode, can be easily and accurately calculated for any existing or proposed structure of known dimensions.

3. Rigidity and structural damping to resist potential aerodynamic instability, both vertical and torsional, may be augmented in precalculated amounts, by using: (*a*) Deeper stiffening girders or trusses; (*b*) cable stays, tower stays, center stays, and intermediate stays; (*c*) continuous construction; and (*d*) unloaded backstays.

4. Rigidity and structural damping to resist potential torsional instability may be augmented in precalculated amounts by: (*a*) Using transverse diagonal stays; (*b*) installing a double system of lateral bracing; (*c*) increasing the torsional stiffness of the towers; (*d*) raising the points of suspender connection relative to the center of gravity of the section; and (*e*) lowering the center of gravity of the section (for example, by the use of through construction).

5. Positive damping, opposing or nullifying potential aerodynamic instability, includes hysteresis damping, friction damping (structural or artificial), passive atmospheric damping, and positive aerodynamic damping due to relative velocities. Subject to determination or confirmation of the basic coefficients, all these factors can be formulated and predictively computed.

6. If the total positive damping is known, the critical wind velocities at which aerodynamic instability may appear can be precalculated—as can the potential amplitude response at any specified higher velocity.

7. The basic information for predetermining potential aerodynamic instability, both in sign and in intensity, is supplied by the static lift graphs and torque graphs. These graphs are known or can be predicted for conventional sections and, for unusual sections, can be easily secured by simple wind-tunnel tests on a stationary section model.

8. The wind-tunnel characteristics of an H-section can be predicted from the section ratio d/b in the case of solid girders and from the equivalent section ratio in the case of open trusses.

9. For zero or minimum vertical instability, the optimum section ratios are from $d/b = 0.22$ to $d/b = 0.24$. Deeper sections are potentially unstable against vertical oscillations in the high-velocity (catastrophic) range. Shallower sections are potentially unstable in the low-velocity range. Section ratios of from 0.12 to 0.17 are the most unstable at low wind velocities. A section ratio of $d/b = 0$ is a second optimum.

10. For zero or minimum torsional instability, the optimum section ratios are from $d/b = 0$ to $d/b = 0.06$. All deeper sections are "unstable" sections; that is, they are potentially unstable in the high-velocity (catastrophic) range. Section ratios of from 0.10 to 0.15 are the most unstable (in torsion) in the high-velocity range. The critical velocity initiating the high-velocity range increases toward infinity as the section ratio is reduced.

11. For any given section ratio (more easily for "stable" sections), vertical and torsional stability up to any specified wind velocity can be assured by providing required values of rigidity, or positive damping, or both. These required values are easily precalculated.

12. Potential vertical instability may be minimized or eliminated by using: (*a*) Section ratios, or equivalent section ratios, equal to 0.24 or less (avoiding section ratios of from 0.12 to 0.17); (*b*) the optimum section ratios of from 0.22 to 0.24 (or, as a second choice, ratios close to zero); (*c*) sections yielding static lift graphs of very flat or zero slope; (*d*) sections yielding lift graphs of small slope and large ordinates throughout a specified range of angles of attack; (*e*) open sidewalks; (*f*) outside brackets; and (*g*) streamlining (but only when the resulting equivalent section ratio is consistent with the foregoing recommendations).

13. Potential torsional instability may be minimized or eliminated by using: (*a*) Section ratios equal to or less than 0.10; (*b*) section ratios as close to zero as possible; (*c*) sections yielding static torque graphs of very flat or zero slope; (*d*) sections yielding static torque graphs of small slope and large ordinates (after correction for moment of drag forces) throughout a specified range of angles of attack; (*e*) open sidewalks; (*f*) outside brackets; (*g*) streamlining when the resulting equivalent section ratio or the resulting torque graph is consistent with the foregoing recommendations; and (*h*) multiple girder sections with central open deck.

14. A completely open deck, or open roadway with closed sidewalks, may

lose more in atmospheric damping than is gained in reduced aerodynamic instability.

15. Friction damping varies inversely with amplitude. It is helpful in resisting the initiation of oscillations, but has little effect after any substantial amplitude is attained.

16. Aerodynamic instability is not explained as the result of narrow width. For equal section ratios and equal weight per square foot, a wider bridge has higher rates of amplification and higher amplitudes, both vertical and angular, and requires a higher coefficient of rigidity K or a higher structural damping, or both, to counteract potential instability.

17. For bridges of equal or equivalent section ratios, potential aerodynamic instability is inversely proportional to $\sqrt{K/B}$, in which B is the width factor b^2/w.

18. At any given wind velocity in a range that is unstable for one or more modes of oscillation, the mode (vertical or torsional) yielding the highest rate of amplification (net negative damping) at that wind velocity will tend to prevail. The potential succession of modes with changing wind velocity may thus be precalculated if desired, but is unimportant. For purposes of design, the highest precalculated value of negative damping up to a specified wind velocity (see charts) should be matched against the potential mode of lowest K or of lowest positive damping.

19. For assured aerodynamic stability (zero amplification) of a "stable" section at all wind velocities, a structural damping δ_s should be provided equal to the maximum negative damping precalculated or charted for the section in the low-velocity range.

20. For assured aerodynamic stability (zero amplification) of an "unstable" section up to any specified wind velocity, a minimum required value of the product $\delta_s \sqrt{K/B}$ should be provided as precalculated or charted for the section at the specified wind velocity.

21. Increase in dead load, without reducing the depth and section of the girders or trusses, will produce a small or negligible improvement in aerodynamic stability, which may be outweighed by the resulting reduction in atmospheric damping. If advantage is taken of the increased dead load to reduce the girder section (by the deflection theory), the coefficient of rigidity K will remain unchanged and the aerodynamic stability will be materially reduced. The use of a lighter floor construction, with the necessary corresponding increase in the girder section, will actually improve aerodynamic stability by a substantial and easily calculable amount.

22. To aid in checking the aerodynamic stability of a proposed bridge design quickly, three alternate criteria of progressively increasing scientific accuracy are developed: (*a*) The stiffness ratio K/B shall exceed 300; (*b*) the aerodynamic stability constant $R\ \sqrt{K/B}$ shall exceed 5; and (*c*) the aerodynamic stability constant $R\ \sqrt{K/B}$ shall exceed the required value for the section, as tabulated or as plotted in a graph for different section ratios. Bridge designs with exceptionally favorable or unfavorable sections or relative magnitudes of structural and atmospheric damping require or warrant individual analyses of potential instability.

23. The required stiffening of a suspension bridge to assure satisfactory aerodynamic behavior is given in a simple, practical specification:

> The stiffening system shall be proportioned to yield $E\,I$ not less than $b\,l^4/(120\,\sqrt{f})$; otherwise, the design shall receive special investigation for aerodynamic stability.

24. The criteria in conclusions 22 and 23 are finally reduced to an even simpler, practical rule:

> The depth of stiffening girders or trusses shall be not less than $l/120 + (l/1{,}000)^2$; otherwise, the design shall receive special investigation for aerodynamic stability.

25. Specific gaps and inadequacies in available experimental data have been indicated as guides for test programs to confirm, amplify, or modify the present indicated conclusions and to bring the practical solution of the problem closer to finality.

Acknowledgments.—In undertaking and completing the task represented by this study, the writer has been as much spurred by challenging questions and criticisms as he has been heartened by the rare instances of encouragement and cooperation. To all who have contributed, either knowingly or unknowingly, including the many anonymous reviewers who recorded their comments, the writer takes this opportunity of acknowledging his indebtedness.

The writer owes a special debt of gratitude to Carl H. Gronquist, M. Am. Soc. C. E., who, during many arduous months of generous collaboration, contributed helpful suggestions, checked derivations of formulas and numerical applications, reviewed manuscript, and prepared illustrations.

Paper No. 2244

ERECTION OF HYDRAULIC TURBINES AND GENERATORS

By Andrew M. Komora,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Paul E. Gisiger, Frank I. Morgan, J. F. Roberts, D. E. Brainard, and Andrew M. Komora.

Synopsis

Most engineers who have installed hydroelectric generators have discovered that certain units operate perfectly whereas others perform in a manner leaving much to be desired. Construction methods and procedures differ widely, and the writer believes that, by adhering to certain fundamentals in erection procedure, most units can be assembled so as to operate perfectly. The purpose of this paper is to offer suggestions for the perfection of such methods and procedures.

The construction procedure for assembling and erecting turbines and generators recommended in this paper is based principally on the methods used by the Tennessee Valley Authority (TVA). The installations vary from the low-head, large-diameter Kaplan-type turbines at Pickwick Landing, Tenn., to the relatively high-head Francis-type units at Hiwassee, N. C.[2] The fundamental rules apply to all types of installations and give comparable results. The steps in the erection are presented under six headings, or "stages," in the order in which they generally occur.

Stage 1. Placing and Erecting Turbine Embedded Parts

Fig. 1 illustrates cross sections through two typical turbine types, indicating the nomenclature generally used by engineers and construction personnel. Although the paper refers expressly to the typical "Kaplan" installation, the general procedure is applicable to all types.

It is assumed that, just prior to placing the embedded part of the first turbine, the concrete for the power-house substructure has been poured as high

---

Note.—Published in March, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

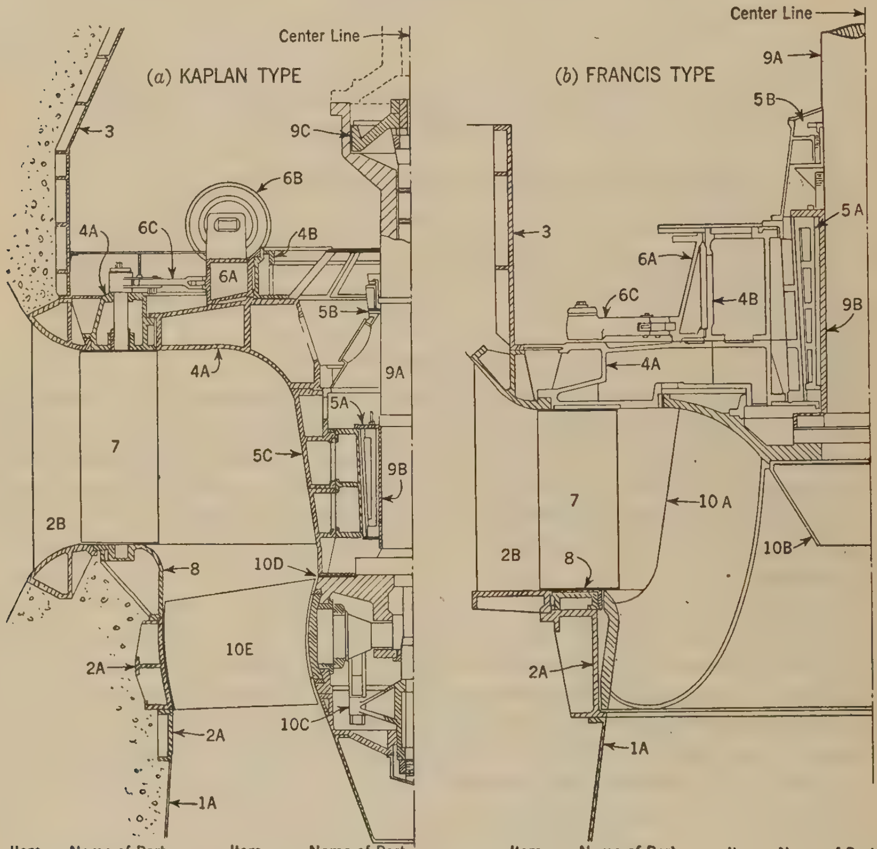
as possible. In the case of a concrete scroll case, the largest part of the scroll-case floor will have been poured, including the scroll-case walls. A recess large enough for working room is left to receive the draft-tube liner. Concrete piers are erected high enough to receive the speed ring but with sufficient clearance for placing screw jacks and steel shims under it.



Item	Name of Part
1A	Draft Tube Liner
2A	Discharge Ring
2B	Speed Ring
3	Pit Liner
4A	Cover Plate
4B	Cover Plate Extension
5A	Guide Bearing
5B	Stuffing Box
5C	Head Cover Barrel
6A	Shifting Ring
6B	Operating Cylinder and Rods
6C	Levers and Links
7	Guide Vanes
8	Guide Vane Ring
9A	Main Shaft
9B	Shaft Sleeves
9C	Reservomotor Piston
10A	Runner
10B	Runner Tip
10C	Runner Blade Mechanism
10D	Runner Hub and Cap
10E	Runner Blades

Fig. 1.—Sections of Typical Turbine Types

The draft-tube liner is then set in place, centered, and alined approximately to grade. It is anchored securely to U-bolts placed in the concrete. The speed ring is next assembled, either in place or on an assembly deck, depending on handling facilities and space requirements. Great care is necessary to level the ring as closely as possible. Strong supporting blocks, preferably cut from H-sections, are used in addition to screw jacks. It is not necessary to spend much time centering the ring on the theoretical power-house center lines or to bring it exactly to the grade called for on the plans (see Stage 6). The entire procedure for the unit assembly is dependent on the final elevation and center lines of the speed ring. The lower and upper discharge rings are assembled in place and centered as closely as possible to the speed-ring center. The ultimate runner clearances will depend on how accurately this phase of the work is done. At this point all bolted contact joints have been coated with red lead and linseed oil.

After assembling the rings, the draft-tube liner is fastened to the lower discharge ring. The method of fastening varies with different manufacturers and installations, but most modern draft-tube liners are welded to the discharge rings. Careful "stitch" welding in light layers and peening avoid the danger of distorting the parent metal.

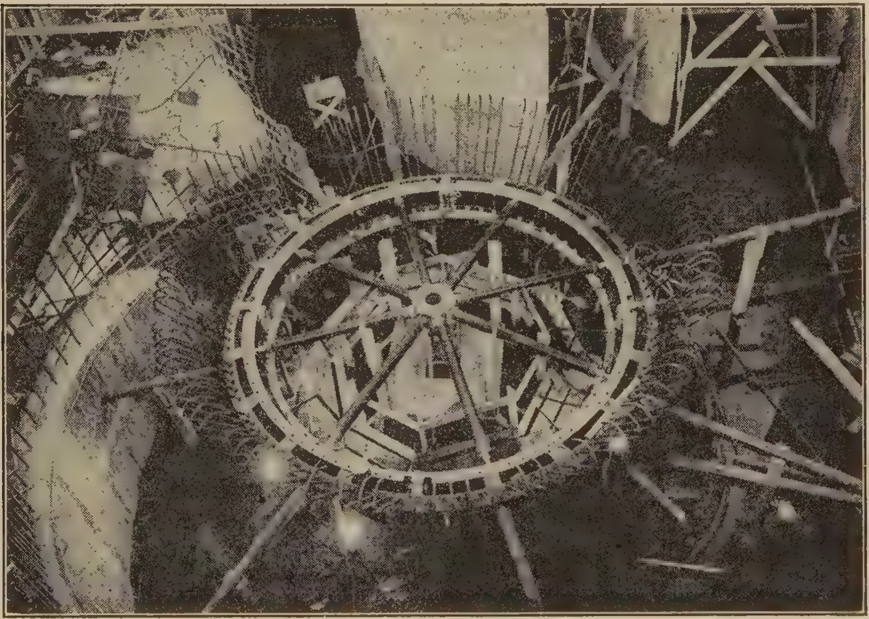


FIG. 2.—SPEED-RING ASSEMBLY SHOWING METHOD OF BRACING

Double extra strong 6-in. pipe, or its equivalent, is best to brace the speed ring rigidly, inside and outside (see Fig. 2). It is false economy to use light struts since good substantial center struts can be made by most job forces. One "spider" will suffice for many installations by merely splicing it to the arms, or by cutting, to fit various speed rings of different diameters. The jacking bolts at the ends of the struts should be about 2 in. in diameter and should be tack-welded to the ring. The external struts should be placed opposite those on the inside of the speed ring to avoid distortion. They should be supported by shores at close centers to preclude the possibility of sag. The ring should be "trued up" for roundness by jacking with the struts, and then it should be leveled.

In leveling, it is necessary to erect a separate tower for the instrument. Whether a level or a transit is used depends on the engineer's preference. The sighting target can be made up of cross hairs mounted on a micrometer head which in turn is mounted on a heavy steel base. The speed ring, the discharge rings, and the draft-tube liner are now ready for concrete and grout (see Stage 2).

The lower and upper pit liners are assembled on to the speed ring after the ring has been completely grouted. Reasonable care is needed in alining and centering the pit liner, but this precaution should not be carried to extremes. The principal thing is to center the operating cylinder bases, as closely as possible, on the center line of the unit. Of primary importance to designers and manufacturers is the fact that the plane of the operating cylinder bases cannot be held perpendicular to the true center lines of the cylinder assembly. The bases may be alined perfectly, but it will be found invariably that they are out of line after the scroll-case concrete has set. To remedy this condition, some manufacturers provide a "dutchman" or filler piece to be inserted between the operating cylinder and the base on the pit liner. Measurements are taken between the operating cylinders and their bases after final alinement and the filler pieces are machined so as to take up any discrepancy. It is recommended that the bases be made thick enough to allow for facing in the field. This operation can be performed with a job-constructed facing rig made of a slow-speed air motor to which a heavy slotted plate with a cutting tool is mounted.

A poor practice among some designers and manufacturers is to require that the pit liner be welded to the speed ring for watertightness. There is always a good chance of distorting the speed ring during the welding operation. A watertight joint can be obtained by providing a V cut in the speed-ring flange or pit-liner base (possibly both), and by inserting a rubber filler slightly larger than the V cut. Care must also be exercised to avoid distorting the speed ring in welding the various membering joints in the pit liner. Welds should be made in thin layers, and peened.

STAGE 2. GROUTING OF SPEED RING

The speed ring on a hydraulic unit is generally designed to support a large part of the superimposed scroll-case roof, the entire generator, including rotor, the water-wheel runner, and the hydraulic thrust. It is highly essential, therefore, that a good grouting job be obtained under the speed ring, to avoid the possibility of an open joint or seam.

The concrete around the lower and upper discharge rings should be poured in relatively short lifts to within about 6 in. of the speed ring, the actual distance depending on the design of the speed ring and on job conditions. Then the concrete is allowed to stand for seven or eight days, being cooled with a water spray to shrink it as much as possible.

Procedures and proportions for mixing grout in turbine installations probably vary more with different construction organizations than any of the other operations. In an effort to devise a consistent standard, a series of grouting tests was conducted at Wilson Dam during the fall and winter of 1941. As a result of these studies the writer recommends that grout headers, about 4 or 5 ft high and spaced at 3-ft or 4-ft centers, be inserted in the speed ring. He prefers them to be 1½ in., or larger, in diameter, with funnels to facilitate pouring grout. Small vent holes, 0.5 in. to 0.75 in., should be provided in the speed ring, spaced in a staggered manner, one being placed in each ribbed corner. Pouring should begin simultaneously at several points on the speed ring and the grout should be worked uniformly away from each header. For one to two hours, or until all signs of free water and laitance have disappeared, the grout should be rodded thoroughly. When there is evidence that pure grout is escaping from any vent hole, this hole is plugged. This procedure is followed on all vent holes around the speed ring, and all vents are reopened at about 10-min intervals and checked for free water.

The following specifications are recommended in grouting turbine speed rings:

1. Water-cement ratios are to be as low as possible, but not lower than 0.50 in confined areas;
2. Coarse aggregates are to be added to the grout as working conditions will permit; and
3. The grout is to be rodded continually for at least an hour, or until all of the free water and laitance is expelled.

Stage 3. Pouring Concrete

Designers will lay out the pours around a unit in equal segments, say 4 to 6 sections, depending on the physical size of the turbine. Alternate segments will then be poured so as to equalize the radial thrust on the speed ring and pit liner. As a general rule, a seven-day interval (or more) is necessary between horizontal lifts and a three-day interval between vertical lifts. This will allow for more rapid cooling of the individual pours, thus minimizing the shrinkage effect on the unit. Alternate lifts are poured simultaneously and at slow rates not to exceed 1 ft an hour. In no case should mechanical vibrators be allowed closer than 10 ft from the unit as there is always danger of jarring loose a strut or stay, thus causing possible misalinement or distortion of the speed ring.

Stage 4. Erection of Turbine Internal Parts Including Stationary and Rotating Elements

The starting point of all assembly of the internal parts of the turbine is the guide-vane ring. In some installations, this is fixed at the time the speed ring and upper discharge ring are installed and is an integral part of these members (see point 8, Fig. 1(*a*)). In other installations, the guide-vane ring is a separate member; it is necessary that the ring be centered as closely as possible to the discharge ring and fixed in its final position by dowels.

The outer cover plate is assembled in place and bolted loosely to the speed ring. A steel mandrel, having the same diameter as the guide-vane trunnions, is inserted through the upper guide-vane bushing in the outer cover plate and into the lower guide-vane bushing in the guide-vane ring. This check is made in each set of bushings. It may be necessary to shift the outer cover plate during this operation in order to aline the upper and lower bushings properly. In some instances, it may be necessary to scrape the bushings to prevent binding of the guide-vane stems. When the bushings are properly alined, the outer cover plate is bolted rigidly to the speed ring and a sufficient number of dowel holes are drilled to fix the position of the outer cover plate with respect to the speed ring.

The outer cover plate is then raised as a unit and blocked up on timber cribbing; the guide vanes are next installed in accordance with factory match marks; the outer cover plate is lowered in place, bolted and doweled to the speed ring; and each of the guide vanes is centered vertically so that the clearance is the same between the guide vane and the guide-vane ring and outer cover plate.

The inner head cover (the lower point 4A, Fig. 1(*a*)) is bolted to the head cover barrel (point 5C, Fig. 1(*a*)). (Dowel holes joining these pieces usually are drilled in the factory.) These two pieces should be installed as a unit. The head cover barrel is centered with the discharge ring and the inner cover plate is then doweled to the outer cover, using undersize dowels. The cover-plate extension (point 4B, Fig. 1(*a*)) and shifting ring (point 6A, Fig. 1) are installed in the order named. During this operation, the runner is generally being assembled on an erection pedestal in another part of the building. The operating cylinders (point 6B, Fig. 1(*a*)) are assembled to their bases on the pit liner. Great care must be exercised in this operation to aline the cylinders concentrically with the shifting ring. The rods are generally alined with the shifting ring at the mid-stroke position in order to equalize the radial throw-out between the fully open and closed position. As mentioned, the pit liner will be distorted somewhat due to the shrinkage of the concrete. It would be a fortunate coincidence if the operating cylinder base stayed in alinement. In most cases it is necessary to insert a machined filler plate between the operating cylinder and the pit-liner support. A better method is to have the manufacturer weld a base plate of sufficient thickness to the pit liner to allow for machining on the job. Accurate measurements, for alinement requirements, can be taken during the assembly of the operating cylinders and the base plate can be milled with a job-facing tool. The operating cylinders and shifting ring are to be removed.

The runner and shaft assembly presents no serious difficulties. The clearances between the runner blades (point 10E, Fig. 1(*a*)) must be equalized, if necessary by inserting shims in the operating links (point 10C, Fig. 1(*a*)). The packing around the runner hub is inserted carefully and tightened with the gland ring. The hub is tested with air pressure to insure the tightness of the packing. The inner cover plate (lower point 4A, Fig. 1(*a*)) is removed from the turbine pit and mounted on the runner assembly and bolted to the head cover barrel (point 5C, Fig. 1(*a*)). The stuffing-box housing (point 5B, Fig. 1(*a*)) is now mounted around the shaft. This provides a temporary support for the runner and shaft assembly. The entire assembly is next placed in the turbine pit.

The inner head cover is bolted and doweled rigidly to the outer head cover. The runner and shaft are centered as closely as possible in the upper discharge ring (point 2A, Fig. 1(*a*)) and the head cover barrel, respectively. The shaft is then plumbed as accurately as possible. It is advisable to place jacking struts between the shaft and some convenient point on the inner head cover to hold the shaft in vertical alinement during the generator assembly. Fixed tram points are placed in the inner head cover just above the lower guide bearing. It will be necessary to use these points after the turbine shaft is coupled to the generator shaft. The guide-bearing housing and shoes should be inserted and centered about the center of the shaft throw-out. Generally, running clearances of from 0.004 in. to 0.006 in. are used in the final adjustment. It is advisable to use long copper shims between the turbine guide-bearing shoes and the shaft. The shoes are jacked firmly against these shims and left in this position until the generator shaft is alined to the turbine. In this connection, "wedge-type" shoes are most practicable—that is, shoes with tapered back seats—because, as wear occurs, they can be readjusted easily to maintain the proper running clearances.

STAGE 5. ERECTION OF GENERATOR-MECHANICAL FEATURES

Only the mechanical features of generator erection which tie in to the turbine are discussed in this paper. Generator erection in detail has been covered capably elsewhere.[3, 4]

Great care should be exercised in establishing the correct grades for the main bracket and stator sole plates (6F). The turbine shaft generally will be resting on a temporary seat from one fourth to three fourths of an inch below its final grade before being coupled to the generator. This clearance, plus an additional allowance of from 0.030 to 0.050 in. for main bearing-bracket deflection (depending on the bracket span and loading) should be taken into account when computing the final elevation of the sole plates.

It is highly desirable to center and aline the generator shaft and bearing bracket to the turbine shaft before final centering and alinement of the stator. The generator shaft is centered on the thrust bearing before being placed in the pit. The thrust-bearing shoes are all set to initial adjustment before the rotor is placed. At this point both the main bracket and stator sole plates are grouted. It has been found that grout with a water-cement ratio of 0.40 is best suited for this purpose. This grout is dry enough so that it can be placed under the bearing plates without the use of forms and does not shrink on setting up.

Some generator manufacturers use a radial type bracket, whereas others use through girders with side arm stiffeners. In the latter case, it is recommended that the side arms be not fastened and doweled to the sole plates until the unit has been loaded to about three quarters of its rated capacity. The added deflection caused by the hydraulic thrust will tend to close-in the guide-bearing shoes (point 6E, Fig. 3) and thus cause excessive heating if the side arms are fastened down initially.

After the bearing-bracket sole plates are grouted, the remainder of the generator erection can be completed. The generator shaft is centered accurately and plumbed to the turbine shaft. Four heavy plumb bobs suspended on piano wires at the quarter points can best be used for this purpose. Using temporary coupling bolts, the turbine shaft and runner are brought up slowly

to the generator shaft. It is customary practice to make the permanent coupling bolts 1 to 2 mils oversize, which necessitates freezing the bolts in dry ice or forcing them in place with hydraulic jacks. Either method is satisfactory and the choice depends on job conditions. The bolts are pre-stressed uniformly

and to such an extent that the total tension developed will be in excess of the combined weight of the turbine, turbine shaft, and the maximum hydraulic thrust, and, in the case of the Kaplan types, the maximum internal pressures. This will assure that the turbine and generator shaft coupling faces are in positive contact under all conditions. In the old days, the general order used to be to "slug her up till she rings and then take another turn." In some instances, this resulted in a permanent deformation in the coupling flanges with resultant misalinement of shafts. The customary stretch in bolts is from 0.006 to 0.012 mill, depending on the number, size, and length of bolts, and on the total suspended load.

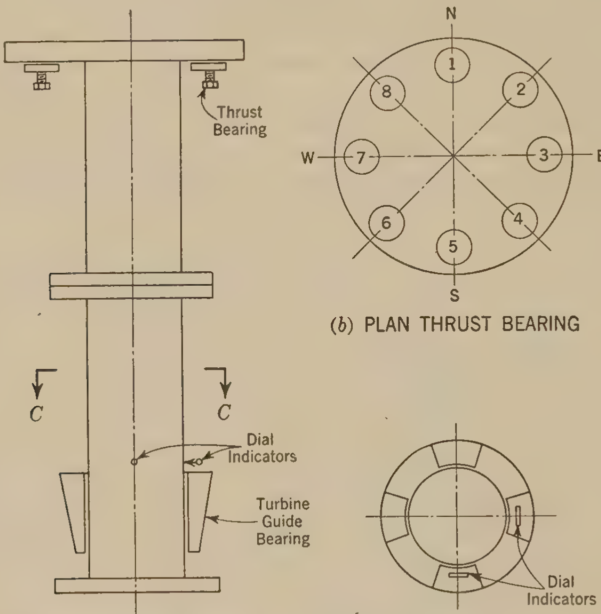
The customary procedure is to have the turbine shaft shipped to the generator manufacturer for final fitting up to, and alining with, the generator shaft —a needless expenditure of time and money. With present precision machining methods, the chance of misalining the coupling flanges is negligible. The holes for the coupling bolts can be subdrilled in the shop $\frac{1}{8}$ in. undersize and line reamed in the field after the two shafts are drawn together. One generator manufacturer uses this method in fitting his rotor to the shaft in the field. For a cutting unit, he uses an automobile cylinder honing machine fitted up with a cutting tool.

After the turbine shaft is coupled permanently to the generator shaft, the entire unit is free to swing on the thrust bearing. The thrust-bearing shoes are set up as uniformly as possible. They are generally adjusted by either the "feel" method or the "slugged arc"[4] method. The first requires a highly skilled mechanic and the second is much more accurate. By "feel" each shoe is adjusted progressively around the thrust bearing. The amount of tension on each adjusting screw is determined by the mechanic by observation and "feel" of the wrench. At best, this is a guess on the operator's part. Basically, the "slugged arc" method consists of measuring an arc at a known radius of a hand-calibrating wrench. Each of the adjusting screws under the thrust shoes is loosened completely, progressively and one at a time. The screws are tightened by a hand-calibrating wrench, care being exercised to obtain the same tension on each screw. The arc is measured by a graduated scale and the values are plotted. The loose shoes are tightened and the tight shoes are loosened by amounts depending on the plotted values. The "slugged arc" measurements are repeated and the values again plotted. Theoretically, they should all fall on the same horizontal line. An experienced operator generally can make a uniform adjustment on the second trial.

The following method of adjusting thrust-bearing shoes was evolved on the job by G. L. Teague and has been used successfully on two large machines (see Fig. 4). The combined assembly consisting of rotor, generator and turbine shafts, and runner is plumbed as accurately as possible. The initial thrust of each individual thrust shoe is immaterial. Two indicators are placed at the lower guide bearing at the quarter points (see Fig. 4(*c*)).

Compression is applied on the thrust shoes progressively, beginning with shoe No. 1 and continuing to shoe No. 8 (Fig. 4(*b*)). If either indicator shows the least movement during the adjustment on any individual shoe, the setting is stopped and the process is repeated on the next shoe in numerical order. Obviously the setting up of shoe No. 1 will not produce any movement in the west-east direction, but will produce motion in the north-south direction. The adjustment of shoe No. 2 will produce a movement which will show up on both indicators in Fig. 4(*c*). The procedure is repeated until the slightest adjustment on any individual shoe produces a movement on either indicator. This simple method will work with any number of thrust shoes.

It is absolutely essential that, whatever method is used, each thrust shoe be adjusted to as uniform a loading as possible. The successful running of the unit will depend to a very high degree on this adjustment.



(*b*) PLAN THRUST BEARING

(*a*) ELEVATION OF SHAFT (*c*) VIEW *C-C*

FIG. 4.—THRUST-BEARING ADJUSTMENT

In recent years, it has been customary to make a "rotation" check on the combined assembled unit. This check consists in rotating the unit mechanically (by jacking or attaching cables from the power-house crane to the rotor spider) through four 90° turns and taking plumb readings at several points. The bearing shoes are coated with a heavy graphite and oil lubricant prior to the mechanical rotation to preclude the possibility of scarring the bearing surfaces. It has also been found advisable to disregard the readings on the initial 90° turn because the heavy lubricant is "ironed out" between the shoes and the runner place in this turn.

A typical rotation check is shown in Table 1, in which Fig. (*b*) testifies that the axis of the shaft described a circle of rotation at the lower guide bearing of 0.0055 in. The center of this circle is 2 mils south and $1\frac{1}{4}$ mils west from the theoretical center line. The initial or zero point was $1\frac{1}{4}$ mils south and zero mils east and west. The shaft was replumbed so that the final position was 1 mil west and zero mils north and south.

In a great many installations, the thrust collar is not an integral part of the shaft but is shrunk or keyed to the shaft in the field. In such cases, a rotation check would indicate whether or not the face of the thrust collar was set normal to the shaft. It is conceivable that a thrust collar could be set a few mils from a normal position and the setting of the thrust shoes equalized in this position. Plumb readings would indicate that the shaft was vertical and centralized in the turbine guide bearing. However, in actual operation the shaft would describe a cone; that is, it would wobble within the turbine guide bearing with an amplitude depending on the ratio of the bearing diameter to the combined length of the turbine and generator shafts and the amount the thrust collar was set out of normal to the shaft. The rotation check could be omitted in the case of an integral thrust collar and generator shaft. Present-day machining methods are very precise so that there is little danger of the thrust collar being out of true with the shaft. The shaft is rotated in a lathe after machining and polishing, and careful throw-out measurements are made with dial indicators.

[a] These are micrometer readings for the final centering of the turbine and guide bearing (not necessarily at El. 439.9).

The slight added cost of an integral thrust collar and shaft is warranted over that of keyed or shrunk hub. The integral thrust hub and shaft is easier to install and the results are more certain. In some installations having shrunk hubs, several weeks were spent in alining the units.

STAGE 6. ALLOWABLE TOLERANCES

In some installations, much unnecessary time and effort have been spent in alining or centering a unit to theoretical elevations and center lines. Deciding the necessary degree of accuracy requires a certain amount of "horse sense." Obviously, in erecting a high-head unit with a steel scroll case, which in turn connects to a steel penstock, closer tolerances are adhered to than in a low-head unit with a concrete scroll case. In steel scroll cases, especially in the riveted type, a certain amount of creepage will occur as the plates are assembled to the speed ring, making it necessary to field drill the connecting joint to the penstock. In such cases, greater tolerances can be allowed than, say, in cast steel machined scroll cases where it is necessary to meet fixed points.

Speed rings are set and held as level as is humanly possible. A tolerance of 0.001 in. per ft of speed-ring diameter should be the maximum allowable deviation from a true horizontal plane. There are cases in which, in spite of all precautions, the rings get out of level more than the amount specified (0.001 in. per ft) during the concreting operations. The cover plates and the guide-bearing housing can be adjusted, in such cases, to compensate for the added "outage" and still hold the turbine shaft in vertical alinement.

The remainder of the turbine parts, such as guide vanes, head covers, guide-vane linkages, operating cylinders, distributor rings, etc., are assembled as closely to specified dimensions as machined fits will permit. With the foregoing suggestions in mind, it is possible to summarize the principal erection tolerances as shown in Table 2.

TABLE 2.—SUMMARY OF PRINCIPAL ERECTION TOLERANCES, IN INCHES

ACKNOWLEDGMENTS

Engineering work for the TVA was under the general supervision of Theodore B. Parker, M. Am. Soc. C. E., chief engineer; George R. Rich, M. Am. Soc. C. E., chief design engineer; A. L. Pauls, M. Am. Soc. C. E., chief construction engineer; and H. J. Petersen, head of the Mechanical Design Section.

The writer wishes to express his sincere thanks and appreciation to the many turbine mechanics and erectors employed by the Authority, and especially to J. S. Kuzawa, formerly master mechanic, for their many helpful suggestions and instructions in the art of assembling turbines; and to Sam McCluer, associate materials engineer, for conducting the grouting tests.

DISCUSSION

Paul E. Gisiger,[5] M. Am. Soc. C. E.—A useful summary is presented of the main points to be observed in the erection of Kaplan and Francis wheel hydroelectric generating units. The writer would like to add one recommendation to this competently presented paper—namely, that those who are in actual charge of erection make and keep a permanent record of all elevations, clearances, tolerances, etc., established at the time of erection. This record should be checked and if necessary supplemented immediately before the unit goes into regular operation.

The writer has several times regretted the lack of such a record. It is fairly obvious that the levels and tolerances established during erection of a hydroelectric unit are not permanent. Even the best of concrete is subjected to slight changes of volume and shape due to the factors of shrinkage and creep, apart from temperature variations and elastic deformations. The dislocations caused by these factors are generally of equal, if not higher, order of magnitude than the tolerances within which a unit can be erected. The resulting changes in alinement are in most cases inconsequential and may be unnoticed for years, but occasionally they are large enough to require correction and then the question arises as to how much change has taken place since the time when the unit was erected. The horizontal alinement of a generator stator may have changed, the runner blades of a Kaplan turbine may have left a trace on some sector of the circumference of the discharge ring, a bearing may show signs of pressure concentrated on one side, or a shaft may be found to be slightly out of plumb. In each case several causes may be responsible for the change. Without an accurate record for reference it is difficult, if not impossible, to judge the nature and causes of the trouble and to apply suitable remedies.

There are normally at least three parties concerned with the erection of a hydroelectric unit—the purchaser, the turbine manufacturer, and the generator manufacturer. If something does get out of plumb or alinement, it is natural for the equipment manufacturers to question the structure on which this equipment is supported. All the interested parties then need a complete record of the condition of the unit at the beginning of its useful life.

From this viewpoint it cannot be recommended too strongly that a complete record be kept of each unit, giving all key measurements and elevations such as, for instance, diameters of the discharge ring in at least four directions, elevations of marked points of the speed ring, elevations of the points of support of the main bearing brackets, and elevations of the stator base plates. In addition to these points on parts of the generating unit itself, it will be helpful to maintain a record of observation points that permit following any slight change in the structural supports. Such points may be located, for instance, on the two main diameters at the lowest accessible points of the pit liner and at corresponding locations higher up on the concrete foundation of the generator stators. The cost of installing such observation points or bench marks at the time of erection is insignificant when compared to the value of the information they may reveal during the life of the unit.

---

[5] Structural Engr., Pennsylvania Water and Power Co. and Safe Harbor Water Power Corp., Baltimore, Md.

FRANK I. MORGAN,[6] ESQ.—A longfelt need has been met by the publication of this interesting paper. The writer wishes to add his comments in the hope that Mr. Komora will clarify a few points. For example, under "Stage 1. Placing and Erecting Turbine Embedded Parts," the author states: "Whether a level or transit is used [in setting equipment] depends on the engineer's preference." Is it not true that there is no choice since the transit is not a sufficiently accurate instrument for this purpose? The use of a high-grade level is quite essential to insure accurate results.

The author mentions difficulties experienced with the I-beam type of bearing bracket because of improper shimming, etc., of the side arms. This has been a serious problem and much trouble has been experienced with guide bearings because distortion of the bearing retainer resulted from increased deflection under load. This defect has been corrected in later designs by hinging the side arms. It would be interesting to learn how the bearing clearance is determined, with the machine under load as recommended by the author.

Mr. Komora mentions the use of four plumb lines when plumbing the shaft. Why are four lines necessary? It should be possible to obtain all the data with two plumb lines 90° apart—reducing the amount of work considerably.

The author states that it is customary to make the coupling bolts 1 to 2 mils oversize. What are the particular benefits of this procedure? This practice requires considerable extra time and labor during subsequent dismantling work. Furthermore, such tight fitting bolts tend to distort the faces of the flanges and to make difficult the accurate determination of the stress, in the bolts, during the process of tightening. A light tapping fit for coupling bolts is considered adequate. If the bolts are properly stressed when tightened, the friction between the coupling faces should be sufficient to transmit the torque. In one particular case the bolt holes in one flange of a shaft coupling were inadvertently reamed oversize. The unit, a large one, was assembled with the coupling in this condition, and an inspection quite some time after the unit had been in service, under load, showed that no movement had taken place in the coupling.

Mr. Komora is quite emphatic in his condemnation of the practice of shipping the turbine shaft to the generator manufacturer, there to be assembled with the generator shaft and the entire assembly checked for truth in a lathe. Such procedure is advisable until the erection of large units, on which this course has not been followed, has proved satisfactory. In at least one case, such a check revealed considerable inaccuracy which could be corrected only by remachining. Had the shafts reached the field, serious delay would have resulted. Shop assembly also makes it unnecessary to ream coupling bolt holes in the field.

In Table 1 the actual throw of a particular shaft is given as 0.0055 in. The author states (see heading, "Stage 5. Erection of Generator-Mechanical Features"), "The center of this circle [the shaft throw] is 2 mils south and $1\frac{1}{4}$ mils west from the theoretical center line. * * * The shaft was replumbed so that the final position was 1 mil west and zero mils north and south." Five mils is extremely small for the throw of a shaft, and since the center of the throw is but 2 mils away from the true center the position of the shaft is almost ideal—making any changes in its location somewhat inconsistent with the author's statement that much unnecessary time and effort has been spent in alining units. In this particular case the clearance of the guide bearing in which this shaft operates is probably 12 or 16 mils; therefore, the throw of the shaft plus the error in the position of the center would still be small enough to be within the bearing clearance. Units having shaft throws of 50 mils are operating successfully although this is, by no means, a desirable condition.

---

[6] Maintenance Engr., Pennsylvania Water and Power Co. and Safe Harbor Water Power Corp., Baltimore, Md.

Has Mr. Komora had experience in plumbing the shafts and checking the throw of units equipped with spring type thrust bearings? With this type of thrust bearing the shaft may be made absolutely plumb and centered in the turbine guide bearing. As soon as the rotor is turned, however, the shaft will no longer be plumb because of unequal yielding of the springs in the thrust bearing. Thus, the final setting must be a compromise.

The author states that a period of several weeks has been spent in alining units having shrunk hubs. If the surface of the hub (more properly, the thrust block) is not normal to the shaft axis, how can the unit be alined correctly since no amount of adjustment of the thrust bearing will eliminate this error?

J. F. Roberts,[7] M. Am. Soc. C. E.—This description of the field erection practice of the TVA on large hydraulic turbines of both the Francis and Kaplan types is interesting and will be of great assistance to engineers with similar problems. During wartime when the privately owned power companies are not able to do any appreciable amount of extension work or to develop new power facilities, it is gratifying that government owned corporations and commissions are allowed to publish data on their projects. This opinion has been expressed by several engineers connected with private power companies.

Mr. Komora's brief comments regarding the grouting of embedded parts could have been amplified considerably. The writer was intimately connected with the experiments conducted at Wilson Dam by the TVA in an effort to study the results of various grouting procedures. Some special compounds were tested, especially those which tend to cause expansion on setting. Although in some cases these gave excellent results, it has been found difficult in practice to obtain uniformly good results because construction forces object to the careful measurements and accurate proportioning of ingredients that seem necessary. In certain cases a slight excess of water entirely ruined the effects of the agents which were supposed to cause expansion on setting. In the final analysis it was found that more uniform results could be obtained with a straight cement mixture, provided that such a mixture was rodded for a sufficient length of time to work all the free water out of the mixture.

Mr. Komora mentions that mechanical vibrators should not be placed closer than 10 ft to the unit to avoid possibility of distortion of the parts of the machinery. Originally, the writer was in accord with this opinion, but further experience has indicated the advisability and extreme usefulness of the small sized vibrators especially in grouting work where rodding and tamping are difficult. These small vibrators, which will pass through a $2\frac{1}{4}$-in. hole, have been of material assistance in compacting the grout, and, if the embedded parts are properly anchored down and the height of the pour or lift of concrete is kept to reasonable limits, as outlined by Mr. Komora, no difficulties should be encountered in moving, shifting, or distorting the embedded castings.

---

[7] Mgr., Hydr. Dept., Allis Chalmers Mfg. Co., Milwaukee, Wis.

Closer cooperation between the designers of the machinery itself and the designers of the concrete structures would be helpful. Wherever possible the undersurface of castings that are to be grouted in should be constructed with a slope such as to avoid dead pockets, as it is very difficult to produce a satisfactory grouting job under a large horizontal surface.

Mr. Komora mentions the use of temporary coupling bolts for lifting the turbine runner and shaft into position. Although this idea works satisfactorily, using a quicker and easier method the turbine shaft and runner are brought up to the generator coupling by means of four or more hydraulic jacks equally spaced around the coupling. These can be supported on the head cover or in some cases satisfactory results have been obtained by mounting the jacks on horizontal plates suspended with two long bolts through the generator coupling bolt holes. Turbine runners and shafts weighing as much as 200 tons have been lifted into final position in less than one hour with this arrangement. By checking the gap between the couplings at frequent intervals, or placing dial indicators to observe the movement, the couplings can be brought up absolutely parallel with no danger of binding.

Many civil engineers fail to appreciate the extreme flexibility of large castings when subjected to hydrostatic pressures such as those which may be exerted by large masses of liquid concrete. Turbines with runner openings from 20 to 24 ft in diameter, having speed rings with over-all dimensions of from 30 to 37 ft in diameter, are easily distorted and have to be securely held in order to maintain a true circle. Runner clearances on large Kaplan and propeller type units vary from 0.120 in. to 0.180 in. on a radius. Few large installations can be maintained truly round, the average discrepancy being 0.020 in. to 0.030 in. on the radius. Where an insufficient number of radial struts are used to hold these castings round, flat spots may be found between the braces. It is advisable to take twenty to thirty equally spaced readings around the circumference to secure an accurate picture of the condition of such rings. Temperature also is an important factor. Daily readings on embedded parts show a gradual distortion as the maximum temperature in the setting concrete is obtained and then a gradual return to the original conditions as this heat is dissipated. Continuous sprays of cooling water on embedded metal parts help to reduce this distortion.

This paper and similar ones materially assist manufacturers in giving field construction engineers a better understanding of the problems to be encountered and of the accuracy of the desired results.

D. E. Brainard,[8] Esq.—Proper installation is an essential prerequisite for successful operation of hydroelectric machinery. Designers may profit greatly from the experience of those who erect their equipment. Therefore, the author's orderly recording of salient points is welcome. The following supplementary comments are offered from the point of view of the generator manufacturer.

---

[8] Motor and Generator Eng. Div., General Electric Co., Schenectady, N. Y.

The author has outlined a procedure for minimizing the tendency of the side arms of a girder-type thrust bearing bracket to pinch the guide bearing. In a number of cases, the side arms are attached to the main beams with a hinged joint so that the function of transverse stiffening may be performed without any twisting of the main beams.

Since 1933, at the insistence of certain operating groups, the use of a jacking fit on coupling bolts has flourished. Most manufacturers saw no benefit from the tight fit and the resulting tendency to score the bolts, and preferred to make the bolts and the holes "line and line" so that the bolts could be driven in by a rawhide mallet. With few exceptions, customers now accept the "light driving fit."

Coupling bolts should be stretched in excess of the load imposed on the bolts by the weight of the water-wheel parts, the hydraulic thrust, and the cylinder oil pressure, if any. For Francis-type wheels, however, this stretch may be as small as 0.002 in. The bolts should not be stretched more than necessary in a given case, as excessive tightening may lead to galling the threads.

The author questions the value of factory fitting of coupling bolts and alinement of water-wheel and generator shafts. Certainly, there is a size of unit below which the additional expense of this operation is not justifiable. For large units there appears to be an advantage in employing factory facilities to handle the heavy and sometimes cumbersome parts involved in fitting the bolts. The assurance that the parts will run true when reassembled appears to be a good investment.

The intricate procedure outlined for obtaining proper distribution of load among the shoes of a thrust bearing is required by only one type of bearing. One of the generator manufacturers originated and produces a type of thrust bearing that provides inherent distribution of the load over the bearing surfaces and also automatically compensates for changes in the line-up of the unit which would disturb the loading of a rigidly supported bearing.

The rotation check described in the paper as "customary" has been required by only one customer. It is possible to determine whether a shaft is straight and plumb by checking from tight wires without the laborious process of turning the shaft and rotor. The almost universal practice of making a factory check with the thrust collar on the shaft has been found in practice to give adequate protection against inaccuracies.

A thrust collar forged integral with the shaft does have certain definite advantages, but this feature can be used only when the thrust bearing is below the rotor. This "overhung" design with no upper guide bearing and often no exciter was developed on moderate-sized, low-speed units where the stator and rotor could be made accessible for inspection or repair by disassembling a minimum of related parts without disturbance to the shaft alinement and bearing assembly. This size of unit allowed space for reasonably convenient disassembly of the thrust bearing. As the size and resulting importance of units increased and as the runaway speeds were raised by water-wheel developments, upper guide bearings were added, largely eliminating the element of simplicity. When the output and speed of a generator become such as to require a relatively small diameter, space does not permit reasonably convenient disassembly of the thrust bearing if it is located below the rotor. So, except for a very limited range of size and speed, it is desirable to use the "conventional" mechanical arrangement with the thrust bearing above the rotor. Top location of the thrust bearing reduces its size and permits handling it with the crane.

Andrew M. Komora,[9] M. Am. Soc. C. E.—As Mr. Roberts states, the grouting of embedded parts of a turbine is highly important. It is regretted that, because of space limitations imposed by the restrictions of World War II, it was impossible to include the results of the experiments conducted at Wilson Dam with various grouting procedures. Perhaps these results can be published later as a special phase of turbine erection.

Construction men, especially concrete-placing crews, have a mania for using vibrators close to the turbine-embedded parts. For proper engineering use small vibrators can be permitted under turbine parts if they are securely anchored.

The suggestion made by Mr. Roberts that the turbine and shaft can be raised into position by means of hydraulic jacks is a good one. In certain cases, however, it is more feasible to use temporary coupling bolts as the design of the unit does not lend itself to the use of hydraulic jacks. As stated by Mr. Roberts, it cannot be overemphasized that large-diameter speed rings and pit liners must be secured and braced at close intervals to preclude the possibility of distortion due to concreting.

As emphasized by Messrs. Morgan and Brainard, the use of hinged side arms of a girder-type thrust bearing should eliminate the tendency to pinch the guide bearing when the unit is operating under load. The writer agrees with Mr. Brainard that the coupling bolts should be stretched only slightly in excess of the load imposed on the bolts by weight of the water-wheel parts, the hydraulic thrust, and the cylinder oil pressure, if any. In many installations, the stretch required to take such loads will produce a stress in the bolts close to the allowable working limit.

The only possibility that the turbine and generator shafts made by different manufacturers will not match is the one chance that the coupling faces might not be at right angles to the axis of the shaft. The writer has yet to see an instance in which they failed to be at right angles. It may be accepted that the cost of reaming the coupling holes in the field is far less than that of shipping the entire shaft from one plant to another.

The writer agrees with Mr. Brainard that the rotation check has little, if any, significance in the case of integral thrust collars. It is still of great value in installations where the thrust collar is an independent unit and is either keyed or shrunk on to the shaft.

Thrust collars, forged integral with the shaft, have been used on units up to 60,000 kw with very good results. In general, the designs that are used on integral thrust collars present fewer erection problems to the field forces.

The writer wishes to acknowledge, gratefully, the discussions of Messrs. Gisiger, Morgan, Roberts, and Brainard.

SHEAR AND BOND STRESSES IN REINFORCED CONCRETE

By Stanley U. Benscoter[1] and Samuel T. Logan,[2]
Juniors, Am. Soc. C. E.

With Discussion by Messrs. F. R. Shanley, B. J. Aleck, Dean Peabody, Jr., William E. Wilbur, L. E. Grinter, Anders Bull, Victor R. Bergman, Phil M. Ferguson, and Stanley U. Benscoter and Samuel T. Logan.

Introduction

Formulas in common use for computing shear and bond stresses in reinforced concrete beams are based on the assumption that the member is subjected to symmetrical bending without thrust. The object of this paper is to demonstrate the error involved in applying them to members that carry thrust, and to develop general formulas which are applicable to prismatic members with or without thrust. The necessity for such formulas becomes apparent upon realization that practically all members of rigid frames are subjected to thrust as well as bending. The paper provides a new viewpoint for the problem of shear and bond stresses in reinforced concrete and is offered for the purpose of promoting discussion on the problem.

Notation

The following letter symbols, adopted for use in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials,[3] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = area of cross section of steel;
b = width of a member;
c = distance from the centroid of a section to the fiber with maximum unit stress;

Note.—Published in March, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate Engr., Bureau of Aeronautics, Navy Building, Washington, D. C.

[2] 1st Lt., Corps of Engrs., U. S. Army, Camp Joseph T. Robinson, Ark.

[3] ASA—Z10a—1932.

d = effective depth of a beam:

$k\,d$ = part of the depth that defines the distance from the compressive fiber to the neutral axis;

$\alpha\,d$ = part of the depth that defines the distance from the compressive fiber to the compressive steel;

I = moment of inertia;

$j\,d$ = internal moment arm = $\left(1 - \frac{k}{3}\right) d$;

k = a proportion of the effective depth (see d);

n = the modular ratio;

$p = \frac{A}{b\,d}$ = ratio of steel (compressive or tensile) to the sectional area of the beam;

Q = an integral defined by Eq. 4;

S = section modulus;

T = force acting on tensile reinforcement, dT being a small increment of such force;

u = unit bond stress;

V = total shear;

v = unit shearing stress;

x = a lateral distance, dx (see Eq. 1 and Fig. 1) denoting an element of width b;

y = a vertical distance measured from the centroidal axis: y_0 = the vertical distance between the centroidal axis and a point lying in the tensile region (see Figs. 1 and 2);

α = a proportion of the effective depth (see d);

Σ_o = perimeter of tensile steel.

Subscripts c and t used with the foregoing nomenclature denote "compression" and "tension," respectively. Subscript m denotes "maximum."

BEAM WITHOUT THRUST

A differential slice of a beam, subjected to bending and shear, is shown in Fig. 1 with the forces that act upon the slice. The centroidal axis and the neutral axis coincide. The distances c_c and c_t are the distances from the centroidal axis to the extreme fibers. The forces acting on the tensile reinforcement are T and $T + dT$. Equilibrium of the differential length of the tension bar (or bars) requires that the bond stress u be given by:

$$u = \frac{1}{\Sigma_o} \frac{dT}{dx} \quad \text{.......................... (1)}$$

On any horizontal plane between the neutral axis and the tension steel, such as is indicated by the distance y_0, the shearing stress v is given by:

$$v = \frac{1}{b} \frac{dT}{dx} \quad \text{.......................... (2)}$$

From structural mechanics the well-known formula for shearing stress in a beam may be taken as

$$v = \frac{V\,Q}{I\,b} \quad \text{(3)}$$

in which Q is defined by the integral,

$$Q = \int_{y_0}^{c_t} y\,dA \quad \text{(4)}$$

in which y is measured from the centroidal axis. For the case illustrated in Fig. 1, the quantity Q is merely the moment (about the centroidal axis) of the transformed tensile steel area and, hence, is given by

$$Q = n\,A_t\,c_t \quad \text{(5)}$$

in which A_t is the tensile steel area. Substitution of Eq. 5 into Eq. 3 gives

$$v = \frac{V\,n\,A_t\,c_t}{I\,b} \quad \text{(6)}$$

Two section moduli S_c and S_t may be defined for the beam as

$$S_c = \frac{I}{c_c}\text{; and } S_t = \frac{I}{c_t} \quad \text{(7)}$$

The first modulus S_c may be divided into the bending moment to obtain the maximum compressive stress, and the second modulus may be used similarly to compute the stress in the tensile steel. Introducing S_t into Eq. 6 gives the following formula for the shearing stress,

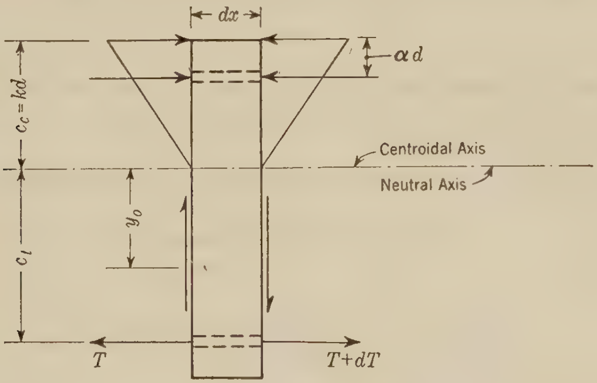

FIG. 1.—MEMBER WITHOUT THRUST

$$v = \frac{V\,n\,A_t}{b\,S_t} \quad \text{(8a)}$$

From Eqs. 1, 2, and 8*a* it may be seen that the corresponding formula for bond stress is

$$u = \frac{V\,n\,A_t}{\Sigma_o\,S_t} \quad \text{(8b)}$$

since

$$u = \left(\frac{b}{\Sigma_o}\right) v \quad \text{(9)}$$

The usefulness of Eqs. 8 depends upon having a knowledge of the section modulus S_t. The following formulas may be derived for S_c and S_t,

$$S_c = \frac{b\,d^2}{6}\left[2\,k^2 + 6\,p_c\,(n-1)\,\frac{(k-\alpha)^2}{k} + 6\,n\,p_t\,\frac{(1-k)^2}{k}\right] \ldots. (10a)$$

and

$$S_t = \frac{b\,d^2}{6}\left[\frac{2\,k^3}{1-k} + 6\,p_c\,(n-1)\,\frac{(k-\alpha)^2}{1-k} + 6\,n\,p_t\,(1-k)\right] \ldots (10b)$$

Since the neutral axis is also the centroidal axis, an equation of moments of areas about this axis can be written as follows:

$$(k-\alpha)(n-1)\,A_c\,d + \frac{b}{2}\,(k\,d)^2 = n\,A_t\,d\,(1-k) \ldots\ldots\ldots\ldots (11)$$

Since Eq. 11 gives a linear relationship between A_c and A_t, it is a simple matter to eliminate either p_c or p_t from Eqs. 10. If p_t is eliminated the formulas for S_c and S_t become:

$$S_c = \frac{b\,d^2}{6}\left[k\,(3-k) + \frac{6\,p_c\,(n-1)(k-\alpha)(1-\alpha)}{k}\right] \ldots\ldots (12a)$$

and

$$S_t = \frac{b\,d^2}{6}\left[\frac{k^2\,(3-k)}{1-k} + \frac{6\,p_c\,(n-1)(k-\alpha)(1-\alpha)}{1-k}\right] \ldots\ldots (12b)$$

It is possible that reinforced concrete beams may be designed more conveniently by using the section modulus concept than by the methods now in common usage. This may be particularly true for designers who work alternatively with steel, timber, and concrete.

If a beam does not contain compressive steel, the formula for S_t becomes:

$$S_t = \frac{k^2\,(3-k)}{1-k}\left(\frac{b\,d^2}{6}\right) (\text{when } p_c = 0) \ldots\ldots\ldots\ldots\ldots (13)$$

From Eq. 11,

$$A_t = \frac{k^2}{n\,(1-k)}\left(\frac{b\,d}{2}\right) (\text{ when } p_c = 0) \ldots\ldots\ldots\ldots\ldots (14)$$

Substituting Eqs. 13 and 14 in Eqs. 8:

$$v = \frac{3\,V}{(3-k)\,b\,d} = \frac{V}{b\,j\,d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15a)$$

and

$$u = \frac{3\,V}{(3-k)\,\Sigma_o\,d} = \frac{V}{\Sigma_o\,j\,d} \ldots\ldots\ldots\ldots\ldots\ldots (15b)$$

in which $j = 1 - \frac{k}{3}$. These formulas, which are in common use, are seen to be in exact agreement with Eqs. 8 for beams without compressive reinforcement. When a beam contains compressive steel, Eqs. 8 give the correct formulas for v and u, whereas Eqs. 15 are somewhat in error.

MEMBER WITH THRUST

In the case of a member carrying thrust and bending, the neutral axis and the centroidal axis do not coincide. The centroidal axis always lies within the compressive region, as indicated in Fig. 2. The formulas for v and u, given by Eqs. 8, are also applicable to this case. The shear stress v will be the shear stress occurring at any point between the neutral axis and the tensile steel. This is the shear stress which is of interest in reinforced concrete design since it is equal in magnitude to the diagonal tensile stress.

FIG. 3.—INTERNAL STRESS DISTRIBUTIONS

In order that the use of Eqs. 8 may be clear it may be well to emphasize certain characteristics of the section properties of a member with thrust. The distance y in Eq. 4 and the distance c_t in Eq. 5 are measured from the centroidal axis (not the neutral axis). The integral Q, for determining the shearing stresses in any elastic beam, is always computed about the centroidal axis. For given values of thrust and moment the neutral axis can be located. This determines the compressive region. The centroidal axis lies at the center of gravity of the transformed area which includes the total transformed steel area as well as the area of concrete in compression. Any change in the value of the thrust or moment changes the location of the neutral axis. This changes the transformed area and hence changes the location of the centroidal axis. More specifically, all of the flexural properties of the section (the transformed area, the neutral axis, the centroidal axis, the section moduli, and the moment of inertia) change with a change in the eccentricity of the thrust. When the eccentricity is known, all of the flexural properties can be computed. The case that occurs most commonly is that of a beam with constant thrust from end to end. The moments vary along the span and hence the eccentricity of the thrust varies along the span. This means that the flexural properties vary along the span. If the loading on a beam is changed, the flexural properties at a given section will change, assuming that the change in loading produces a change in the moment or thrust at the given section.

Due to the complicated algebraic relationships which arise in a stress analysis of a reinforced concrete member with thrust and bending, it is generally found convenient to use trial-and-error methods. The neutral axis must be located and the flexural properties determined in order to establish the allowable compressive stress in accord with the 1940 Joint Committee Code.[4] A convenient procedure for making this stress analysis was presented in 1942.[5] Such an analysis yields the section modulus S_t which is required in Eqs. 8 for computing v and u. An example will illustrate the significance of the shearing stress given by Eq. 8a.

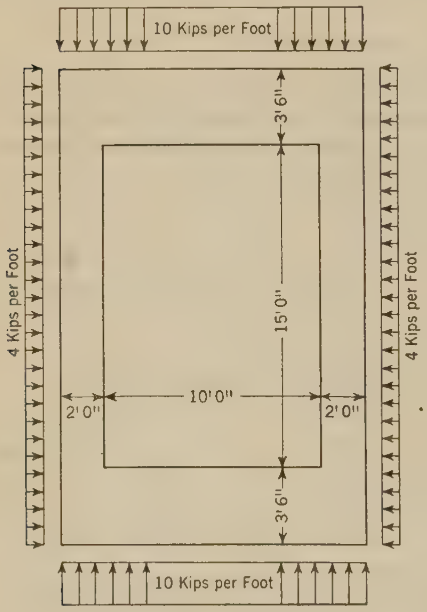

Fig. 4.—Rectangular Conduit with Loads

Fig. 3 shows a section of a member subjected to an eccentric thrust of 44 kips and a shear of 47.5 kips. Since the process of locating the neutral axis and computing the normal stresses is well known these values are shown without discussion. The moment of inertia of the transformed section may be computed readily by straightforward procedures, and the section modulus S_t

[4] "Recommended Practice and Standard Specifications for Concrete and Reinforced Concrete," *Proceedings*, Am. Soc. C. E., Pt. 2, June, 1940, Eq. 17, p. 73.

[5] "Thrust and Symmetrical Bending in Reinforced Concrete," by Stanley U. Benscoter, *Civil Engineering*, April, 1942, p. 214.

may be computed to be as shown. The shearing stress diagram is the feature of interest in this example. From the general formula (Eq. 3) it is possible to compute the shear stress at various points within the compressive region and thus to plot the shear-stress diagram. This diagram is of parabolic shape with a slight irregularity at the depth of the compressive steel. The maximum value v_m occurs at the centroidal axis. The stress v, which occurs between the neutral axis and the tensile steel, is only 43% of the maximum v_m. It is this stress v which is equal to the diagonal tensile stress and which governs the beam design. The value of v_m is generally of no interest. A dotted line is shown in Fig. 3 to indicate the shear stress that would be obtained from the formula in the 1940 Joint Committee Code[6] (or Eq. 15a using $j = \frac{7}{8}$). The stress v is 65% of the value given by the code.

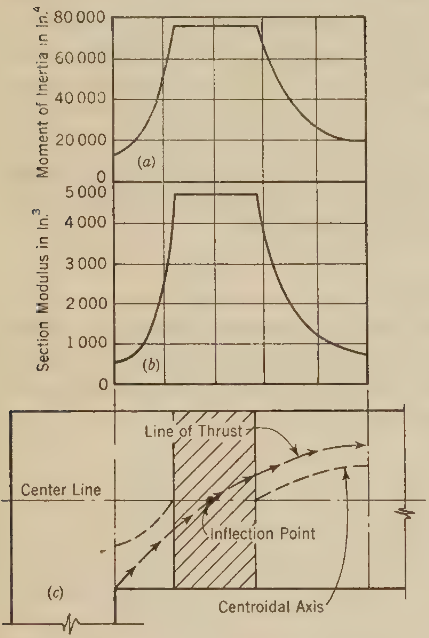

FIG. 5.—SECTION MODULUS AND MOMENT OF INERTIA

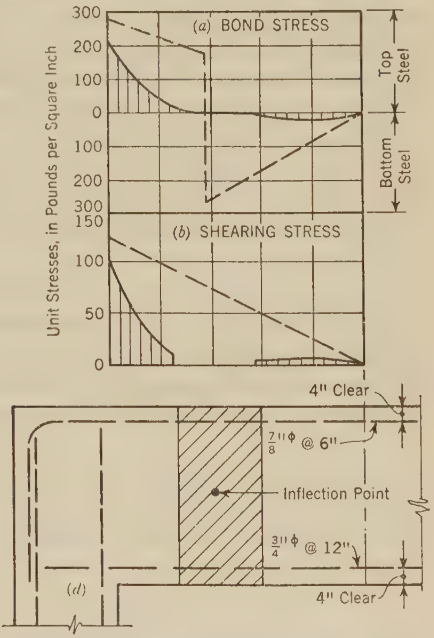

FIG. 6.—BOND AND SHEARING STRESSES

It is of interest to construct bond and shear-stress diagrams along a member. Fig. 4 shows a slice, 1 ft thick, of a rectangular conduit with loads roughly equivalent to the effects of an 80-ft fill. The weight of the conduit has been neglected for convenience. Moments in the frame were computed by moment distribution assuming each member to have infinite rigidity over its supports. Only the clear span of the top slab will be used for discussion. The moment in the top slab at the face of the support is found to be 78.1 ft-kips, the shear is 50 kips, and the thrust is 44 kips. Dividing the moment by the thrust gives an eccentricity of the thrust equal to 21.3 in. From this information the neutral axis may be located and the section modulus S_t found to be 535 in.^{3} The shear and bond stresses are found from Eqs. 8 to be (using $n = 10$): $v = 94$ lb per sq in. and $u = 204$ lb per sq in., respectively.

---

[6] "Recommended Practice and Standard Specifications for Concrete and Reinforced Concrete," *Proceedings*, Am. Soc. C. E., Pt. 2, June, 1940, Eq. 1, p. 52.

Similar analyses were made at various sections of the member which correspond to every 1 in. difference of thrust eccentricity. The section of Fig. 3 was taken at 3 in. from the face of the support in the top slab of the conduit. The locations of the centroidal axis and the line of thrust are shown in Fig. 5(*c*). The variations of the moment of inertia and the section modulus S_t are shown in Figs. 5(*a*) and 5(*b*), respectively. These diagrams illustrate the divergence of a reinforced concrete beam from the ideal straight homogeneous beam which is assumed in the development of flexural theory.

Diagrams of bond and shearing stresses are shown in Fig. 6. The solid lines indicate the stresses as computed by Eqs. 8, and the dashed lines indicate the stresses as computed from the formulas of the 1940 Joint Committee Code. No shearing stress is shown for the shaded region of the beam, since the thrust falls within the kern in this region. There is no diagonal tension in this region.

Stress analysis of reinforced concrete is still in serious need of both theoretical and experimental research to eliminate the unnecessary safety factors which are now inherent in standard design procedures. The experimental research work is needed on actual rigid-frame structures.

Conclusion

Formulas for bond and shearing stresses have been developed which are applicable to members with or without thrust. These formulas are correct in so far as ordinary flexural theory is applicable to reinforced concrete and yield the commonly used formulas as a special case.

DISCUSSION

F. R. Shanley,[7] Esq.—Airplane structural designers frequently abandon the classical formula for transverse shear stress and use a more general method[8] in which the shear flow is determined directly from the differences in axial force at adjacent cross sections along the beam. In effect, this amounts to a direct use of Eq. 2. If the axial stresses have been determined at relatively close stations, the additional work involved to obtain the shear and bond stresses is negligible. The use of the method for bond stresses has been demonstrated by Fred B. Seely.[9]

The main reason for adopting this method in airplane analysis was that the conventional shear stress formula does not account for variations in the cross section along the beam. For instance, a taper in depth may relieve the shear stresses greatly, but this cannot be shown by a formula that deals with only one section at a time. The general method would seem particularly useful for beams in which some of the steel bars are placed at an angle. Another advantage is that the effects of all variables, including compression loading, are included in computing the bending stresses and need not be considered again in determining shear or bond stresses.

The "unit" method, as it is called, is quite sensitive to abrupt changes in cross section. If the sections used for analysis are fairly close together, the resulting shear stresses will appear abnormally high. Some of this effect is relieved by local distortion of the cross section, or by yielding of a ductile material, but the designer regards abnormally high shear stresses as danger signals, indicating poor structural continuity. This might be rather important in dealing with a brittle material like concrete.

B. J. Aleck,[10] Jun. Am. Soc. C. E.—As the authors indicate, common formulas sometimes yield conservative shear and bond stresses, when a member is subjected to axial load. The writer finds the authors' results somewhat incomplete, however, and not always conservative. For example, using the authors' variables:

$$T = n\,A_t\left(\frac{M}{S_t} - \frac{P}{A}\right) \qquad \text{(16)}$$

in which A is the area of the transformed cross section; and the unit shear stress (with P constant) is:

$$v = \frac{1}{b}\frac{dT}{dx} = \frac{n\,A_t}{b}\left(\frac{\frac{dM}{dx}}{S_t} - \frac{M}{S^2{}_t}\frac{dS_t}{dx} + \frac{P}{A^2}\frac{dA}{dx}\right) \qquad \text{(17)}$$

[9] "Resistance of Materials," by Fred B. Seely, John Wiley & Sons, Inc., New York, N. Y., 2d Ed., 1935, p. 386.

[10] Research Engr. (Materials and Structures), Curtiss-Wright, Buffalo, N. Y.

Considering an element as shown in Fig. 7:

$$\frac{dM}{dx} = V - P\,\frac{dc_t}{dx} \quad\text{......................}(18)$$

Hence

$$v = \frac{n\,A_t}{b}\left(\frac{V}{S_t} - \frac{P}{S_t}\frac{dc_t}{dx} - \frac{M}{S^2{}_t}\frac{dS_t}{dx} + \frac{P}{A^2}\frac{dA}{dx}\right) \quad\text{...........}(19)$$

The authors' solution evidently corresponds to the result if the last three terms in Eq. 19 were to vanish (see Eq. 8*a*). As the prospect of evaluating the derivatives in Eq. 19 is discouraging, the same formula will be derived in terms of simpler variables; thus, if M_s is the moment of all external forces about the tension steel and $j\,d$ is the distance between the resultant compressive force in the concrete and compression steel and the force in the tension steel:

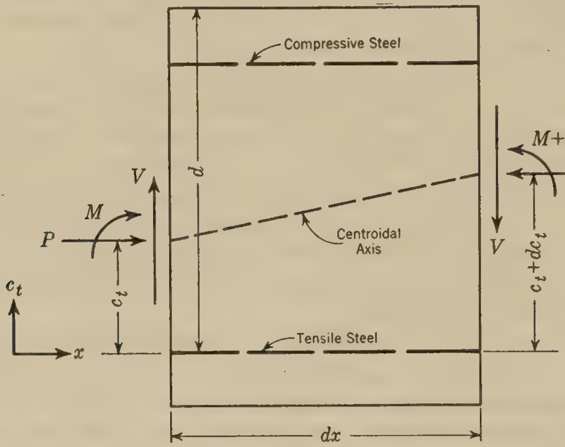

FIG. 7.

$$T = \frac{M_s}{j\,d} - P \quad\text{.........................}(20)$$

and

$$v = \frac{1}{b}\frac{dT}{dx} = \frac{\dfrac{dM_s}{dx}}{b\,j\,d} - \frac{M_s}{j^2\,b\,d}\frac{dj}{dx} = \frac{V}{b\,j\,d} - \frac{M_s}{j^2\,b\,d}\frac{dj}{dx} \quad\text{.........}(21)$$

The resultant resisting compressive force, C, is equal to

$$C = b\,d\,f_c\left[\frac{k}{2} + \left(1 - \frac{\alpha}{k}\right)(n-1)\,p_c\right] \quad\text{............}(22a)$$

Also,

$$P\,e = M_s = b\,d^2\,f_c\left[\frac{k}{2}\left(1 - \frac{k}{3}\right) + (1-\alpha)\left(1 - \frac{\alpha}{k}\right)(n-1)\,p_c\right] \quad\text{..}(22b)$$

and

$$P = C - T = b\,d\,f_c$$

$$\times\left[\frac{k}{2} + \left(1 - \frac{\alpha}{k}\right)(n-1)\,p_c - \left(\frac{1}{k} - 1\right)n\,p\right] = \text{constant}\ldots(22c)$$

Eqs. 22 are well known. Moving from one section to the next, k and f_c change with x. Differentiating Eq. 22c with respect to k:

$$\frac{df_c}{dk} = -\frac{f^2_c\, b\, d}{P}\left[\frac{1}{2} + \frac{\alpha}{k^2}(n-1)\,p_c + \frac{1}{k^2}\,n\,p\right] \ldots\ldots\ldots\ldots (23)$$

Differentiating Eq. 22b with respect to x, using Eq. 23:

$$\frac{dk}{dx} = \frac{V}{f_c\, b\, d^2}$$

$$\times \frac{1}{\dfrac{1}{2} - \dfrac{k}{3} + \dfrac{\alpha}{k^2}(1-\alpha)(n-1)\,p_c - \dfrac{e}{d}\left[\dfrac{1}{2} + \dfrac{\alpha}{k^2}(n-1)\,p_c + \dfrac{1}{k^2}\,n\,p\right]} \ldots (24)$$

$$j = \frac{M_s}{C\,d} = \frac{\dfrac{k}{2}\left(1 - \dfrac{k}{3}\right) + (1-\alpha)\left(1 - \dfrac{\alpha}{k}\right)(n-1)\,p_c}{\dfrac{k}{2} + \left(1 - \dfrac{\alpha}{k}\right)(n-1)\,p_c} \ldots\ldots (25)$$

$$\frac{dj}{dk} = \frac{b\,d\,f_c}{C}\left\{\frac{1}{2} - \frac{k}{3} + \frac{\alpha}{k^2}(1-\alpha)(n-1)\,p_c - j\left[\frac{1}{2} + \frac{\alpha}{k^2}(n-1)\,p_c\right]\right\} \ldots (26)$$

and

$$\frac{dj}{dx} = \frac{dj}{dk}\frac{dk}{dx} = \frac{V}{C\,d}\,B \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

In Eq. 27,

$$B = \frac{\dfrac{1}{2} - \dfrac{k}{3} + \dfrac{\alpha}{k^2}(1-\alpha)(n-1)\,p_c - j\left[\dfrac{1}{2} + \dfrac{\alpha}{k^2}(n-1)\,p_c\right]}{\dfrac{1}{2} - \dfrac{k}{3} + \dfrac{\alpha}{k^2}(1-\alpha)(n-1)\,p_c - \dfrac{e}{d}\left[\dfrac{1}{2} + \dfrac{\alpha}{k^2}(n-1)\,p_c + \dfrac{n\,p}{k^2}\right]} \ldots (28)$$

Therefore,

$$v = \frac{V}{b\,j\,d} - \frac{M_s}{b\,j^2\,d}\frac{dj}{dx} = \frac{V}{b\,j\,d}(1 - B) \ldots\ldots\ldots\ldots\ldots (29)$$

Eq. 29 represents the complete answer. To facilitate simple comparisons it is convenient to compare results when $p_c = 0$. In this case,

$$v = \frac{V}{b\,j\,d}\left[\frac{2\,p\,n\,(1+k)}{k\,(k + 4\,p\,n)}\right]_{p_c=0} \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

whereas the authors' formula leads to

$$v = \frac{V}{b\,j\,d}\left[\frac{\left(1 - \dfrac{k}{2}\right)\left(1 - \dfrac{k}{3}\right)}{1 - k + \dfrac{k^2}{3} + \dfrac{k^3}{12\,p\,n}}\right]_{p_c=0} \ldots\ldots\ldots\ldots\ldots (31)$$

Eq. 30 is readily plotted on a graph as $\dfrac{v\,b\,d}{V}$ versus $p\,n$, for k held constant at 1.0, 0.9, 0.8, etc. Some idea of possible divergence of answers is afforded when

$k = 0.6$ and $p\,n = 0.05$. Then, Eq. 30 yields 52.4% of Eq. 31 and 33.3% of the code value.

More important is the lack of conservatism of both the code and authors' formulas when the axial load is tensile. Thus if $k = 0.20$ and $p\,n = 0.12$, the shearing stress according to Eq. 30 is 212% of that given by the code and 206% of that given by Eq. 31.

After this theoretical discussion, the inadequacy of these results should be emphasized. Some questions that deserve consideration are:

1. How good a criterion is shear for diagonal tension?[11] One authority states: "The vertical shearing stress is not the numerical equivalent of the diagonal tension stress; nor is there any definite relation between them."

2. How accurate is the assumed stress distribution?

   (a) Is the concrete carrying tension (in flexure)? How much?
   (b) Is the stress diagram linear over the transformed section?
   (c) How much load does the compressive steel carry?[12]

3. Is the allowable shear stress given by code to be used with the new formula? Tests should be conducted, especially when axial load is tension.

4. What is the correct value of p to use in the region where bars are lapped? What allowance should be made for variation of effective p-value in this region?

DEAN PEABODY, JR.,[13] M. AM. SOC. C. E.—An alternate method of computing the bond stresses u in tensile reinforcing steel, and the shear stresses v in the concrete between the tensile steel and the neutral axis, is developed in this paper. Also, the variation of shear stress v between the neutral axis and the extreme fiber in compression is discussed. For these computations the transformed area procedure is used. The authors consider only the case of sections that have cracked close enough to the neutral axis for the tensile stresses in the concrete to be neglected.

Beam Without Thrust.—Eqs. 8 use the section modulus S_t, which can be computed by Eq. 12*b* or 13. To compute S_t the neutral axis ratio k must be determined by the usual reinforced concrete equations, by tables or plots, or by the use of the transformed area. A designer working "alternatively with steel, timber, and concrete" could determine j at once, after reviewing the theory sufficiently to compute k. Only for the beam with tension steel does $j = 1 - \frac{k}{3}$, as stated in the "Notation" and, also, immediately following Eqs. 15. However, if compression steel is used, the moment arm $j\,d$ is the distance between the resultant tensile force and the resultant of the compressive forces, and the moment arm ratio j no longer equals $1 - \frac{k}{3}$. If j is determined correctly for beams with compression steel, Eqs. 15 are not "somewhat in error" but give the same result as Eqs. 8. The use of Eqs. 15 or 8 would seem a matter of personal opinion.

Member with Thrust.—This material is valuable, as the designer has not often investigated the shear stresses in columns subjected to bending, nor included the direct thrust in the design of beams. The authors discuss only the case of compressive stresses on part of the section with the concrete cracked on the tension side. This is a common case for a beam with a direct thrust, but many columns have sections with compressive stresses over the entire area. In such a case the easiest procedure would employ the transformed area, determine the centroidal axis, and use Eq. 3. In fact, the writer would rather use Eq. 3 for all cases of thrust: First, because the maximum shear stress occurs at the centroidal axis (as in Fig. 3) and can be determined by this method; and, second, because Eqs. 8 cannot be used for the shear stress near the tension steel until the transformed area computations furnish the centroidal axis, neutral axis, and moment of inertia. Having proceeded thus far with the transformed area, Eq. 3 can be used as expeditiously as Eq. 8*a*.

In the sixth paragraph from the end of the paper, the authors note that Eq. 15*a* does not give the correct shear stress v in the concrete between the tension steel and the neutral axis (Fig. 3). Their estimate of an error of 65% is not correct, because it is assumed that $j = 1 - \frac{k}{3} = \frac{7}{8}$. The distance between the resultant compressive force and the resultant tension force, if denoted $j\,d$, is less than this and the error is greater (the writer computes $j = 0.83$). However, Eq. 15*a* should never be used for members with thrust. It was derived for the case in which the compressive force C equals the tensile force T; and this is never true for members with thrust. In other words, Eq. 15*a* holds when the centroidal and neutral axes coincide.

Diagonal Tension.—Under the heading, "Members with Thrust," the authors state that the shear stress v is equal in magnitude to the diagonal tensile stress. This is not accurate, because the principal tensile stress s_t on any particle is equal to:

$$s_t = \frac{f}{2} \pm \frac{1}{2}\sqrt{f^2 + 4\,v^2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(32)$$

in which f = fiber stress. To avoid the use of Eq. 32, the shear stress v has been employed as a measure of diagonal tension.[14] The tensile stress s_t may be 10% to 20% greater than the shear stress v at sections where diagonal tension is important. It has been the custom to specify allowable shear stresses sufficiently low so that the allowable tensile stress s_t will not be exceeded. The tables of allowable shear stresses in the past and present Joint Committee Codes and the Regulations of the American Concrete Institute have never clearly stated this fact.

For a beam of single span supported at the ends, the principal tensile stress s_t will make the greatest angle (45°) with the longitudinal axis of the beam at or near the supports. The particles in these sections have small fiber stresses f and comparatively large shear stresses v. One may assume that the concrete on the tension side has not cracked all the way to the neutral axis, and a tensile stress may be assigned to the concrete whose shear equivalent is $0.02\,f'_c$ or $0.03\,f'_c$, even for particles just above the tension steel. It would seem logical, then, in the authors' method, to include some of the tension area of the concrete in the transformed area and in the computation of the centroidal axis, the moment of inertia, and the shear stress v.

---

[14] Regulations, A.C.I., 1941, Section 1205*a*.

For continuous beams, the maximum negative moment and the maximum shear force both occur at the support. The assumption of a section cracked to the neutral axis is logical, but designers still assume that the concrete takes a tensile stress whose shear equivalent v equals $0.02 f'_c$ or $0.03 f'_c$ when computing diagonal tension. In continuous beams, the greatest inclination of the principal stress s_t, near the bottom of the beam, will occur close to the point of inflection of the moment diagram. At this point, about one fifth to one fourth the span length from the support, the fiber stresses f are small and the entire concrete area down to the tensile steel might well be used to compute the transformed area and the shear stress. Engineers have never chosen to take time enough to attain this accuracy. However, for members with thrust, cases will arise in which the tension in the concrete is within its allowable stress, and the authors may well consider sections where a part, or the whole, of the concrete tension area is included in the transformed area.

The authors do write briefly about sections whose particles are wholly in compression in the third paragraph from the end of the paper. The statement, "There is no diagonal tension in this region," for such particles is not completely accurate. The principal tensile stress s_t equals:

$$s_t = \frac{f_c}{2} - \frac{1}{2}\sqrt{f^2_c + 4\,v^2} \dots\dots\dots\dots\dots\dots (33)$$

and will have a small, probably negligible, value.

The writer has found this paper stimulating but confesses that he leaves it with a greater respect for the transformed area solution for all cases except the beam without thrust.

William E. Wilbur,[15] M. Am. Soc. C. E.—The subject of combined flexure and direct stress in concrete beams has always been a troublesome one for designers to analyze. In a measure, this is due to two assumptions made in concrete design—namely, a straight-line variation of fiber stress, and no tension in the concrete. It is no part of this discussion to question these assumptions, since they lead to simple and sufficiently accurate formulas. They will be assumed as correct.

In the first part of their paper, the authors derive expressions for unit shear and bond stress in beams subject to bending only. In order not to confuse the nomenclature, let $z\,d$ be the depth from the centroid of the tensile fiber stresses to the centroid of the compressive fiber stresses. Then, for any beam, of any shape, the laws of mechanics give the unit shear at the neutral axis as

$$v = \frac{V}{b\,z\,d} \dots\dots\dots\dots\dots\dots (34a)$$

---

[15] Structural Engr., The Fluor Corp., Kansas City, Mo.

When b is constant, this is the maximum unit shear. For a rectangular section, such as a timber beam, z has the value of $\frac{2}{3}$, and the expression becomes

$$v = \frac{3\,V}{2\,b\,d} \qquad \text{(34}b\text{)}$$

For a concrete beam without compressive steel, $z = 1 - k/3$, or "j," and Eq. 34a becomes Eq. 15a. For an I-beam or plate girder with web thickness b, z is nearly unity, and substitution in Eq. 34a gives the common approximation

$$v = \frac{V}{b\,d} \qquad \text{(34}c\text{)}$$

When there is compressive steel in a concrete beam, the value of z will be exactly the same as j only when the compressive steel is at the centroid of the compressive concrete fiber stresses. Substitution of $k/3$ for α in Eqs. 11 and 12 will be found to result in the same values of Eqs. 15 as those given by the authors.

In actual design, the area of compressive steel is usually relatively small, and the value of α is not far from $k/3$. It follows, then, that the value of v will not vary greatly from the value $\frac{V}{b\,j\,d}$ (Eq. 15a) and that expression will nearly always be sufficiently exact for practical purposes.

In the latter part of their paper, the authors discuss the case of flexure and direct stress. They are correct in their statement (see heading, "Member with Thrust") that "Any change in the value of the thrust or moment changes the location of the neutral axis," and hence all the properties of the section. In discussion of a previous paper[16] the writer demonstrated a simple method for determining the fiber stresses in this case, without recourse to special diagrams or complicated formulas.

The authors are incorrect in their statement that "The integral Q * * * is always computed about the centroidal axis," and this error leads to the irrational results shown in their Fig. 3.

Consider a beam subject to flexure, or flexure and direct stress, with maximum fiber stresses at two adjacent sections of f and $(f + \Delta f)$, respectively (see Fig. 8). The hatched area represents the difference between the fiber stresses at the two sections, and is a measure of the horizontal shear. The horizontal shear at S, for example, is measured by the part of the hatched area between S and the extreme fiber. It is obvious that the horizontal shear is maximum at the neutral axis, and cannot be otherwise, on the assumption of no tension in the concrete.

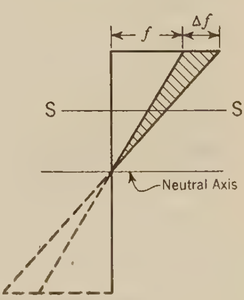

FIG. 8.

If Eq. 34a is applied to the example in Fig. 3, and z is taken as approximately equal to $38 - (\frac{1}{3} \times 19.2)$, the maximum unit shear, between the neutral axis and the tensile steel, is found to be approximately 125 lb per sq in.

---

[16] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 385.

The effect of the thrust, then, by decreasing the value of z, is to increase somewhat the maximum unit shear over that in a member with flexure only; and the authors have done well to call this to the attention of designers.

When the thrust is so great as to produce compression over the entire section, the centroidal axis and the neutral axis will coincide, and z will approach the value of $\frac{2}{3}$. The writer cannot agree with the authors' statement (third from the last paragraph) that there is no diagonal tension when the thrust falls within the kern. Diagonal tension will always accompany shear, but in this case the unit diagonal tension will no longer be numerically equal to the unit shear.

L. E. GRINTER,[17] M. AM. SOC. C. E.—The authors approach their problem with the logic of straightforward analysis. They accept the usual assumptions of the analysis of reinforced concrete beams and derive the standard formulas introducing such generalizations as will permit them to study the influence, on the cross section, of a thrust as well as a bending moment. Their thesis is that the thrust must be considered for the design of the cross section to resist shear and bond stresses properly.

Perhaps without intention they have chosen an example that is about the strongest reasonable case for supporting that thesis. It is a beam having a prismatic ratio (length over depth) of less than three as contrasted to a common ratio in building design of from ten to twenty. Moreover, this deep beam must resist a great thrust produced by uniform lateral pressure of the earth over the 22-ft height of the structure. Figs. 5 and 6 establish certain major discrepancies between the theoretical bond and diagonal tension stresses (not shear stress as labeled in Fig. 6) for the structure studied. Less serious discrepancies, probably of little consequence, can be anticipated for building frames, but this is no criticism of the paper, which gives only casual attention to building frames and appears intended as a study of heavy foundation structures. It is an excellent brief presentation of an interesting thesis.

The writer has ardently supported mathematical analysis as about the only device available to the designer for the production of a balanced structure; but the designer must stop and analyze the real meaning of such calculated stresses as $\frac{V}{b\,j\,d}$ to reach a logical decision as to where the refinement proposed by the authors is valuable and where it is merely theoretical "excess baggage."

A few assumptions used by the authors may be reviewed profitably because similar assumptions are always necessary for the analysis of any structure. The analysis of moments and thrusts follows from assumptions as to the loads shown as vertical uniform pressures on the top and bottom of the box (Fig. 4). Such pressure lines are never uniform but are actually curved. Likewise, the side pressures vary; they increase toward the bottom and are also likely to be unsymmetrical with respect to the vertical axis. These factors seldom can be brought into a design because they are not determined by theory but by local conditions.

---

[17] Vice-Pres. and Dean, Graduate School, Illinois Inst. of Technology, Chicago, Ill.

Based upon conventional load assumptions, a designer computes a set of moments using stiffness factors, in all likelihood computed from I-values obtained as $\frac{b\,d^3}{12}$. If he tries the refinement of using I-values in agreement with the transformed section (see Eqs. 10), what transformed section shall he use? Evidently, since each member of a frame usually has one or more points of contraflexure, the transformed section could be either the usual one or an upside down section. In reality, over a large part of the length of the beam the effective section is certainly a section of uncracked concrete, since a crack covers only a fraction of an inch. Actually, the beam has a constantly varying moment of inertia, the degree of variation being unknown. In desperation, engineers can be excused for abandoning the idea of using the transformed section and of adopting $\frac{b\,d^3}{12}$ for the moment of inertia in determining stiffness factors; but in doing so they must not forget that this crude assumption has had its inevitable influence on computations for bending moments.

Then there is the problem of the corner action which cannot be solved by common methods of analysis. Perhaps the designer takes the theoretical span of the beam as the clear span; perhaps he chooses the span center-to-center of columns; or perhaps with corner fillets he uses less than the clear spacing between columns as the span. Whichever he chooses, the result expressed as a bending moment diagram is only an approximation—a result of judgment as well as of mathematical analysis.

Such crudities of analysis are even more obvious when the member contains both a bending moment and a thrust. The fit of a structure within confining material may shift a line of thrust by a small distance that would be of no consequence if it represented the vertical reaction under a horizontal beam; but, if it represented the location of a longitudinal thrust acting on a vertical member, it may have an enormous influence upon the stress in the member because a shift of even 1 in. in the eccentricity of a longitudinal thrust could be disastrous.

Finally, Figs. 5 and 6 reveal the theoretical fact that section moduli, fiber stresses, bending moments, bond and shearing stresses all change sharply, whereas common sense dictates that such changes are actually gradual because stress builds up slowly and not suddenly. This inaccuracy is the result of the designer's inability to treat the structure mathematically as a series of small particles. He must adopt gross procedures such as the treatment of an entire beam cross section as a single element.

It is necessary to analyze the suggestions offered in this paper with these facts in mind in order to decide just where the proposed equations should be used. The specification formula, $v = \frac{V}{b\,j\,d} < 120$ or 240, is not a statement about any stress that actually exists in the structure. It is just a rule for controlling a size of cross section, more justified by experiment and observation of its satisfaction in practical cases than by its theoretical derivation. In other words, whether the calculated shearing stress $\frac{V}{b\,j\,d}$ is high or low is immaterial if the specification writer takes care of that fact in his choice of an allowable working stress in shear.

The example offered by the authors seems to be an exaggerated case, and the effect of thrust on bond and shear in beams or columns of common length-depth ratio may not usually be of sufficient importance to consider. If most of the inaccuracies that have been mentioned in this discussion exist in the analysis of a given reinforced concrete structure, it is unlikely that the designer can hope to know the stress at a given point any closer than ± 25%. That being so, he can obtain little benefit from the theory presented in the paper unless the influence of the thrust on bond or diagonal tension proved to be of about this magnitude.

It is worth noting in Fig. 3 that the theoretical shear reaches 180 lb per sq in. on a cross section where the shear formula gives 120 lb per sq in. and the authors' theory shows the critical shear causing diagonal tension to be only 78 lb per sq in. Presumably, shear in reinforced concrete is not very serious if it cannot produce diagonal tension. However, it is well to recognize that the formulas in the paper, which show very low shear stresses, refer only to shears in the diagonal tension areas of the beam; elsewhere, larger shears than those given by $v = \frac{V}{b\,j\,d}$ may exist. Even though such increased shears may not be serious, the authors have called attention to a change in stress pattern that designers have probably been overlooking. It is a serious fault to overlook possible stress conditions. They have a habit of suddenly becoming critical. For example, the authors have not advised designers to look for the possibility that a negative thrust (a tension) can upset their computations by producing a more serious diagonal tension and bond condition than those represented by the formula $v = \frac{V}{b\,j\,d}$. Nevertheless, the theory presented by the authors can be applied to the case of negative thrust.

Anders Bull,[18] M. Am. Soc. C. E.—It is suggested in the paper that reinforced concrete beams may be designed more conveniently by the section modulus concept than by the methods in common use. This may be true for beams in plain bending, where the section moduli S_c and S_t are referred to the centroidal axis which, in that case, coincides with the neutral axis. When thrust is also acting, however, the fact that the two axes no longer coincide leads to complications.

Formulas published by the writer[19] in 1921, although similar to Eqs. 12, are applicable to both types of problems. A bending moment M and a thrust P', applied at a distance a from the center line of tensile steel, may be replaced, according to a well-known principle, by an eccentric force $P = P'$, acting at a distance $e = a + \frac{M}{P}$ from the tensile steel; that is:

$$P\,e = P\,a + M \quad \text{(35)}$$

---

[18] Civ. Engr., Board of Transportation, New York, N. Y.

[19] "Computing Stresses in Reinforced Concrete Arches and Other Structures," by Anders Bull, *Concrete* (Detroit, Mich.), December, 1921, p. 242.

When no thrust is acting, the term $P\ a$ drops out $(0 \times \infty)$, in which case $P\ e = M$.

Treating $P\ e$ as the moment, the equilibrium equations for rotation about the respective centers of flange strain yield, for a linear stress distribution, the following formulas in which f denotes the critical stresses:

$$\frac{d}{e} = \frac{6\, p_c\, (n-1)\, (k-\alpha) - 6\, p_t\, (1-k) + 3\, k^2}{6\, p_c\, (n-1)\, (k-\alpha)\, (1-\alpha) + 3\, k^2 - k^3} \ldots\ldots\ldots (36)$$

$$P\ e = b\, d^2 \frac{6\, p_c\, (n-1)\, (k-\alpha)\, (1-\alpha) + 3\, k^2 - k^3}{6\, k} f_c \ldots\ldots (37a)$$

$$P\ e = b\, d^2 \frac{6\, p_c (n-1)\, (k-\alpha)\, (1-\alpha) + 3\, k^2 - k^3}{6\, n\, (1-k)} f_t \ldots\ldots (37b)$$

Designating the fractions in Eqs. 37 by C_c and C_t, respectively:

$$f_c = \frac{P\ e}{b\, d^2\, C_c} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38a)$$

and

$$f_t = \frac{P\ e}{b\, d^2\, C_t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38b)$$

Only for plain bending, when $P\ e = M$, do the denominators in Eqs. 38 represent the section moduli of the cross section about the neutral axis.

The average shearing and bond stresses are found to be:

$$v_{\text{avg}} = \frac{V}{b\, d} \left(\frac{d}{e} + \frac{p_t}{C_t} \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (39a)$$

and

$$u_{\text{avg}} = \frac{V}{b\, \Sigma_0} \left(\frac{d}{e} + \frac{p_t}{C_t} \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (39b)$$

There are numerical tables[19] from which C_c and C_t can be determined conveniently, using p_t and $\frac{d}{e}$ for arguments. When the tables are not available, the problem is solved by first determining the value of k which is the only unknown in Eqs. 37. This is easily done by means of Eq. 36, which is resolved into the following third-degree equation:

$$\frac{d}{e} k^3 + 3 \left(1 - \frac{d}{e} \right) k^2 + 6 \left[p_c\, (n-1) \left(1 - \frac{d}{e} + \alpha \frac{d}{e} \right) + p_t\, n \right] k$$

$$= 6 \left[p_c\, \alpha\, (n-1) \left(1 - \frac{d}{e} + \alpha \frac{d}{e} \right) + p_t\, n \right] \ldots\ldots\ldots\ldots (40)$$

For plain bending $\frac{d}{e} = 0$, and Eq. 40 is reduced to:

$$k^2 + 2\, [p_c\, (n-1) + p_t\, n]\, k = 2\, [p_c\, \alpha\, (n-1) + p_t\, n] \ldots\ldots (41)$$

Evidently the hypothetical example chosen by the authors has not been correctly treated, since the external and internal moments do not balance. For a cross section 3 in. from the face of the support (Fig. 3), the moment due to roof load is 791 in.-kips, and the moment due to thrust is $44 \times 16.2 = 713$ in.-kips—a total external moment of 1,504 in.-kips. Since the center of steel is 4.4 in. from the surface, the stresses indicated in the diagram could develop only the following internal moments:

$$
\begin{array}{lr}
\text{Concrete}\ldots\ldots\ldots\ldots 12 \times 19.2 \times \dfrac{414}{2} \times \dfrac{2}{3} \times 19.2 & = 610{,}470 \\
\text{Compression steel}\ldots 0.442 \times 9 \times 414 \times \dfrac{14.8}{19.2} \times 14.8 & = 18{,}800 \\
\text{Tension steel}\ldots\ldots\ldots 1.203 \times 10 \times 417 \times 18.4 & = 92{,}310 \\
\hline
\text{Total internal moment (inch-pounds)}\ldots\ldots\ldots\ldots & = 721{,}580
\end{array}
$$

—an amount which suffices for balancing the moment due to thrust only.

Furthermore, with a thrust of 44 kips applied 3 in. above the bottom of the slab, there could be no point of inflection as in Fig. 5, the roof load moment at the center of span being $\left(78.1 - \dfrac{10 \times 5^2}{2}\right) 12 = -563$ in.-kips on which is superimposed a thrust moment of about $44 \left(\dfrac{42}{2} - 3\right) = +792$ in.-kips, making a total of $+229$ in.-kips. The "line of thrust" shown in Fig. 5 has no physical meaning, as the thrust remains at the same height throughout the span.

FIG. 9

For comparison, Fig. 9 shows the stresses obtained from Eqs. 36 to 40. The thrust is applied 6.7 in. from the bottom of the slab, being the resultant of

$3.5 \times 4 = 14$ kips acting at the center of the cross section and $7.5 \times 4 = 30$ kips acting at the bottom.

A novel feature of the paper is the distribution of the shearing stresses across a transverse section. The findings are interesting from a theoretical point of view, but their practical value may be questioned, as the average shearing stress is so much more easily determined. The assumptions on which reinforced concrete design is based are far from consistent in regard to tensile stresses in concrete. Such stresses are considered when diagonal but are disregarded when longitudinal, although the latter stresses obviously contribute to the bending strength. The aim is to simplify the computations. For the same reason any highly refined treatment would seem somewhat futile. After all, the allowable stresses governing the design are determined by the cut-and-try method. The possibility of future excavation alongside a subway structure like the one in Fig. 4 must also be considered as it may cause the thrust to be removed temporarily, eliminating its relieving effect on the shearing stresses.

The significance of the bulging shape of the shear distribution curve is easily seen by investigating another cross section, located a little closer to the center of span. The new stress distribution line (inclined dashed line in Fig. 9) is then found to intersect the old line at the centroidal axis, showing that the compressive stresses below the axis are reduced whereas those above are increased. These changes conform to the shape of the curve, whose first derivative $\frac{dx}{dy}$ is proportional to the change in compressive stress at any given height y.

Victor R. Bergman,[20] Assoc. M. Am. Soc. C. E.—In calling attention to the errors that can result from a careless application of the commonly used formulas for shear and bond stresses to beams subjected to thrust as well as bending, the authors have performed a useful service. However, their paper contains a few questionable points which the writer wishes to discuss. For example, $j\,d$ is not in general exactly equal to $\left(1 - \frac{k}{3}\right) d$, even for beams without thrust. The relationship does not hold quite true for T-beams or even for prismatic beams with compressive steel. For the case of beams carrying thrust, the expressed relationship is very definitely in error. The writer would prefer to substitute for the authors' definition of $j\,d$ that given in the Joint Committee Code[21]—"$j\,d$ = the moment arm of the internal force couple."

Fig. 2 is drawn incorrectly, because the compressive stress triangles are depicted as if the $k\,d$-distances were equal for the two sections. Such is not the case, because, as the authors state under the heading, "Member with Thrust," "Any change in the value of the thrust or moment changes the location of the neutral axis." This fact is illustrated in Fig. 10, which shows a definite shift in the position of the neutral axis in the distance dx.

[20] Structural Designer, The Kellex Corp., New York, N. Y.

[21] "Recommended Practice and Standard Specifications for Concrete and Reinforced Concrete," *Proceedings*, Am. Soc. C. E., Pt. 2, June, 1940, p. 53.

From Fig. 10, using the notation shown, and taking moments about any point at the level of the force $C + \Delta C$, it is possible to write (approximately):

$$\Delta T\left(d - \frac{k\,d}{3} + \frac{h}{3}\right) = V\,dx - C\,\frac{h}{3} \quad \ldots\ldots\ldots\ldots\ldots (42)$$

and, since $v\,b\,dx = \Delta T$:

$$v = \frac{V\,dx - C\,(h/3)}{\left(d - \frac{k\,d}{3} + \frac{h}{3}\right)(b)\,(dx)} \quad \ldots\ldots\ldots\ldots\ldots (43)$$

Eq. 43 is slightly approximate, because it assumes the location of each resultant compressive force at one third of its respective $k\,d$-distance from the top of the member, thus ignoring the modifying effect of the compressive steel. An accurate determination of the positions of the resultant compressive forces can be made easily by well-known methods, if desired.

Fig. 11.—Member with Thrust—Internal Stress Distribution (V = 47.5 Kips; and n = 10)

The writer has applied Eq. 43 to the case shown in Fig. 3, by first locating the neutral axis of a section parallel to that shown in Fig. 3, but 1 in. closer to the left support (Fig. 4). The neutral axis for this new section is approximately 18.15 in. from the bottom of the beam, thus making h = 1.05 in. and $C = 44{,}000 + 1.2 \times 3{,}950 = 48{,}740$ lb. Then, approximately,

$$v = \frac{(47{,}500)\,(1) - (48{,}740)\left(\frac{1.05}{3}\right)}{\left(37.6 - 6.4 + \frac{1.05}{3}\right)(12)\,(1)} = 80 \text{ lb per sq in.},$$

which agrees fairly well with the authors' determination. An even better agreement could be achieved by: (1) Computing the actual position of the resultant compressive forces; and (2) using a dx-distance smaller than 1 in.

It should be noted carefully that the writer has not used the length $j\,d$ in this determination of v.

Another and probably more instructive and useful approach to this problem is to consider the section (Fig. 3) as resisting: (1) A direct compression of 44,000 lb applied at the center of gravity of the transformed area; and (2) a bending moment whose value is 44,000 (10.9 − 3.0) = 348,000 in–lb.

The stress diagram of Fig. 3 (slightly modified by corrections) is reproduced in Fig. 11(*a*) where the combined stress diagram is resolved into two component parts—that due to direct compression and that due to bending, as shown separately in Fig. 11(*b*) and Fig. 11(*c*), respectively. The direct compressive stress of Fig. 11(*b*) is obtained simply enough by dividing the 44,000-lb thrust by the transformed area A_{TR}. The section shown in Fig. 3 has a transformed area, $A_{TR} = (12)\,(19.2) + (10 - 1)\,(0.44) + (10)\,(1.2) = 230.4 + 4.0 + 12.0 = 246.4$ sq in., and a direct compressive stress (in pounds per square inch) of $\frac{44{,}000}{246.4} = 179\,-$. This stress can be obtained also from Fig. 11(*a*) by a simple proportion; thus (in pounds per square inch): $\frac{8.3}{19.2}\,(412) = 178\,+$.

With this stress value and the relationships shown in Fig. 11(*a*), the stresses of Fig. 11(*c*) are found easily. The stresses acting on the section in Fig. 11(*c*) result solely from flexure and therefore should, and do, produce equal compressive and tensile forces, C and T, which can be computed as follows: $C = \frac{233}{2}\,(12)\,(10.9) + (233)\,\frac{6.5}{10.9}\,(4.0) = 15{,}800$ lb; and $T = \frac{179}{2}\,(12)\,(8.3) + 5{,}740\,(1.2) = 8{,}920 + 6{,}880 = 15{,}800$ lb. These two forces form a resisting couple whose lever arm, calculated by standard procedure, is 22.0 in. This couple, whose numerical value is 15,800 × 22.0 = 348,000 in-lb, exactly balances the bending moment already referred to, caused by the thrust of 44,000 lb acting at a distance of 7.9 in. from the center of gravity of the transformed section.

The authors state that "A dotted line is shown in Fig. 3 to indicate the shear stress that would be obtained from the formula in the 1940 Joint Committee Code[6] (or Eq. 15*a* using $j = \frac{7}{8}$)." Although it is true that the use of $\frac{7}{8}$ for $j\,d$ in Eq. 15*a* will give the erroneous result indicated by the authors, it should be understood clearly that the error is caused by a mistake in the evaluation of $j\,d$ rather than in the formula, which is correct.

The Joint Committee Code defines $j\,d$ as "the moment arm of the internal force couple." Bearing this definition in mind, a glance at Fig. 3 should make apparent the fallacy involved in taking $j\,d$ as $\frac{7}{8}\,d$ (= 32.9 in.), or even as $\left(1 - \frac{k}{3}\right) d$ (= 31.2 in.). The stresses shown as acting on the section do not produce the equal, opposite forces required for a couple. The writer's value of 22.0 in. for the moment arm of the resisting couple (Fig. 11(*c*)), is the proper value of $j\,d$ for use in Eq. 15*a*.

Substituting numerical values, $v_m = \frac{47{,}500}{12 \times 22.0} = 180$ lb per sq in., which checks exactly the authors' finding for v_m.

To verify the value of $v = 78$ lb per sq in. given in Fig. 3, it is necessary first to determine what proportion of the total resisting moment is furnished by the tensile steel (see Fig. 11(*c*)). The position of the resultant compressive force is found readily to lie at a distance of 3.7 in. from the bottom of the beam ($10.9/3 = 3.6$ in. could be used with but trifling error). The proportion of the total resisting moment, furnished by the tensile steel, is now found to be: $\frac{(1.2)\,(5{,}740)\,(37.6 - 3.7)}{348{,}000} = 0.67$.

If the tensile steel carried all of the tension involved in the resisting couple, the shearing stress, v, would equal: $\frac{47{,}500}{12\,(37.6 - 3.7)} = 117$ lb per sq in. Actually, $v = 0.67 \times 117 = 78$ lb per sq in., which agrees with the authors' value.

The writer has presented two additional methods of calculating shearing stresses in beams subject to thrust. Whether or not the individual designer will consider either method preferable to that furnished by the authors is a matter of personal choice.

Phil M. Ferguson,[22] M. Am. Soc. C. E.—The limitations that attend the proper use of the ordinary formulas for bond and shearing stress in reinforced concrete beams are discussed in this paper. In view of many discussions in recent years relative to the divergence between calculated and actual steel stresses, especially where direct stress is involved, any one would be cautious about insisting on any value of bond stress as a true value. Shrinkage and flow of concrete alter these stresses significantly, even though designers do not usually include their effect in calculations. This is not to disparage the calculations given in this paper and those presented herewith, but rather to emphasize the artificial base upon which both practice and theory now rest. So long as specifications and practice maintain this artificial base, designers, in order to be consistent, must use calculations of this type.

Since bond stress is measured by the change in tensile steel stress, it is entirely logical that direct compressive stress, as it reduces the steel stress, should also reduce the bond stress. However, differences as great as those shown in Fig. 6 are somewhat startling and might seriously modify a design.

The question immediately arises as to whether there are many situations where the ordinary formulas—

$$u = \frac{V}{\Sigma_o \frac{7}{8} d} \qquad \text{(44a)}$$

and

$$v = \frac{V}{b \frac{7}{8} d} \qquad \text{(44b)}$$

—are inadequate. These formulas are simple and commonly known. They fit beams not subject to direct stress. Does the small direct stress which may be present in many beams in a continuous frame generally limit their usefulness? If not, designers are not apt to adopt the authors' formulas for general use. The proposed formulas are simple enough in appearance, but contain a very troublesome term S_n. It will be recalled that S_n is based on a centroid which shifts with the ratio between M and P. Although not a complex calculation, the determination of S_n is lengthy enough to cause one to avoid it wherever possible. No simpler equation seems to be available for those cases where direct stress really modifies bond or shear significantly. Investigation reveals, however, that small axial compressive loads acting on ordinary beams do not modify bond and shear stresses seriously enough to be a matter of concern. This might be more accurately stated by saying that no compressive force will modify shear or bond stresses as much as 10% unless it is large enough, relative to the moment, to produce an e/h-ratio (Fig. 12) of less than unity.

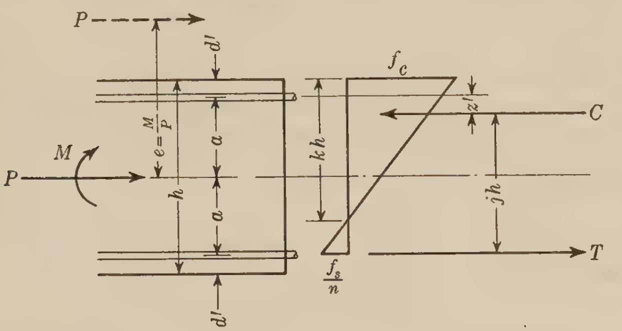

FIG. 12

Although some of this might have been ascertained by applying the authors' method to a few sample cases, it seemed desirable to investigate the theoretical relationships more thoroughly in order to establish the general area of significant difference. The following proofs include the familiar terms k and j as fractional parts of the over-all depth h, the total depth, instead of the effective depth d. This is in accordance with the notation commonly used in combined direct stress and bending.

The applied M and P (at mid-depth) are held in equilibrium by a resultant compression C and a tension T (Fig. 12). Summation of moments about the tension steel gives $C\,j\,h = M + P\,(0.5\,h - d')$, and

$$C = \frac{M + P\,(0.5\,h - d')}{j\,h} \quad \text{.................... (45)}$$

Since $C = T + P$, $\frac{dC}{dx} = \frac{dT}{dx}$. Also $dT = u\,\Sigma_o\,dx$. Hence, $u\,\Sigma_o = \frac{dT}{dx} = \frac{dC}{dx}$

$$= \frac{1}{j\,h}\,\frac{dM}{dx} - \frac{M + P\,(0.5\,h - d')}{(j\,h)^2}\,h\,\frac{dj}{dx} = \frac{V}{j\,h} - \frac{P\,e + P\,(0.5\,h - d')}{j^2\,h}\,\frac{dj}{dx}\text{; and}$$

$$u = \frac{V}{\Sigma_o\,j\,h}\left[1 - \frac{P}{V}\,\frac{(e + 0.5\,h - d')}{j}\,\frac{dj}{dx}\right] \quad \text{.............. (46)}$$

Although Eq. 46 might seem to indicate that the correction term in the bracket depends upon V and possibly upon P, it will be shown that a proper evaluation of the term $\frac{dj}{dx}$ results in the elimination of all the load terms from this expression, with the exception of e, the equivalent eccentricity of the load. An expression for $\frac{dj}{dx}$ will now be found.

The resultant compression C can be located by taking moments of the compressive forces about the center line of the compression steel:

$$\left(\frac{f_c}{2} b\,k\,h\right)\left(\frac{k\,h}{3} - d'\right) = C\,z' = \left[\frac{f_c}{2} b\,k\,h + p'\,b\,h\,n\,f_c\left(\frac{k\,h - d'}{k\,h}\right)\right] z'$$

$$z' = \frac{k^2\left(\frac{k}{3} - \frac{d'}{h}\right)}{2\,p'\,n\left(k - \frac{d'}{h}\right) + k^2}\,h \ldots\ldots\ldots\ldots(47)$$

It will be noted that $p'\,n$ is used instead of the value $p'\,(n-1)$, sometimes preferred. The value of n is not usually accurate enough to justify any distinction. Since $z' + j\,h$ is the distance between tension and compression steel, which is fixed, $\frac{dz'}{dx} + h\,\frac{dj}{dx} = 0$, and

$$\frac{dj}{dx} = -\frac{1}{h}\frac{dz'}{dx} \ldots\ldots\ldots\ldots(48)$$

Differentiating Eq. 47:

$$\frac{dz'}{dx} = h\left[\frac{k^2 - 2\frac{d'}{h}k - 2\left(\frac{z'}{h}\right)(p'\,n + k)}{2\,p'\,n\left(k - \frac{d'}{h}\right) + k^2}\right]\frac{dk}{dx} \ldots\ldots\ldots(49)$$

Hence,

$$\frac{dj}{dx} = -\frac{1}{h}\frac{dz'}{dx} = -\left[\frac{k^2 - 2\frac{d'}{h}k - 2\frac{z'}{h}(p'\,n + k)}{2\,p'\,n\left(k - \frac{d'}{h}\right) + k^2}\right]\frac{dk}{dx} = -R\,\frac{dk}{dx} \ldots(50)$$

In Eq. 50,

$$R = \frac{k^2 - 2\frac{d'}{h}k - 2\frac{z'}{h}(p'\,n + k)}{2\,p'\,n\left(k - \frac{d'}{h}\right) + k^2} \ldots\ldots\ldots\ldots(51)$$

Formulas relating k to $\frac{e}{h}$ are available in several textbooks, but can be derived by writing the equilibrium equation for the moment of T and C about the eccentric position of the load shown in Fig. 12. It is convenient to subdivide C into its components—C_1 on the compressive steel and C_2 on the concrete:

$$\Sigma M_P = C_1\,(e - a) + C_2\left(e - \frac{h}{2} + \frac{k\,h}{3}\right) - T\,(e + a)$$

$$= p'\,b\,h\,n\,f_c\left(\frac{k\,h - d'}{k\,h}\right)(e - a) + \frac{1}{2}f_c\,b\,k\,h\left(e - \frac{h}{2} + \frac{k\,h}{3}\right)$$

$$-\,p\,b\,h\,n\,f_c\left(\frac{h - d' - k\,h}{k\,h}\right)(e + a) = 0 \ldots\ldots\ldots(52a)$$

or

$$p'\,n\left(k-\frac{d'}{h}\right)(e-a)+\frac{k^2}{2}\left(e-\frac{h}{2}\right)+\frac{k^3\,h}{6}$$
$$-\,p\,n\left(1-\frac{d'}{h}-k\right)(e+a)=0\ldots\ldots\ldots\ldots\ldots(52b)$$

Differentiating Eq. 52*b* with respect to x and collecting terms gives the equation:

$$\frac{dk}{dx}\left[p'\,n\,(e-a)+k\left(e-\frac{h}{2}\right)+\frac{1}{2}k^2\,h+p\,n\,(e+a)\right]$$
$$=-\frac{de}{dx}\left[p'\,n\left(k-\frac{d'}{h}\right)-p\,n\left(1-\frac{d'}{h}-k\right)+\frac{k^2}{2}\right]\ldots\ldots(53a)$$

Since $de=\dfrac{dM}{P}$, or $\dfrac{de}{dx}=\dfrac{dM}{dx}\dfrac{1}{P}=\dfrac{V}{P}$,

$$\frac{dk}{dx}=-\frac{V}{P\,h}\left[\frac{p'\,n\left(k-\dfrac{d'}{h}\right)-p\,n\left(1-\dfrac{d'}{h}-k\right)+\dfrac{k^2}{2}}{p'\,n\left(\dfrac{e}{h}-\dfrac{a}{h}\right)+k\left(\dfrac{e}{h}-\dfrac{1}{2}+\dfrac{k}{2}\right)+p\,n\left(\dfrac{e}{h}+\dfrac{a}{h}\right)}\right]$$
$$=-\frac{V}{P\,h}B\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(53b)$$

In Eq. 53*b*, B is the quantity in the bracket. The value of B simplifies either for symmetrical steel or for no compressive steel. If $p'\,n=p\,n$,

$$B=\frac{2\,p\,n\,k-p\,n+k^2/2}{2\,p\,n\dfrac{e}{h}+k\left(\dfrac{e}{h}-\dfrac{1}{2}+\dfrac{k}{2}\right)}\ldots\ldots\ldots\ldots\ldots\ldots(54)$$

The value of $\dfrac{dk}{dx}$ from Eq. 53*b* may be substituted into Eq. 50:

$$\frac{dj}{dx}=-R\,\frac{dk}{dx}=+\frac{V}{P\,h}B\,R\ldots\ldots\ldots\ldots\ldots\ldots(55)$$

Eq. 46 now becomes:

$$u=\frac{V}{\Sigma_o\,j\,h}\left[1-\frac{P}{V}\,\frac{(e+0.5\,h-d')}{j}\,\frac{V}{P\,h}\,B\,R\right]$$
$$=\frac{V}{\Sigma_o\,j\,h}\left[1-\left(\frac{e}{h}+\frac{1}{2}-\frac{d'}{h}\right)\frac{B\,R}{j}\right]\ldots\ldots\ldots\ldots\ldots(56)$$

The bracket might be considered the modification term except that common practice substitutes $\frac{7}{8}\,d$ for $j\,h$ in ordinary beam design and this is not a good substitution here. Including the necessary correction, the equation becomes:

$$u=\frac{V}{\Sigma_o\,\frac{7}{8}\,d}\left\{\frac{0.875}{j}\,\frac{d}{h}\left[1-\left(\frac{e}{h}+\frac{1}{2}-\frac{d'}{h}\right)\frac{B\,R}{j}\right]\right\}=\frac{V}{\Sigma_o\times\frac{7}{8}\,d}$$

times a modification term$\ldots\ldots\ldots\ldots\ldots\ldots(57)$

The modification term is lengthy, but is not otherwise difficult to evaluate. In practice, the authors' equation $u = \frac{V\,A_s\,n}{\Sigma_o\,S_n}$ usually would be preferable if a correction is needed; but it does not indicate what controls the modification and gives no idea of whether this modification is important or otherwise. Eqs. 57, 53*b*, and 50 show that the modification term depends on $p\,n$, $p'\,n$, $\frac{d'}{h}$, and $\frac{e}{h}$; or that, for a given beam, it will vary solely with the $\frac{e}{h}$-ratio, since $\frac{e}{h}$ controls k. Eq. 52*b* can be used to find either $\frac{e}{h}$ or k if the other is known; or almost any textbook contains k-curves for the case of symmetrical reinforcement.

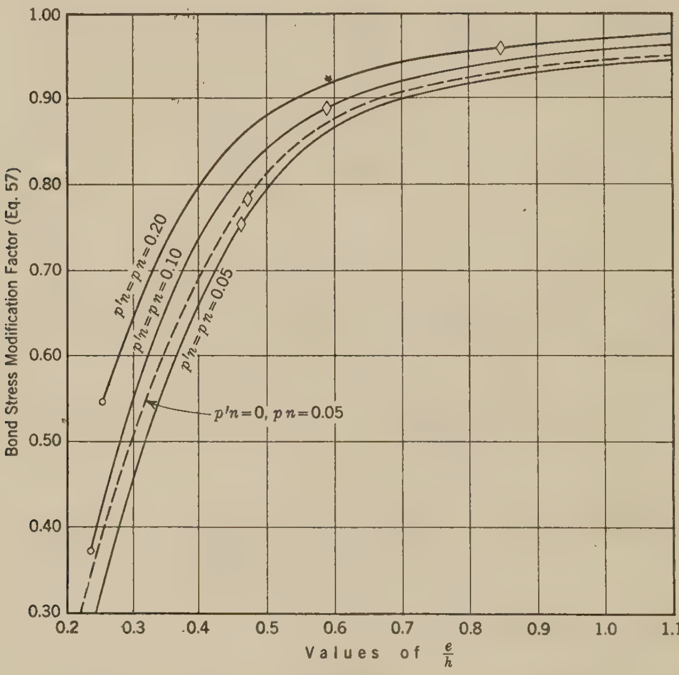

FIG. 13

The modification term is too lengthy to visualize. Fig. 13 shows the modification term $\left(\text{for } \frac{d'}{h} = 0.10\right)$ plotted against $\frac{e}{h}$ for cases of symmetrical reinforcement varying from $p\,n = 0.05$ to 0.20 and for one case of no compressive steel. The value $p = \frac{A_s}{b\,h}$ is based on steel in one face. These curves are terminated on the left at the $\frac{e}{h}$-value which gives zero stress on the tension steel. Any smaller $\frac{e}{h}$-ratio puts this steel in compression. The value of $\frac{e}{h}$ on each curve that corresponds to a neutral axis at the mid-depth of the member has been marked by a small diamond.

These curves indicate that for this $\frac{d'}{h}$-ratio, unless $\frac{e}{h}$ is less than 0.7, the modification term will be 0.9 or more, since the steel usually will not be less than that indicated by $p\,n = 0.05$. Few designers will care to make any correction for larger $\frac{e}{h}$-values than this, since it is well known that the usual bond formula is very approximate at best and a 10% change on the safe side is not very important.

If designers retain the use of the usual formula wherever $\frac{e}{h}$-values exceed 0.7, the proposed formula will not be necessary in most cases. In ordinary beams, values of $\frac{e}{h}$ as low as 0.7 will occur only where thrusts are relatively large or where moments are relatively small. The case of relatively large thrusts at sections critical for bond is rather infrequent; and the bond is rarely of interest where the moment is relatively small. Columns will frequently be loaded to give $\frac{e}{h}$-values as small as 0.7; but bond in columns is seldom a serious matter.

Since horizontal shear on the tension side of the neutral axis is directly related to the bond stress, these same conclusions should apply to shear calculations in this part of the beam. However, it seems improper to say that this shear is a satisfactory measure of the most serious diagonal tension in the beam. It must be noted that the greater shear near the centroid will tend to cause an increased diagonal tension there, and that the small axial compression might only cause the diagonal tension to increase less rapidly than v.

Fig. 3 gives data to illustrate this point. In the compressive area, it seems reasonable to apply the usual formula for maximum diagonal tension:

$$t = \frac{f}{2} + \sqrt{\left(\frac{f}{2}\right)^2 + v^2} \quad \text{......................} (58)$$

At a point 5 in. from the neutral axis (in the direction of the centroid), $f = 108$ lb per sq in., $v = 164$ lb per sq in., and $t = -54 + \sqrt{(54)^2 + (164)^2} = -54 + 173 = 119$ lb per sq in. This is remarkably close to the 120 lb per sq in. given by Eq. 44*b*. This matter needs further study before any modification of present methods is proposed.

Stanley U. Benscoter,[23] and Samuel T. Logan,[24] Juniors, Am. Soc. C. E.—The discussions provide a number of interesting and useful additions to the solution of the problem presented in the paper. It has been properly noted in several discussions that the definition of $j\,d$, as given by the writers, is not strictly correct. However, as a matter of convenience, the definition is commonly used in design practice. Professor Peabody has correctly criticized the writers' misleading statement regarding the validity of the standard shearing stress formula in members without thrust having compressive steel.

---

[23] Associate Engr., Bureau of Aeronautics, Navy Bldg., Washington, D. C.

[24] 1st Lt., Corps of Engrs., U. S. Army, Vicksburg, Miss.

Several discussers have correctly noted that the neutral axis is not parallel to the reinforcement as shown in Fig. 2. Messrs. Aleck, Ferguson, and Bergman have developed formulas based on the slope of the neutral axis with respect to the reinforcement. It should be noted carefully that the formulas proposed by the writers do not include any effect of the rate of change of flexural properties along the member. Consequently, the factors that enter into the formulas, and the development of the formulas, can be completely illustrated by a figure which neglects the slope of the neutral axis.

The application of the classical shearing stress formula to reinforced concrete, as given by Eq. 3, can be developed in undergraduate classrooms in a manner such as that used by the writers. In the graduate classroom a more comprehensive development can be given as illustrated by Eq. 19. This formula considers the rate of change of the flexural properties along the member. An additional term could be obtained by regarding the thrust P as a variable in order to obtain a formula applicable to arches.

Some discussion of Eq. 19 may be worth while. If all terms except the first are dropped, the writers' formula is obtained. It appears that the additional terms beyond the first term are more or less compensating. This is suggested by the fact that calculations presented by Mr. Bergman, based on a consideration of the rate of change of k along the member, agree well with the values computed from the writers' formulas. Thus, a dilemma which the writers are unable to resolve is presented. Why does a method of analysis which considers the rate of change of flexural properties along the member give values which agree with those computed from a formula which does not consider the rate of change of flexural properties?

For further illustration of this dilemma, consider Eqs. 28 and 29. For the member without compressive steel the formula for B becomes

$$B = \frac{\frac{1}{2} - \frac{k}{3} - \frac{j}{2}}{\frac{1}{2} - \frac{k}{3} - \frac{e}{d}\left(\frac{1}{2} + \frac{n\,p}{k^2}\right)} \qquad \text{(59)}$$

The quantity $(1 - B)$ becomes

$$1 - B = \frac{3\,dk^2 - dk^3 - 3\,e\,k^2 - 6\,e\,n\,p}{3\,dk^2 - 2\,dk^3 - 3\,e\,k^2 - 6\,e\,n\,p} \qquad \text{(60)}$$

When $P_c = 0$, Eqs. 22 become

$$P\,e = b\,d^2 f_c \frac{k}{2}\left(1 - \frac{k}{3}\right) \qquad \text{(61a)}$$

and

$$P = b\,d\,f_c\left[\frac{k}{2} - \left(\frac{1}{k} - 1\right) n\,p\right] \qquad \text{(61b)}$$

Dividing Eq. 61*a* by Eq. 61*b* gives

$$e = \frac{dk^2\,(3 - k)}{3\,k^2 - 6\,(1 - k)\,n\,p} \qquad \text{(62)}$$

Substituting Eq. 62 into Eq. 60 gives

$$1 - B = \frac{2\,(k-2)\,(k-3)\,n\,p}{k^3 + 4\,(k^2 - 3\,k + 3)\,n\,p} \qquad (63)$$

If Eq. 63 is substituted into Eq. 29, the resulting formula for v will be the same as Eq. 31. Thus, Eq. 30 is in error, and the computations, based on Eq. 30, lead to incorrect conclusions. It is especially worthy of note that a formula can be derived, based on the rate of change of k and j along the member, which is exactly the same as the writers' formula which does not consider the rate of change of flexural properties along the member. This dilemma must be resolved by future research.

A few comments on formulas involving k and j rather than the section modulus may be in order. Just as in the case of tapered beams without thrust,[25] the shearing stress may be calculated from the formula,

$$v = \frac{V_1}{b\,j\,d} \qquad (64)$$

in which V_1 is a reduced shear. The beam column of reinforced concrete is prismatic externally but nonprismatic internally. Although the surface elements are parallel, thus giving the member a prismatic shape externally, the resultant internal tensile and compressive forces are not parallel.

The reduced shear V_1 is calculated from the total shear V by deducting a reduction factor. This reduction factor is proportional to the tangent of the angle δ_1 made by the internal compressive force with a normal to the cross section. Thus, V_1 may be written as

$$V_1 = V - C \tan \delta_1 \qquad (65)$$

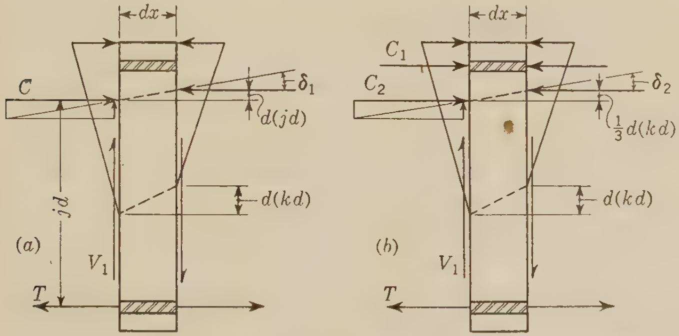

FIG. 14.—SHEAR REDUCTION FACTOR

The validity of Eqs. 64 and 65 may be demonstrated readily by using Eq. 2 and referring to Fig. 14(*a*). Eqs. 64 and 65 correspond to Eq. 21, Eq. 43, or Eq. 46. The compressive force C can be expressed in terms of k. The quantity

---

[25] "Recommended Practice and Standard Specifications for Concrete and Reinforced Concrete," *Proceedings*, Am. Soc. C. E., Pt. 2, June, 1940, Eq. 5*a*, p. 56.

$\tan \delta_1$ can be expressed in terms of derivatives of k and j in various ways such as,

$$\tan \delta_1 = d \frac{dj}{dx} \qquad (66a)$$

$$\tan \delta_1 = d \frac{dj}{dk} \frac{dk}{dx} \qquad (66b)$$

$$\tan \delta_1 = d \frac{dj}{de} \frac{de}{dx} \qquad (66c)$$

$$\tan \delta_1 = d \frac{dj}{dk} \frac{dk}{de} \frac{de}{dx} \qquad (66d)$$

or

$$\tan \delta_1 = \frac{V\,d}{P} \frac{dj}{dk} \frac{dk}{de} \qquad (66e)$$

Eq. 66e has been used by Professor Ferguson. The factor $-\frac{dj}{dk}$ is given as R in Eq. 51. The product $d\frac{dk}{de}$ is given as B in Eq. 54. The first factor is a function of k only, whereas the second factor is a function of both k and e. These derivatives are properties of the cross section and are rather complicated. By a simple expedient the first factor may be eliminated.

Consider the forces acting on the differential slice of the member as shown in Fig. 14(b). The total compression has been divided into two parts—the force C_1 consisting of the stress in the compressive steel and the force C_2 consisting of the concrete stress. The entire reduction factor used in computing the reduced shear V_1 is affected by the slope of C_2 with respect to the tensile steel since the force C_1 is parallel to the tensile steel. Thus, the formula for V_1 may be written

$$V_1 = V - C_2 \tan \delta_2 \qquad (67)$$

The formula for $\tan \delta_2$ may be written

$$\tan \delta_2 = -\frac{d}{3} \frac{dk}{dx} \qquad (68a)$$

$$\tan \delta_2 = -\frac{d}{3} \frac{dk}{de} \frac{de}{dx} \qquad (68b)$$

or

$$\tan \delta_2 = -\frac{V}{3} \frac{d}{P} \frac{dk}{de} \qquad (68c)$$

Thus, Eqs. 67 and 68c appear to provide the most convenient method for calculating shear and bond stresses in terms of k rather than in terms of the section modulus. Actually, the use of the writers' formula in terms of the section modulus will require less time.

Mr. Shanley has suggested the unit shear method which has been used rather extensively in aeronautical engineering in recent years. Unfortunately, the civil engineer seldom has sufficient time in design practice to use such a method. However, the method is commonly used as a research tool to check the validity of formulas upon which the civil engineer must depend. The first of the two numerical calculations presented by Mr. Bergman illustrates the application of the unit shear method to the problem treated by the writers.

Several discussers mention the possibility of some tensile stress existing near the neutral axis. However, it is not safe to consider tensile stresses in designing horizontal members. In such members it must be assumed that a shrinkage crack exists entirely through the member at the section being analyzed. The irregular surfaces in contact at the crack can transmit shearing stress but cannot transmit tensile stress. On the other hand, it is highly improbable that vertical walls or columns have horizontal shrinkage cracks. Consequently, vertical members with large thrust eccentricity, such as cantilever retaining wall stems, are designed in a manner that is unnecessarily conservative.

Mr. Wilbur maintains that the formula $\frac{V}{b\,j\,d}$ is equally satisfactory for members with or without thrust. He presents a stress diagram in Fig. 8 which is correct for members without thrust and mistakenly assumes it to be correct for members with thrust. Hence, an incorrect value for the maximum shearing stress is computed.

Dean Grinter correctly notes that, for straight members having a length-to-depth ratio of ten to one or greater, the formula $\frac{V}{b\,j\,d}$ should give satisfactory accuracy. Actually, the eccentricity of the thrust is the criterion that determines this accuracy. It is well that Dean Grinter has called attention to the fact that, with tensile thrust, the formula $\frac{V}{b\,j\,d}$ underestimates the shear and bond stresses.

Mr. Bull offers Eq. 39*a* for computing shearing stress. This formula may be reduced to $\frac{V}{b\,j\,d}$. Hence, Mr. Bull also maintains that $\frac{V}{b\,j\,d}$ may be used for all thrust eccentricities, which is incorrect, and his stress calculations are likewise incorrect. The "line of thrust" in the writers' paper is the same as the "pressure line" in the paper to which Mr. Bull refers.[19]

Mr. Bergman has presented two instructive methods of stress calculation. These methods provide a clarification of internal stress relationships. In the second calculation Mr. Bergman introduces an unusual definition of $j\,d$ as the distance between the resultant tensile and compressive forces which remain after the thrust has been subtracted from the internal stress diagram. This definition is in strict literal agreement with the 1940 Joint Committee Code. When this definition is employed, the stress computed from $\frac{V}{b\,j\,d}$ is the maximum stress v_m at the centroid rather than the value between the neutral axis and the tensile steel. This maximum stress is not the value that the designer should compare with the allowable stress, and it is highly improbable that the writers of the code intended to recommend such a procedure.

Professor Ferguson correctly notes the artificial base upon which all reinforced concrete stress analysis rests. He presents a development which is of considerable value to the designer in showing the range of thrust eccentricity where the formula $\frac{V}{b\,j\,d}$ gives stresses that are too high with compressive thrust. Fig. 13 illustrates the matter clearly. The writers' formulas should be used in the range of small eccentricities. Structures with heavy loading, such as the structure used by the writers as an illustration, fall in this class. Most arches are in this class. Since the formula $\frac{V}{b\,j\,d}$ requires longer to evaluate correctly than the formula recommended by the writers, there is little reason to use the formula $\frac{V}{b\,j\,d}$ in any member with thrust.

Professor Ferguson has developed formulas in terms of the over-all depth h rather than in terms of an effective depth d. Beam-column stress analysis should be divided into two classifications. One class should consist of members having the thrust within the kern and the other class should consist of members having the thrust outside the kern. In the first class the total depth h should be used in order that the thickness of the tensile steel covering will enter into the stress calculations. In the second class some conveniently defined effective depth should be used specifically to assure that the thickness of the tensile steel covering does not enter into the stress calculations.

Professor Ferguson calls attention to the fact that higher diagonal tensile stresses may exist in the compressive region, near the neutral axis, than in the region between the neutral axis and the tensile steel. In the example given by the writers this condition is very marked, because the compressive stresses in the example are very low whereas the shearing stresses are high. The high diagonal tensile stresses will exist only over a short distance along the cross section. However, they should be given some attention by future research.

Both theoretical and experimental research is needed in reinforced concrete stress analysis. Strains must be measured on actual rigid frame structures in the field. The civil engineer must learn to attach electrical strain gages to reinforcing rods as well as to insert plugs in the compressive face of members to obtain strain readings. Such field experimentation is sorely needed for the improvement of reinforced concrete design methods.

COEFFICIENTS FOR VELOCITY DISTRIBUTION IN OPEN-CHANNEL FLOW

BY WILLIAM S. EISENLOHR, JR.,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. A. A. KALINSKE, EDWARD H. TAYLOR, E. R. VAN DRIEST, HUNTER ROUSE AND JOHN S. MCNOWN, AND WILLIAM S. EISENLOHR, JR.

SYNOPSIS

Where it is necessary to take into consideration the nonuniform distribution of velocity of water flowing in open channels, it is customary to use the velocity head based on the mean velocity and a coefficient. This coefficient is fixed by the equation selected: It is the ratio of either the mean of the squares of the local velocities to the square of the mean, or the mean of the cubes of the local velocities to the cube of the mean velocity. The Chézy and Manning equations are frequently considered to be energy equations but this paper shows that, from the nature of their coefficients, they are truly momentum equations. They will not yield practical solutions when considered as energy equations except for uniform velocity distribution. The proper coefficient to be used in momentum equations is then shown to be C_m, the ratio of the mean of the squares of the local velocities to the square of the mean velocity.

INTRODUCTION

In the practical solution of most problems involving a stream of water flowing in a pipe or open channel it is not necessary to consider the variation of velocity throughout the cross section; use of the average velocity will give sufficiently accurate results. Textbooks on hydraulics, therefore, merely develop the equations of flow through an elemental stream tube and the resulting equations are then used for total flows. There are problems in nonuniform flow, however, in which a substantial part of the total change in momentum and kinetic energy between two cross sections may be due to a change in the distribution of velocity as distinguished from a change in the mean velocity. In such problems the nonuniform distribution of velocity must be taken into account by integrating, over the cross section, the equation of flow through an elemental stream tube.

NOTE.—Published in January, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Associate Hydr. Engr., Water Resources Branch, U. S. Geological Survey, Washington, D. C.

The momentum and kinetic energy of a stream of water are functions of the square and cube of the velocity, respectively. Therefore, the total momentum and kinetic energy possessed by a stream at any cross section are the sums of the momentums and energies of the flow in the different parts of the cross section. Practically, the same result can be obtained by using the average velocity and a coefficient which has been evaluated by the integration process for the particular velocity distribution being studied. These coefficients are always greater than unity. They appear to be so related[2] that for ordinary use the coefficient of momentum can be taken as

$$C_m = 1 + \frac{\epsilon^2}{3} \qquad (1a)$$

and the coefficient of energy as

$$C_e = 1 + \epsilon^2 \qquad (1b)$$

in which $\epsilon = \frac{u_{\max}}{V} - 1$. Some confusion seems to exist as to which coefficient should be used, as it is difficult to appraise correctly the factors involved in such a choice if one is accustomed to the use of formulas based on the mean velocity alone.[2a] The purpose of this paper is to explain the various factors involved and show their proper use. The usual desire is to apply some "correction coefficient" to the ordinary formula and let that suffice. Although the use of a proper coefficient is the practical solution, it should be realized that such a coefficient is the result of integrating the fundamental hydraulic equation involved, and is in no sense a "correction." To understand properly the various coefficients it will be necessary to consider the fundamental principles involved, and to develop the equations for integration. This can be done best by an illustrative example for which purpose the "Bernoulli" equation has been chosen. The numerical values of such coefficients are usually obtained from observations of the velocity distribution in the flow problem being studied or from some characteristic of flow which will yield a reasonable approximation of the velocity distribution.

NOTATION

The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Hydraulics,[3] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942. Subscripts denoting particular values are given at the end.

A = area, total cross sectional;
a = acceleration, linear;
B = bulk or volume (see Eq. 14a);
C = coefficient of flow (Chézy) in $V = C\sqrt{R\,S}$;
C_A, C_B = coefficients of force distribution in the energy equation;

[2a] See author's redesignation in the closing discussion.—Ed.

[3] ASA—Z10.2—1942.

C_e = coefficient of energy distribution = $\frac{\overline{u^3}}{V^3}$;
C_m = coefficient of momentum distribution = $\frac{\overline{u^2}}{V^2}$;
F = force;
f = Darcy coefficient of friction = 4λ;
g = gravitational acceleration;
h_f = head, lost by friction;
k = a constant ratio of pressure intensities (see Eqs. 4);
L = length; length of stream tube or channel between sections;
m = mass;
n = coefficient of roughness in the Manning equation;
P = wetted perimeter;
p = pressure per unit area;
Q = discharge (rate of flow);
R = hydraulic radius;
S = friction slope; slope of momentum grade line;
t = time;
u = velocity component in the direction of flow; velocity of flow through a stream tube;
V = mean velocity, $\frac{Q}{A}$;
Z = elevation, above datum;
γ = specific weight;
ϵ = velocity distribution constant = $\frac{u_{\max}}{V} - 1$;
θ = angle between axis of a stream tube and the horizontal, $\sin^{-1}\left(\frac{Z_A - Z_B}{L}\right)$;
λ = resistance coefficient = $\frac{f}{4}$; the ratio of boundary shear to kinetic energy based on the mean velocity;
ρ = density, mass per unit volume = $\frac{\gamma}{g}$;
τ_0 = unit shear at the channel boundary.

Subscripts and Special Characters.—Letter subscripts refer a symbol to various conditions as follows:

A = "section A" (Fig. 1);
B = "section B" (Fig. 1);
A-B = "between section A and section B";
e = "energy equation";
m = "momentum equation";
n = "normal to the sides of a stream tube" (see Eqs. 4);
p = "pressure";
r = "resisting";
u = "uniform velocity distribution."

A bar over a symbol signifies the average value of the quantity indicated. Subscripts 1 and 2 refer a symbol to stream tubes 1 and 2 (Figs. 1, 2), respectively.

MOMENTUM VS. ENERGY

Standard textbooks on hydraulics usually demonstrate the proof of the Bernoulli equation either by the momentum theorem or by the energy principle, although they are not always so labeled. In either case it is usual to assume that the stream is composed of a bundle of "stream tubes" of differential area in cross section. A stream tube may be defined as a small tube bounded by a surface which at every point is tangent to the velocity vector at that point. There is no flow across the bounding surface of a stream tube. (A more correct definition for turbulent flow is that the temporal average of flow across a stream tube boundary is zero.) Flow through the stream tube is then similar to flow through a small pipe of varying cross section. The flow through a single stream tube may be analyzed and the resulting differential equation integrated over the cross section. The basic equation by the momentum theorem or energy principle is that of Newton's second law of motion, $F = m\,a$, wherein the substitution $a = \frac{u^2{}_B - u^2{}_A}{2\,L}$ has been made. The difference between the two methods lies in whichever side of the equation the distance L is placed. If it is placed on the right, the momentum equation becomes:

$$F = m\frac{u^2{}_B - u^2{}_A}{2\,L} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in the form of momentum change per unit time—that is, $\frac{F\,t}{t} = \frac{m\,u}{t}$; and $F = \frac{m\,u}{t}\left(\times\frac{L}{L}\right) = \frac{m\,u^2}{L}$. The change of the momentum with time is equal to the resultant force acting on the mass.

If the distance L is placed on the left the energy relation is

$$F\,L = \tfrac{1}{2}\,m\,(u^2{}_B - u^2{}_A) \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

which states that the change in kinetic energy is the result of work done by the impressed forces. If the change in unit time[3a] is considered, as was done for momentum, and Eq. 3a is divided by $t = 1$:

$$F\,u = \tfrac{1}{2}\,m\,[u^2{}_B - u^2{}_A]_{t=1} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

To apply these equations it is necessary, of course, to have steady flow, or flow which on the average may be regarded as steady. Only under such a condition would the system be in equilibrium.

It is most important to realize the significance of the method of considering the distance L as used in the preceding paragraph. In the momentum equation, L is the length of the stream tube in which the change in momentum takes place. It may have any value desired but it is the same for every stream tube within the stream. In the momentum equation the forces are considered to be acting independent of any motion. On the other hand, in the energy equation the forces must act through a specified distance (u, if Eq. 3b is used). Since the velocity distribution is nonuniform, u is different for each stream tube. This makes an extremely complicated differential equation, the integration of which does not yield a solution suitable for practical use. To simplify the problem, most textbook writers assume a uniform distribution of velocity when deriving the Bernoulli equation by means of the energy principle. Using this assumption, u is the same for each stream tube. The distances through which the forces act are thus the same for all stream tubes. The integration then can be performed in the same way as for the momentum equation and the result is an equation identical with that derived from the momentum theorem. An equation is thus derived by the energy principle, based on assumed uniform velocity distribution, giving the same answer as that derived by the momentum theorem. The result is an understandable confusion as to whether to use the coefficient of momentum distribution or the coefficient of energy distribution.

[3a] See redesignation in closing discussion, expressed by Eq. 41c.—Ed.

The Momentum Theorem

Many ideas frequently thought of in terms of the energy relation are really momentum concepts. The following paragraph is taken almost verbatim from the explanation given by L. Prandtl.[4]

The value of the momentum theorem is that it contains statements about conditions along the boundaries of a region only. The internal forces cancel by the principle of action and reaction, when summing over all the masses of the system, leaving only the external forces to be considered. Now the change in momentum of a mass of fluid which is bounded in any way, and is in steady motion, is due entirely to the fact that the boundaries of the fluid are displaced by the motion; every particle of the fluid in the interior is replaced by another which has taken up its velocity. What happens at the boundaries may be shown in the case of a stream tube. It is an essential feature of the momentum theorem that every individual mass belonging to the system shall remain in the system and that no new masses shall enter it. Thus the boundary surfaces drawn for the purpose of applying the theorem are not displaced with the flow; they are "fluid surfaces." Hence in the case of the stream tube there is a mass dm which leaves the downstream end of the stream tube in unit time. During the same time, by the law of continuity, an equal mass enters the upstream end of the stream tube. Thus, in unit time the stream tube contributes to the total change in momentum the positive momentum $dm\ u_B$ at the downstream end and at the same time the negative momentum $dm\ u_A$ is contributed at the upstream end. These changes in momentum per unit time may immediately be expressed as forces exerted from outside on the mass of fluid in question across the cross sections at the ends of the stream tube.

Development of the Momentum Equation

Proceeding now to develop the equation of flow according to the momentum theorem, consider the channel shown in Fig. 1. The stream can be considered to be divided into stream tubes of differential area dA. The change in momentum between sections A and B is the result of the external forces. The pressure force on the upstream end is $p_A\, dA_A$, and on the downstream end is $p_B\, dA_B$. Another basic assumption that must be made is that the flow is gradually varied. With this assumption the development can be simplified by letting $dA_A = dA_B = dA$ without restricting the variation in velocity.

---

[4] "The Physics of Solids and Fluids with Recent Developments," Pt. 2, by L. Prandtl, 1936, p. 223.

(The validity of this assumption is easily shown. Let $p_A = p + \delta p$; $p_B = p$; $dA_A = dA$, and $dA_B = dA + \delta A$. In addition to the pressure forces on the ends of the stream tube, there is also a component in the direction of motion of the normal pressure p_n on the sides of the stream tube, which is equivalent

FIG. 1.—MOMENTUM DIAGRAM; ALSO ENERGY DIAGRAM AT $t = 0$

to $p_n\, \delta A$. Since p_n lies between p_A and p_B it can be expressed as $p + k\, \delta p$. The pressure forces are then:

$$F_p = p_A\, dA_A + p_n\, \delta A - p_B\, dA_B \tag{4a}$$

$$F_p = (p + \delta p)\, dA + (p + k\, \delta p)\, \delta A - p\, (dA + \delta A) \tag{4b}$$

and

$$F_p = \delta p\, dA + k\, \delta p\, \delta A \tag{4c}$$

The first term of Eq. 4c is the equivalent of the resultant pressure force as obtained by assuming equal areas. The only error introduced in this assumption is the neglect of the term $k\, \delta p\, \delta A$ which, as the product of two differentials, is negligible.)

The resultant pressure force is then $(p_A - p_B)\, dA$. The gravity force is the component along the axis of the stream tube of the weight of the tube, $\gamma\, L\, dA$, which is $\gamma\, L\, dA \sin \theta$. In addition to the pressure and gravity forces, there is the resisting force along the boundary of the stream tube. For the present this will be designated simply $dF_{r,m}$.

Inserting the foregoing quantities in Eq. 2:

$$p_A\,dA - p_B\,dA + \gamma\,L\,dA\,\sin\theta - dF_{r,m} = \rho\,L\,dA\,\frac{u^2{}_B - u^2{}_A}{2\,L} \quad\ldots\ldots(5)$$

substituting for $\sin\theta$ and rearranging[4a]:

$$dF_{r,m} = \left[\left(\frac{p_A}{\gamma} + Z_A\right)dA - \left(\frac{p_B}{\gamma} + Z_B\right)dA + \frac{u^2{}_A}{2\,g}\,dA - \frac{u^2{}_B}{2\,g}\,dA\right]\gamma \quad\ldots(6)$$

The total resisting force $F_{r,m}$ can now be obtained by integrating the right side of the equation with respect to dA. This is the important step. Since $\left(\frac{p}{\gamma} + Z\right)$ is the height of the water surface above the datum plane, it is the same for all stream tubes. The integration of the first two terms is easily performed. The last two terms cannot be integrated in their present forms.

The coefficient for nonuniform distribution of velocity is now introduced. The term C_m is defined as the coefficient of momentum distribution due to nonuniform distribution of velocity. It is expressed as:

$$C_m = \frac{\overline{u^2}}{V^2} \qquad \text{or} \qquad C_m = \frac{\int u^2\,dA}{V^2\,A}.$$

Integrating Eq. 6:

$$F_{r,m} = \left[\left(\frac{p_A}{\gamma} + Z_A\right) - \left(\frac{p_B}{\gamma} + Z_B\right) + C_{m,A}\,\frac{V^2{}_A}{2\,g} - C_{m,B}\,\frac{V^2{}_B}{2\,g}\right]\gamma\,A \quad\ldots(7)$$

It was shown previously that integrating the momentum equation canceled all the internal forces and left only the external forces. Therefore, $F_{r,m}$ must represent the total shearing stress along the channel boundary between A and B. If this force is replaced by an equivalent negative force on B equal to $\gamma\,h_{f,A-B}\,A$ (in which h_f is an expression in terms of "loss of head due to friction" of the shear at the boundary) the usual form of the Bernoulli equation is derived with the velocity distribution coefficients and the friction term included:

$$\gamma\,h_{f,A-B}\,A = \left[\left(\frac{p_A}{\gamma}+Z_A\right) - \left(\frac{p_B}{\gamma}+Z_B\right) + C_{m,A}\,\frac{V^2{}_A}{2\,g} - C_{m,B}\,\frac{V^2{}_B}{2\,g}\right]\gamma\,A \quad\ldots(8a)$$

and

$$\frac{p_A}{\gamma} + Z_A + C_{m,A}\,\frac{V^2{}_A}{2\,g} = \frac{p_B}{\gamma} + Z_B + C_{m,B}\,\frac{V^2{}_B}{2\,g} + h_{f,A-B} \quad\ldots\ldots(8b)$$

Instead of replacing $F_{r,m}$ by an equivalent "loss of head force," it can be stated directly in terms of unit shear at the boundary, τ_0. This unit shear is usually expressed in terms of the kinetic energy of the water[5] based on the mean velocity, $\rho\,\frac{V^2}{2}$, by means of a resistance coefficient, λ. The coefficient λ is the same as $\frac{f}{4}$, in which f is the familiar Darcy coefficient of friction.

[4a] See redevelopment of Eqs. 6 and 7, as expressed by Eq. 43 in the closing discussion.—Ed.

[5] "The Physics of Solids and Fluids with Recent Developments," Pt. 2, by L. Prandtl, 1936, p. 275.

The total resisting force may then be put equal to the total shear at the boundary:

$$F_{r,m} = \tau_0 \, P \, L \qquad (9a)$$

and since

$$\tau_0 = \frac{\lambda \rho V^2}{2} = \frac{f \rho V^2}{8} \qquad (9b)$$

substituting values from Eqs. 7 and 9*b* in Eq. 9*a* and transposing,

$$\frac{f \rho V^2}{8} P L = \left[\left(\frac{p_A}{\gamma} + Z_A \right) - \left(\frac{p_B}{\gamma} + Z_B \right) + C_{m,A} \frac{V^2{}_A}{2g} - C_{m,B} \frac{V^2{}_B}{2g} \right] \gamma A \qquad (10a)$$

$$\frac{f}{8} \frac{\rho}{\gamma} \frac{P}{A} V^2 = \frac{\left(\frac{p_A}{\gamma} + Z_A \right) - \left(\frac{p_B}{\gamma} + Z_B \right) + C_{m,A} \frac{V^2{}_A}{2g} - C_{m,B} \frac{V^2{}_B}{2g}}{L} \qquad (10b)$$

and

$$\frac{f}{8g} \frac{1}{R} V^2 = S \qquad (10c)$$

By making the proper substitutions for f in Eq. 10*c*, the Chézy and Manning equations are obtained. Substituting $f = \frac{8g}{C^2}$ gives the familiar Chézy equation—

$$V = C \sqrt{R S} \qquad (11)$$

or substituting $f = \frac{n^2}{0.00858 \, R^{1/3}}$ gives the Manning equation—

$$V = \frac{0.262 \sqrt{g}}{n} R^{1/6} \sqrt{R S} = \frac{1.486}{n} R^{2/3} S^{1/2} \qquad (12)$$

Although the substitution of $f = \frac{n^2}{0.00858 \, R^{1/3}}$ is usually regarded as empirical, it does not affect the rationality of the development of the slope term, which is the concern of this paper. Likewise it is to be emphasized that f is a coefficient of boundary resistance alone and therefore both C and n are coefficients of boundary resistance alone, and are usually considered as such.

The momentum theorem is thus seen to provide a rational method of deriving the Bernoulli, Chézy, and Manning equations in a form which is usable and the one in which they are usually considered. The proper velocity-distribution coefficient to use in such equations is, therefore, $C_m = \frac{\overline{u^2}}{V^2}$

This can also be shown in another and perhaps more direct manner. It was noted previously that the change in momentum per second can be expressed as a force. This force can be measured directly with a pitot tube, and is equal to $\gamma \frac{u^2}{2g} dA$. Therefore, the total force is

$$F_{r,m} = \frac{\gamma}{2g} \int_0^A u^2 \, dA \qquad (13a)$$

For this value can be substituted

$$F_{r,m} = \gamma\, C_m \frac{V^2}{2\,g} A \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13b)$$

in which C_m is the coefficient previously defined. Thus, if one were to integrate over a cross section with a pitot tube, the ratio of the average height of water in the tube, above the free water surface, to the height of water in the tube corresponding to the mean velocity would give the coefficient C_m.

DEVELOPMENT OF THE ENERGY EQUATION

In contrast to the momentum theorem, the energy principle requires that the work done by the forces be evaluated. Work requires motion. The proper method of applying the energy principle to flowing water is to take a mass of water and determine what takes place as work is done upon it. The work done in moving the mass a given distance could be computed if the mass moved as a solid body. Since the present problem concerns nonuniform velocity, such an assumption cannot be made. The work done during a given time interval can be considered, however. Taking the same mass of water as was considered before (see Fig. 1) and letting the forces act for one second will produce the results shown in Fig. 2. Not only has the mass moved with respect to the channel, but each stream tube has also moved with respect to every other stream tube having a different velocity. Thus, the internal forces acting along the boundaries of the stream tubes do not cancel by action and reaction as in the momentum equation, since there must be residual unbalanced forces that

FIG. 2.—ENERGY DIAGRAM AT $t = 1$

produce the relative motion between the stream tubes. The integration of the differential equation will sum up these unbalanced internal forces as well as the external forces and the final equation must contain some expression including them.

Proceeding now to evaluate the terms in Eq. 3*b*, the work done by the pressure forces is $p_A\, dA_A\, u_A - p_B\, dA_B\, u_B$. In this case it is not necessary to specify the $dA_A = dA_B$ but the assumption of gradually varied flow must still be applied. Since the volume $dA_A\, u_A$ must equal $dA_B\, u_B$ and may for convenience be expressed as B (bulk or volume) it follows that the volume in between (shaded volume in Fig. 2), although containing different particles of water at $t = 1$ than it did at $t = 0$, has the same energy content throughout the period considered. Thus the work of the gravity forces can be considered as that required to move B from the position at $dA_A\, u_A$ to the position $dA_B\, u_B$, which, as far as the gravity forces are concerned, is $\gamma\, B$ times the vertical component of the distance between them $Z_A - Z_B$. The resisting force will be expressed as $dF_{r,e}$ and the distance through which it moves is $\bar{u}_{A-B}$, the average velocity in the stream tube. Similarly as with the gravity forces, the change in kinetic energy can be expressed as the change in energy of a mass $\rho\, B$ being moved from a position at $dA_A\, u_A$ to a position at $dA_B\, u_B$. Inserting these quantities in Eq. 3*b*:

$$p_A\, dA_A\, u_A - p_B\, dA_B\, u_B + \gamma\, B\, (Z_A - Z_B) - dF_{r,e}\, \bar{u}_{A-B} = \tfrac{1}{2}\, \rho\, B\, (u^2_B - u^2_A) \qquad (14a)$$

rearranging, and remembering that $B = dA_A\, u_A = dA_B\, u_B$:

$$dF_{r,e}\, \bar{u}_{A-B} = \left[\left(\frac{p_A}{\gamma} + Z_A\right) dA_A\, u_A - \left(\frac{p_B}{\gamma} + Z_B\right) dA_B\, u_B + \frac{u^2_A}{2\,g}\, dA_A\, u_A - \frac{u^2_B}{2\,g}\, dA_B\, u_B\right] \gamma \qquad (14b)$$

To integrate over the cross section to obtain the total resisting force $F_{r,e}$, it is necessary to make substitutions. The term C_e is defined as the coefficient of energy distribution due to nonuniform distribution of velocity evaluated as $C_e = \dfrac{\overline{u^3}}{V^3}$ or $C_e = \dfrac{\int u^3\, dA}{V^3\, A}$. Still other substitutions must be made in the case of the energy equation, however. During the time period from $t = 0$ to $t = 1$, the original plane cross sections at the ends of the reach have been transformed into warped surfaces, and $\left(\dfrac{p}{\gamma} + Z\right)$ is no longer a constant. As u is likewise a variable, the following substitution is made:

$$C_A = \frac{\int \left(\frac{p_A}{\gamma} + Z_A\right) u_A\, dA_A}{\left(\frac{p_A}{\gamma} + Z_A\right)_{\text{avg}} V_A\, A_A} \qquad (15a)$$

$$C_B = \frac{\int \left(\frac{p_B}{\gamma} + Z_B\right) u_B\, dA_B}{\left(\frac{p_B}{\gamma} + Z_B\right)_{\text{avg}} V_B\, A_B} \qquad (15b)$$

By integration, the total resisting force is then:

$$F_{r,e}\,V = \left[C_A \left(\frac{p_A}{\gamma} + Z_A\right)_{\text{avg}} V_A\,A_A - C_B \left(\frac{p_B}{\gamma} + Z_B\right)_{\text{avg}} V_B\,A_B + C_{e,A}\frac{V^2_A}{2\,g} A_A\,V_A - C_{e,B}\frac{V^2_B}{2\,g} A_B\,V_B \right]\gamma \qquad (16a)$$

Since $A\,V = A_A\,V_A = A_B\,V_B$,

$$F_{r,e} = \left[C_A \left(\frac{p_A}{\gamma} + Z_A\right)_{\text{avg}} - C_B \left(\frac{p_B}{\gamma} + Z_B\right)_{\text{avg}} + C_{e,A}\frac{V^2_A}{2\,g} - C_{e,B}\frac{V^2_B}{2\,g} \right]\gamma\,A \qquad (16b)$$

This can be arranged into the form of the Bernoulli equation:

$$C_A \left(\frac{p_A}{\gamma} + Z_A\right)_{\text{avg}} + C_{e,A}\frac{V^2_A}{2\,g} = C_B \left(\frac{p_B}{\gamma} + Z_B\right)_{\text{avg}} + C_{e,B}\frac{V^2_B}{2\,g} + \frac{F_{r,e}}{\gamma\,A} \qquad (16c)$$

It is easily seen that a formula such as Eq. 16*c* is not easily adapted to practical solutions of open-channel problems since $F_{r,e}$ involves internal as well as boundary resistance. It could be argued that the Chézy and Manning equations are purely empirical and therefore the slope could be evaluated by means of Eq. 16*b*, substituted in them, and the proper coefficients computed empirically. Such coefficients would necessarily be coefficients of internal resistance as well as boundary resistance and presumably could vary as compared with coefficients of boundary resistance alone. It is doubtful if such a method would yield practical results.

COMPARISON OF COEFFICIENTS

Eq. 16*b* is identical in form with the momentum equation (Eq. 7). It differs in that the coefficients C_e are quite different from the coefficients C_m, and the additional coefficients C_A and C_B are also present. It must also be realized that, although $F_{r,m}$ in the momentum equation is the resistance at the boundary only, $F_{r,e}$ in the energy equation includes that force as well as the resisting forces exerted by one stream tube upon another due to their relative motion. It is concluded, therefore, that Eq. 16*b* is not suited to practical application.

Most textbooks on hydraulics which use the energy principle to demonstrate the Bernoulli equation assume a uniform distribution of velocity. With this assumption, in rearranging Eq. 14*a* one could use $B = dA_A\,V_A = dA_B\,V_B$; and the distance through which the resisting force moves is V. Likewise, $V^2_A = u^2_A$ and $V^2_B = u^2_B$ can be substituted. The quantity $\left(\frac{p}{\gamma} + Z\right)$ is now constant over the cross section also, and Eq. 14*a* transforms to

$$dF_{r,u}\,V = \left[\left(\frac{p_A}{\gamma} + Z_A\right) V_A\,dA_A - \left(\frac{p_B}{\gamma} + Z_B\right) V_B\,dA_B + \frac{V^2_A}{2\,g} V_A\,dA_A - \frac{V^2_B}{2\,g} V_B\,dA_B \right]\gamma \qquad (17a)$$

which can be integrated without further substitution:

$$F_{r,u} = \left[\left(\frac{p_A}{\gamma} + Z_A\right) - \left(\frac{p_B}{\gamma} + Z_B\right) + \frac{V^2_A}{2\,g} - \frac{V^2_B}{2\,g}\right]\gamma\,A \ldots . (17b)$$

Eq. 17*b* is similar to Eq. 7 and would be identical if Eq. 7 were based on uniform velocity distribution. In such a case C_m would reduce to 1.00. Since uniform distribution of velocity is assumed, the water in all stream tubes moves forward together, there is no relative internal motion, and therefore $F_{r,u}$ would be the force at the boundary alone, as in the case of the momentum equation.

SUMMARY

Having two identical equations for the flow of water with uniform velocity distribution, one based on the momentum theorem and the other based on the energy principle, it is easy to understand how differences can arise in working backward to nonuniform velocity distribution. Apparently many engineers think of the Bernoulli equation as it is normally written as an energy equation exclusively because it can be obtained using energy principles and assuming uniform velocity distribution. This leads to the desire to correct for nonuniform distribution by introducing the coefficient C_e. However, the Bernoulli equation is also a momentum equation[5a] and when so used the proper coefficient for nonuniform velocity distribution is C_m. If it is desired to use the coefficient C_e it must be realized that the other coefficients C_A and C_B must be added and that the nature of the resistance F_r changes also.

The historical background concerning the confusion of coefficients has been presented by B. A. Bakhmeteff,[6] M. Am. Soc. C. E., and the strict hydrodynamical approach was given by G. H. Keulegan[7] at the suggestion of the writer. The present paper is an attempt to interpret the two references cited in terms of demonstrations found in ordinary textbooks.

DISCUSSION

A. A. Kalinske,[8] Assoc. M. Am. Soc. C. E.—Hydraulic engineers are reminded, by this paper, of an item which, although of minor significance in most practical varied-flow problems, is nevertheless of considerable interest, because it reemphasizes the difference between the two fundamental methods of attacking hydraulic problems—namely, the energy and momentum principles. Nothing new is really presented since, as the author mentions at the end of his paper, this particular problem has been very completely discussed in papers by B. A. Bakhmeteff,[6] M. Am. Soc. C. E., and G. H. Keulegan.[7] Nevertheless, it is well that the author has brought it more definitely to the attention of hydraulic engineers.

The writer would like to reinterpret and restate certain ideas mentioned or implied in the paper. First, the fundamental reason that the wrong application of Bernoulli's equation is made to stream cross sections having nonuniform velocity distribution is a faulty understanding of the derivation of Bernoulli's equation. Basically, the expression known as Bernoulli's equation is the integral along a streamline of the Euler differential equation for steady frictionless fluid motion.[9] Euler's equation is obtained from a simple application of Newton's law ($f = m\,a$) to a fluid particle. Of course, since basically the energy and momentum laws stem from Newton's law, these can be used to derive Bernoulli's equation. Because, fundamentally, Bernoulli's equation holds only along a streamline, its use cannot be extended directly to a finite stream cross section except for the special case in which the velocity of all the fluid particles in the cross section of a stream tube is the same.

If an equation of the Bernoulli type is to be used for stream cross sections having nonuniform velocity distribution, it is necessary to derive such an expression from basic dynamic considerations. In any such derivation, of course, the analyst must consider all frictional forces since these are always present for real fluids. This was done by Mr. Keulegan,[7] using both the energy and momentum principles. The author has derived similar expressions in a somewhat less clear, and less rigorous, manner.

The energy principle, as used by Mr. Keulegan and the author, probably could be called the "power" principle since the terms calculated are really the "flow" of energy per unit time and the work done per unit time. The important item to recognize in the use of this principle is that all external and internal energy losses and work done must be taken into account. In using the momentum law only external forces need be considered. Hydraulic engineers will recognize this basic difference in the use of these two principles in the analysis of the hydraulic jump.

In a truly rigorous sense, Eq. 8*a* or Eq. 16*c* should not really be called a Bernoulli equation. Such an equation is basically true only along a streamline, and was originally derived for ideal fluids. Eq. 8*a* is actually a momentum equation and Eq. 16*b* a power equation.

[8] Associate Prof., Univ. of Iowa, Iowa Inst. for Hydr. Research, Iowa City, Iowa.

[9] "Fundamentals of Hydro- and Aero-Mechanics," by L. Prandtl and O. Tietjens, McGraw-Hill Book Co., Inc., New York, N. Y., 1934, p. 112.

The author's analyses, in reality, are concerned with deriving varied-flow equations for open channels. However, neither Eq. 8*b* nor Eq. 16*c* could be used for solving varied-flow problems (for example, obtaining backwater curves), except for very short increments of the distance, L. The reason for this is that the equations have not been integrated with respect to L; instead average values have been used for such variables as A and wall shear. Distance L should have been designated as dL.

The author's statements regarding Eq. 2 and Eq. 3 are basically inaccurate. He states that $a = \frac{u^2_B - u^2_A}{2\,L}$, which, of course, comes from the relation $a = \frac{u\,du}{dL}$ when integrated between points A and B, assuming a as constant. Obviously, there is no reason to assume a as constant in any length of channel. It would have been better if Eq. 5 had been written as:

$$(dp)\,(dA) + \gamma\,(dL)\,(dA)\sin\theta - df_{r,m} = \rho\,(dA)\,u\,(du) \ldots\ldots\ldots (18)$$

Any attempt to integrate Eq. 18 with respect to L (which the author really does) would indicate that an assumption should be made regarding the variation of A with L. The author assumes, of course, that such variation is negligible; this is inconsistent since he does not at the same time assume variation in u as negligible. Similar weaknesses are present in the derivation of Eq. 16*c*, involving the energy principle.

Reference to Mr. Keulegan's handling of this same problem indicates that his final equations are in differential form as far as the distance L is concerned. However, the author's results (which show that the coefficient C_m should be used when only external forces are being calculated, and that C_e should be used when the total energy loss is concerned) agree with Mr. Keulegan's final conclusions. This is the all-important part of the paper and is correct, even though the derivations leading up to these facts are quite inelegant mathematically, and not overly convincing.

It is hoped that this paper will clarify the question of which "velocity-head" correction coefficient should be used, and why, when applying the Bernoulli equation to various practical fluid flow problems. Many engineers have not been too clear in their minds regarding this matter and have accepted textbook statements without a careful analysis of the dynamics involved. A more thorough consideration of classical hydrodynamics and the exercise of greater care in transferring relations developed therein into the field of real fluids would have prevented the various misunderstandings such as have occurred in the practical use of the Bernoulli equation.

EDWARD H. TAYLOR,[10] JUN. AM. SOC. C. E.—Certain assertions in this very interesting paper are somewhat novel, and their acceptance would require a change in the thinking methods of the writers of "standard textbooks on hydraulics." The following statement leading to Eqs. 2 and 3 was of particular interest to the writer:

> "The basic equation by the momentum theorem or energy principle is that of Newton's second law of motion, $F = m\,a$, wherein the substitution

---

[10] Asst. Prof. of Civ. Eng., Univ. of Arizona, Tucson, Ariz.

> $a = \dfrac{u^2{}_B - u^2{}_A}{2\,L}$ has been made. The difference between the two methods lies in whichever side of the equation the distance L is placed."

Since momentum and energy are basically different physically—that is, momentum is a vector quantity and energy a scalar quantity—it appears incorrect to state that one can be obtained from the other by a mere transposition of one factor.

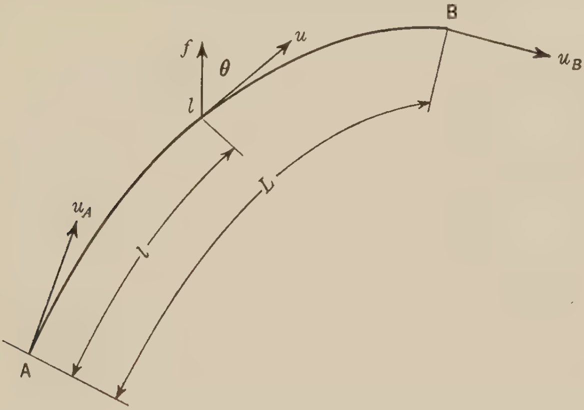

Fig. 3

In other words, the appearance of the length L on one side of the equation or the other should make no difference in the fundamental nature of the equation itself. The F in Eq. 2 and the F in Eqs. 3 are apparently identical. It might be of value to recall that, in a given mechanical system, the force that causes a change in momentum is not, in general, the same force that causes a change in kinetic energy. Forces normal to the path of motion have no effect on the kinetic energy, but definitely influence the momentum. As a simple example, consider a mass particle fastened to a point by a string and describing plane uniform motion about the point.

The key to this situation lies in the substitution, $a = \dfrac{u^2{}_B - u^2{}_A}{2\,L}$. Consider a particle (fluid or otherwise) which follows the path shown in Fig. 3. Here f is the resultant of all forces acting on the particle when it occupies the position l. The equation of motion is:

$$f \cos\theta = m\,\frac{du}{dt} \tag{19}$$

Multiplying both sides of Eq. 19 by dl,

$$f \cos\theta\, dl = m\,\frac{du}{dt}\,dl \tag{20a}$$

or

$$f \cos\theta\, dl = m\,u\,du \tag{20b}$$

Integrating

$$\int_0^L f \cos \theta \, dl = m \left(\frac{u^2_B}{2} - \frac{u^2_A}{2} \right) \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

An average force F may be defined by

$$F = \frac{1}{L} \int_0^L f \cos \theta \, dl \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

provided that its nature be carefully kept in mind. Then,

$$F\,L = m \left(\frac{u^2_B - u^2_A}{2} \right) \text{; or (see Eq. 2) } F = m \left(\frac{u^2_B - u^2_A}{2\,L} \right).$$

Thus, the F of Eq. 2 does not seem to be the resultant force acting on the mass, but rather an average component taken along the path. As far as the writer is aware, the use of the substitution $a = \frac{u^2_B - u^2_A}{2\,L}$ permits no other interpretation. Furthermore, the right-hand member is not the rate of change of momentum (although it is its dimensional equivalent, as shown), but it is the average change in kinetic energy per unit length on the path L. Rate of change of momentum is a vector quantity, by Newton's second law, and Eq. 2 contains no element of direction.

Thus, the writer is led to the conclusion that Eq. 2 is truly an energy equation. This would eventually lead to the further statement that energy coefficients should be used in Eq. 7. The foregoing remarks, although contradictory to the author's general thesis, are in no way intended to be derogatory. They are merely an expression of the writer's understanding of the meaning of momentum and energy.

E. R. VAN DRIEST,[11] ASSOC. M. AM. SOC. C. E.—The theorems of momentum and energy have proved to be very important tools of the hydraulic engineer and therefore their proper application should be understood completely by those who would use them. To be sure, some problems lend themselves more readily to solution by the momentum theorem, whereas others are solved more easily through the use of the energy theorem. Although this paper does not elaborate on the application of these principles, it does attempt to clarify some of the basic facts underlying them.

It is true that the standard textbooks derive the Bernoulli equation by either the application of the Newtonian law to a particle of fluid or the conservation of energy law to a mass; however, in the use of the Newtonian law the acceleration is written as the derivative $u \frac{du}{dL}$ rather than in the restricted form entered in Eq. 2. In most texts the acceleration equation is integrated directly, whereas in certain treatises[9] the line integral is formed along the streamline thus indicating that the work done on the fluid particle is equal to the change in kinetic energy. In this interpretation the left-hand member of Eq. 3a should read $\int_A^B F \, dL$.

---

[11] Associate Prof., Mech. Eng., Massachusetts Inst. of Tech., Cambridge, Mass.

The author's development of Eq. 7 for the case of gradually varied flow is not a strict application of the momentum theorem as such. The theorem states that in steady flow the sum of all external forces acting on a fluid mass is equal to the flow of momentum through the fixed surface bounding that mass at the instant in question. This theorem is expressed by the mathematical relation obtained from the Newtonian law for the L-direction,

$$\sum F_L = \int^{A} \rho\, u^2\, dA \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

If this theorem is applied to the mass of Fig. 1:

$$\int^{A_A} p_A\, dA - \int^{A_B} p_B\, dA + (\text{weight})_L - F_{r,m}$$
$$= \frac{\gamma}{g}\int^{A_B} u^2{}_B\, dA - \frac{\gamma}{g}\int^{A_A} u^2{}_A\, dA \ldots\ldots\ldots\ldots\ldots (24)$$

Rewriting Eq. 24 in terms of the mean velocities across sections A and B, and abbreviating the left-hand member,

$$\sum F_L = \frac{\gamma}{g}\,(C_{m,B}\, V^2{}_B\, A_B - C_{m,A}\, V^2{}_A\, A_A) \ldots\ldots\ldots\ldots (25)$$

It can readily be shown that Eq. 25 can be approximated by Eq. 7 when V_B approaches V_A and the difference between C_B and C_A approaches zero more rapidly than the difference between V_B and V_A. In other words, since the values of C depend only upon the shapes of the velocity distribution curves, as long as the shapes of the curves become similar faster than the velocities (and this is undoubtedly a good assumption for gradually varied flow), the two equations become sensibly the same.

Whereas the momentum theorem has been seen to be applied to the case of gradually varied open-channel flow, the energy theorem is most often used because the energy loss can be evaluated by means of a known formula. Reverting to the general energy theorem—namely, that the work done on a system by external forces is equal to the change in energy of that system—the author has not very carefully derived an energy relation for flow between two sections of an open channel. Reconsidering the case, if an elemental tube of the fluid mass is allowed to move over an interval of time Δt and the work done and energy change over this interval are obtained, then division by Δt will yield the time rate of change of work and energy in the element and summation throughout the entire mass will give the total rate of change of work and energy in the mass at the position considered. The quantity $\frac{p}{\gamma} + Z$ still remains constant over each section so that, upon division by the weight discharge $\gamma\, Q$, the following equation results

$$\left(\frac{p_A}{\gamma} + Z_A\right) - \left(\frac{p_B}{\gamma} + Z_B\right) = \frac{I'}{\gamma\, Q} + \alpha'_B\,\frac{V^2{}_B}{2\,g} - \alpha'_A\,\frac{V^2{}_A}{2\,g} \ldots\ldots (26)$$

in which α' is the "mean-cube" coefficient defined by $\frac{\int u^3\, dA}{V^3\, A}$, and I' represents the rate of internal work done by friction. Although Eq. 26 concerns the energy transformation per second of a mass of fluid per pound of fluid flowing per second, it can be interpreted to state that the work done by the external forces (pressure and gravity), per pound of fluid occupying the space of one pound of discharge as it moves from section A to section B, such that each element has a common displacement irrespective of the time required for each element to travel from A to B, is equal to the change in energy of that pound between sections A and B. Thus, if the internal energy transformation in the fluid volume for the given displacement could be computed or measured, Eq. 26 could be useful, especially for large distortions of the velocity profile.

With reference to the illuminating paper by B. A. Bakhmeteff,[6] M. Am. Soc. C. E., there is attainable an energy relation involving the "mean-square" factor instead of the "mean-cube" factor. The "mean-square" equation is derived readily by considering the work done on an element of fluid as it moves between two sections; thus:

$$\frac{dp}{dL}\,\beta\,dA\,dL + \gamma\,\beta\,dA\,\frac{dZ}{dL}\,dL - dF_r\,dL = \frac{\gamma}{g}\,\beta\,dA\,\frac{d\left(\frac{u^2}{2}\right)}{dL}\,dL \dots\dots (27)$$

in which β is the length of the element, and the differential lengths are inserted to indicate the idea of work. Hence, upon division by $\gamma\,\beta\,dA$ and integrating along the path of motion, there results per pound of fluid on each streamline:

$$\left(\frac{p_A}{\gamma} + Z_A\right) - \left(\frac{p_B}{\gamma} + Z_B\right) = i + \frac{u^2{}_B}{2\,g} - \frac{u^2{}_A}{2\,g} \dots\dots\dots\dots (28)$$

in which i represents the internal work due to friction. Since the integration is between two cross sections of flow, the work and energy equation for the movement of a cross-sectional volume of length dL is given by

$$\int\left(\frac{p_A}{\gamma} + Z_A\right) dA_A\,dL\,\gamma - \int\left(\frac{p_B}{\gamma} + Z_B\right) dA_B\,dL\,\gamma$$
$$= \int i\,dA\,dL\,\gamma + \frac{\gamma}{2\,g}\int u^2{}_B\,dA_B\,dL - \frac{\gamma}{2\,g}\int u^2{}_A\,dA_A\,dL \dots\dots (29)$$

Whence,

$$\left(\frac{p_A}{\gamma} + Z_A\right) - \left(\frac{p_B}{\gamma} + Z_B\right) = \frac{I}{A\,dL\,\gamma} + \alpha_B\,\frac{V^2{}_B}{2\,g} - \alpha_A\,\frac{V^2{}_A}{2\,g} \dots\dots (30)$$

in which α is the "mean-square" coefficient defined by $\frac{\int u^2\,dA}{V^2\,A}$, and I is the internal energy change for the block. It is to be noted that the work done and the energy changed is per pound of fluid which traverses a distance such that each element of it has a common displacement and occupies the cylindrical region that one pound would occupy at any section of the channel. It thus follows that the two equations, Eqs. 26 and 30, compare the energy transformations in fluid volumes for a given displacement, one containing the "mean-cube" coefficients and the other the "mean-square" coefficients; it would seem that either equation is applicable provided the amount of internal energy transformation is known.

Reverting to the purpose of this paper, that of demonstrating the proper use of the correction coefficients for velocity distribution, there seems to be no question but that the "mean-square" factor must be used in the case of the momentum theorem application, whereas in the case of energy, either coefficient may be used depending upon which of the foregoing equations is considered. However, in gradually varied open-channel flow it is apparent that neither factor should be favored in view of the fact that the energy losses are ordinarily computed from empirical equations in which V_B is equal to V_A and in which the coefficients do not enter into the problem at all. In such a method of solution it seems advisable to ignore the correction coefficient entirely; certainly this appears justified since α and α' are close to unity in ordinary cases and experimental evidence[12] is available.

In closing, the writer wishes to emphasize the necessity for mathematical precision in coping with problems of the type investigated in this paper. It is hoped that none of these remarks are taken as discouraging in any manner.

HUNTER ROUSE,[13] M. AM. SOC. C. E., AND JOHN S. MCNOWN,[14] JUN. AM. SOC. C. E.—Attention is again focused by this paper upon the century-old controversy concerning the correct interpretation of the energy and momentum principles in hydraulics. Some aspects of the problem apparently have never yet been presented with adequate substantiation, as witnessed by the disagreement in even the most recent literature on this subject. Perhaps the thought and discussion provoked by the author's analysis will serve to settle at least the principal points of argument which remain. The author's oversimplified approach, unfortunately, has resulted in several conclusions which seem to have fundamental significance but which are in no way justified by a more careful analysis. The writers therefore submit herewith a criticism of the author's presentation together with an original analysis which they believe will clarify the general problem in a simple yet rigorous manner.

The type of motion considered by the author is gradually varied steady flow with a velocity distribution which changes from section to section. The only sound approach to even this particular phase of the general problem is the application of the basic equation of mechanics,

$$F = m \frac{dv}{dt} \dots\dots\dots\dots\dots\dots\dots\dots (31)$$

to a differential volume of fluid, and the subsequent integration of this expression throughout a finite volume according to established principles of the calculus. The author, however, has sought to proceed from particular first integrals of this basic equation—assertedly the fundamental equations of energy and momentum—without fully acknowledging the restrictions which these integrals imposed upon the subsequent analysis. He has, in fact, tacitly attributed to the integrals certain pseudo-differential properties, thereby eliminating from his derivation the very characteristics which distinguish the momentum and energy principles. A typical instance is found under the heading, "Development of the Momentum Equation," which in itself would serve to invalidate the final conclusions of the paper. If the change in velocity along a stream filament is appreciable, it follows that the accompanying change in cross-sectional area must also be appreciable. The fallacy in the author's proof to the contrary lies in treating as a differential expression what is actually the integral of a differential expression over a finite length of stream tube; under such circumstances it is obviously no longer permissible to ignore small quantities as though they were still infinitesimals of higher order than the other terms.

---

[12] Discussion by J. C. Stevens of "Back-Water and Drop-Down Curves for Uniform Channels," by Nagaho Mononobe, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 990.

[13] Director, Iowa Inst. of Hydr. Research, State Univ. of Iowa, Iowa City, Iowa.

[14] Research Engr., Iowa Inst. of Hydr. Research, State Univ. of Iowa, Iowa City, Iowa.

The general energy equation of hydraulics is fundamentally a scalar relationship, in which the boundary forces exerted upon the fluid between two cross sections do not appear because they do no work; it must include, however, a term embodying the dissipation of energy due to fluid deformation. The general momentum equation, on the contrary, is a vector relationship; therefore, all external forces become significant, whereas the internal stresses which produce the energy dissipation yield a force resultant of zero. Although the basic equation of motion may be written as a differential equation of acceleration, impulse-momentum, or work-energy through proper organization of terms, the essential differences between the integral equations of momentum and energy make it impossible to convert either one into the other by a comparable reorganization of terms—unless the type of flow under consideration is so simplified that the distinguishing characteristics of the integral equations disappear. The latter is the case only if the flow is very nearly uniform and the velocity is essentially constant over every section; under these circumstances, the familiar equation of gradually varied flow may be derived upon either a momentum or an energy basis. Once the acceleration becomes appreciable, or the velocity distribution variable, the two methods of approach necessarily lead to quite different mathematical expressions which cannot be interchanged.

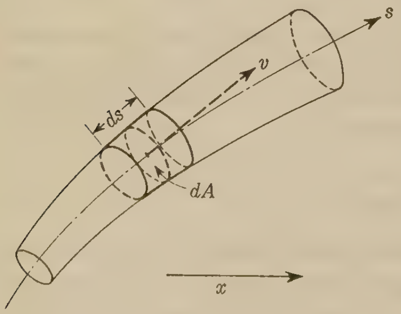

Fig. 4

As has already been pointed out, the basic equations which are sought can be obtained only from consideration of the dynamics of an infinitesimal fluid volume. For simplicity in analysis, the volume selected (see Fig. 4) is bounded by the streamlines forming the wall of a stream tube and by two normal sections a distance ds apart. The external forces acting upon this elementary free body are the attraction of the earth and the pressure and shear exerted by the surrounding fluid, which may be resolved in any direction x and equated to the product of the mass of the element and the corresponding component of its acceleration:

$$\Sigma (dF)_x = dm\, a_x \ldots\ldots\ldots\ldots (32a)$$

The acceleration may be transformed as follows: $a_x = \frac{dv_x}{dt} = \frac{\partial v_x}{\partial s}\frac{ds}{dt} = v\,\frac{\partial v_x}{\partial s}$. Furthermore, dm may be written as $\rho\, ds\, dA$, so that

$$\Sigma (dF)_x = \rho\, v\, \frac{\partial v_x}{\partial s}\, ds\, dA \ldots\ldots\ldots\ldots (32b)$$

Eq. 32*b* expresses, in effect, the equality between the impulse per unit time and the accompanying rate at which the momentum of the fluid element is changed. It should therefore replace Eq. 2, which is neither a basic differential equation nor a correct integral thereof.

A very essential point—possibly the crux of the controversy—must now be noted. Before evaluating any double integral, the two principal variables must first be made independent. Since the quantity dA varies with s, the foregoing equation cannot be integrated correctly along the axis of the stream tube unless means are taken to express dA in terms of a variable which is independent of s. Fortunately, such means are immediately at hand in the fact that $v\, dA = dQ$, the elementary rate of flow through the stream tube, which is necessarily the same at all cross sections; thus,

$$\Sigma (dF)_x = \rho\, \frac{\partial v_x}{\partial s}\, ds\, dQ \ldots\ldots\ldots\ldots (32c)$$

Integration in the s-direction then yields the momentum equation for a finite length of stream tube:

$$\int_{s1}^{s2} \Sigma (dF)_x = \rho\, (v_{x2} - v_{x1})\, dQ \ldots\ldots\ldots\ldots (32d)$$

Since the pressure forces between successive elements are equal and opposite, in the process of summation they cancel, leaving in the term at the left only the external forces of pressure, shear, and gravitational attraction acting upon the filament of fluid. Were it possible to express these forces simply, the foregoing first integral written for flow in the x-direction would yield the correct form of Eq. 5; notably absent is the factor 2 which appears in the denominators of the velocity terms of the author's expression due to his assumption of Eq. 2 as the basic differential equation.

The general equation of momentum for accelerated steady flow is obtained by completing the foregoing integral throughout the volume:

$$\int_{\text{vol}} \Sigma (dF)_x = \int_{Q} \rho\, (v_{x2} - v_{x1})\, dQ = \int_{A2} \rho\, v_{x2}\, v_2\, dA - \int_{A1} \rho\, v_{x1}\, v_1\, dA \ldots (32e)$$

Since internal shears as well as pressures cancel in the process of summation, the left side now represents the x-component of the resultant of all external forces (that is, the end pressures, the boundary pressures, the boundary shear, and the fluid weight), which can be evaluated only through measurement or arbitrary assumption as to type of variation. The right side, which represents the difference in flux of the x-component of momentum past the two end sections, requires equally explicit knowledge as to the corresponding velocity distributions. As a matter of fact, only in case the flow at the two end sections is in essentially the same direction can the equation readily be applied to conditions in which the velocity varies across the flow, under which circumstances it reduces to the alternative forms,

$$\Sigma F = \rho\, Q\, (C_{m2}\, V_2 - C_{m1}\, V_1) = C_{m2}\, \rho\, (V_2)^2 A_2 - C_{m1}\, \rho\, (V_1)^2 A_1 \,.\,.\,(33)$$

in which, as the author has stated,

$$C_m = \frac{1}{A} \int_A \left(\frac{v}{V}\right)^2 dA \ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

It will be seen that Eq. 33 differs considerably from Eq. 8, for the several reasons already discussed.

In an essentially parallel manner, the general energy equation may be derived by equating to the rate of change of energy the rate at which work is done upon the elementary free body of Fig. 4 by the same external forces just considered. It is now necessary, however, to write the component of these forces in the direction of displacement s. Furthermore, it must be noted that the energy of the particle will change as the result of both acceleration and dissipation; the former, of course, is directly expressible in terms of the increase in kinetic energy, but a simple expression for the latter can be written only in terms of the decrease in the total head $H = \frac{v^2}{2\,g} + \frac{p}{\gamma} + Z$ of the element. Thus,

$$\Sigma(dF)_s\, v = \rho\, ds\, dA\, \frac{d\left(\frac{v^2}{2}\right)}{dt} - \gamma\, ds\, dA\, \frac{dH}{dt} \ldots\ldots\ldots\ldots (35a)$$

which is the differential equation of energy suggested to replace Eq. 3. Rearranging the terms on the right side,

$$\Sigma(dF)_s\, v = \rho\, ds\, dA\, \frac{\partial\left(\frac{v^2}{2}\right)}{\partial s}\, \frac{ds}{dt} - \gamma\, ds\, dA\, \frac{\partial H}{\partial s}\, \frac{ds}{dt}$$

$$= \rho\, \frac{\partial\left(\frac{v^2}{2}\right)}{\partial s}\, ds\, dQ - \gamma\, \frac{\partial H}{\partial s}\, ds\, dQ \ldots\ldots\ldots\ldots\ldots (35b)$$

Since dQ, unlike dA, is a constant along the stream tube, Eq. 35b may be integrated at once with respect to s:

$$\int_{s1}^{s2} \Sigma(dF)_s\, v = \frac{\rho}{2}\, [(v_2)^2 - (v_1)^2]\, dQ - \gamma\, (H_2 - H_1)\, dQ \ldots\ldots (35c)$$

Were it practicable to express each individual member of the summation at the left, division by γ and substitution of $v\,dA$ for dQ would yield the correct form of Eq. 14. As in the case of the momentum derivation, however, it should be noted that internal pressures along the stream tube have equal and opposite reactions at points of the same velocity, and hence the net work done by pressures upon the fluid filament will consist only of that at the two end sections. The work done by shear along the filament cannot be evaluated easily, of course; but, in the process of summation over the entire volume, the net internal work done by both pressure and shear is evidently equal to zero. Moreover, since the boundary velocity is zero at all points, the work done by boundary shear must also be zero, leaving at the left of the final equation only the terms for pressure and elevation at the two end sections. The general volume integral, written in terms of the several heads, thus takes the rather obvious form,

$$\int_{A1}\left(\frac{p_1}{\gamma}+Z_1\right)v_1\,dA-\int_{A2}\left(\frac{p_2}{\gamma}+Z_2\right)v_2\,dA$$

$$=\int_{A2}\left[\frac{(v_2)^2}{2\,g}-H_2\right]v_2\,dA-\int_{A1}\left[\frac{(v_1)^2}{2\,g}-H_1\right]v_1\,dA\ldots\ldots\ldots(36)$$

Like the general momentum equation, the foregoing general energy equation may be applied to a given state of flow only if the distribution of velocity and pressure (and hence of total head) is known at both end sections. Unlike the momentum equation, on the other hand, the energy equation involves only the magnitudes of the velocities; however, the velocity distribution here affects both sides of the equation, with the result that the energy principle may usually be applied only if both sections under consideration are located in essentially uniform zones; the pressure distribution is then known (that is, hydrostatic), and the energy equation reduces to the more familiar form of the Bernoulli theorem,

$$C_{e1}\frac{(V_1)^2}{2\,g}+\frac{p_1}{\gamma}+Z_1=C_{e2}\frac{(V_2)^2}{2\,g}+\frac{p_2}{\gamma}+Z_2+H_l\ldots\ldots\ldots(37)$$

in which

$$C_e=\frac{1}{A}\int_{A}\left(\frac{v}{V}\right)^3dA\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(38)$$

and

$$H_l=\frac{1}{A_1}\int_{A1}H_1\frac{v_1}{V_1}\,dA-\frac{1}{A_2}\int_{A2}H_2\frac{v_2}{V_2}dA\ldots\ldots\ldots\ldots\ldots(39)$$

Since Eq. 37 lacks certain unnecessary factors of Eq. 16, yet further clarifies the term for energy dissipation, it is considered preferable by the writers.

From a comparison of the general momentum and energy relationships it will be evident that, although both may describe correctly the same state of flow, the mathematical terminology of the description must be quite different in the two cases. In other words, the inherent distinction between energy as a scalar and momentum as a vector quantity, as well as the presence of a term for lost head in the one equation and terms for boundary pressure and shear in the other, makes it completely impossible to interchange the two equations by any conceivable transformation process. Therefore, despite the author's statements to the contrary, the Bernoulli theorem can in no way be regarded as a form of the momentum equation. As a matter of fact, it is this very difference between these two integral forms of the basic equation of motion which makes them so effective when used in combination. Hence, it is scarcely logical to attempt to show their similarity, but rather to emphasize the distinctions which make them such powerful complementary tools.

In the basic application of these equations to rapidly accelerated flow, pressure changes are generally so great that boundary-shear, lost-head, and velocity-distribution terms may be neglected without appreciable error; the equations of momentum, energy, and continuity then permit direct solution for both the pressure change and the resultant boundary force accompanying any rate of flow. They have also proved to be a useful combination in another extreme type of motion—the gradual establishment of uniform flow beyond the entrance of a pipe or conduit, in which acceleration and boundary pressure become the terms which are ignored. If these various effects are of comparable magnitude, of course, then none can be neglected safely. Typical of such conditions is the problem of rapidly decelerated flow, which still awaits a satisfactory solution by any but empirical methods. In a word, it is still impossible to obtain a quantitative analysis of the general problem of fluid motion without recourse to measurement, because other means are not yet at hand for obtaining the distribution curves for velocity and pressure which are required in the general momentum and energy equations.

Although the type of motion considered by the author is far simpler than the general case, in that acceleration is negligible and the pressure distribution is therefore hydrostatic, the distribution of velocity still remains unknown. Without actual field measurement, in other words, the coefficients C_m and C_e can be estimated only roughly, for scarcely enough is known about boundary resistance and energy dissipation in nonuniform flow to permit even an approximate evaluation by analytical means. To be sure, such estimates will yield average values which are perhaps closer to the truth than the magnitude of unity customarily assumed, but this still provides no trustworthy clue as to the change in either coefficient from section to section. Fortunately, however, the error involved in assuming these coefficients to equal unity is probably no greater than that arising from the present lack of knowledge regarding boundary shear and energy dissipation under nonuniform conditions. Indeed, the common failure to distinguish between the evaluation of boundary shear and energy dissipation in gradually varied flow is actually tantamount to assuming that $C_m = 1 = C_e$, for under such circumstances (but only then) the energy and momentum equations become identical.

Much is made by the author of the asserted fact that the familiar resistance equations stem from momentum (boundary-shear) rather than energy (dissipation) considerations. Actually, the equations in question have been derived solely for the case of uniform flow; under these conditions, of course, boundary shear and energy dissipation are directly proportional, which robs the author's point of all significance. The customary loss coefficients of nonuniform flow, on the other hand, are simply means of evaluating the quantity H_l of Eqs. 37 and 39 in terms of the boundary geometry and the Reynolds number, and hence have no source whatever in the momentum principle. Which type of coefficient to apply in the analysis of gradually varied flow must depend upon whether the momentum or the energy principle is utilized when the true functional relationships for the coefficients are eventually determined. Either principle, of course, would be satisfactory for this purpose; however it is to be noted that the momentum principle is not necessarily the simpler of the two, because of the difficulty in evaluating the longitudinal component of the boundary pressure.

From the foregoing discussion it would appear that such further refinements in applying the momentum and energy equations to even the relatively simple case of gradually varied flow must await considerable progress in analyzing the phenomena of velocity distribution and either boundary shear or energy dissipation. Fortunately, the solution of any one of these three phases of the resistance problem will almost automatically clarify the other two, for all three are closely interrelated—not only through the mechanics of fluid turbulence, but through the correct integral forms of the momentum and energy relationships.

William S. Eisenlohr, Jr.,[15] Assoc. M. Am. Soc. C. E.—The thesis of this paper, as given in the "Synopsis" and "Introduction," is that there are problems in nonuniform flow in which an appreciable part of the total change in momentum and kinetic energy between two cross sections may be due to a change in the velocity distribution as distinguished from a change in the mean velocity. The Chézy and Manning equations are momentum equations. Thus, the coefficient of velocity distribution should be the ratio of the mean of the squares of the local velocities to the square of the mean velocity. That the several discussions of the paper, although critical, have not successfully disproved this thesis will be shown. To do so, however, it will be necessary to present revised demonstrations. At the same time, an effort will be made to clarify some of the original statements.

First, it is necessary to include the concept embodied in Eq. 27 given by Professor Van Driest and derived from the paper by B. A. Bakhmeteff, M. Am. Soc. C. E. Somehow or other, in preparing the paper, the writer lost sight of the concept that there is an energy equation involving the square relation as well as one involving the cube relation of the velocity. Since the difference between momentum and energy no longer is sufficient to account for the use of different coefficients, it becomes appropriate to redesignate the coefficients as follows: C_s (formerly C_m) $= \frac{\overline{u^2}}{V^2}$ = coefficient of velocity distribution based on the second power of the velocity for use in space equations; and C_t (formerly C_e) $= \frac{\overline{u^3}}{V^3}$ = coefficient of velocity distribution based on the third power of the velocity for use in time equations. (The writer prefers the use of the letter C with subscripts, to that of the Greek letter α, since the latter cannot be made on an ordinary typewriter and is difficult to make attractively by hand.)

---

[15] Associate Hydr. Engr., Water Resources Branch, U. S. Geological Survey, Washington, D. C.

The writer stated that the condition of steady, gradually varied flow would be assumed. Perhaps this point should have been given more emphasis. By steady flow is meant that there is no variation in the conditions of flow with respect to time. Gradually varied flow is a condition of flow in which the convergence, divergence, or curvature of the stream tubes occurs so gradually that consideration of the stream tubes as parallel will introduce no appreciable error. In other words, the assumption is made that the vector velocity v can be replaced by u without appreciable error. (A similar assumption is always made in computing the slope S, the quantity $\tan \theta$ being used for $\sin \theta$.) Having made this assumption, the careful distinction between the two made by Messrs. Rouse and McNown is without significance and somewhat confusing. This assumption also gives the element of direction which Professor Taylor finds lacking in Eq. 2.

With the foregoing assumptions always in mind, the equations for gradually varied flow in open channels will be developed. The basic equation is the momentum equation expressing Newton's second law of motion—the rate of change of momentum is proportional to the impressed force, and takes place in the direction of the straight line in which the force acts. Therefore:

$$dF_R = dm \frac{d\mathrm{v}}{dt} \qquad \text{(40)}$$

in which F_R is the resultant force and v is the vector velocity. By the assumption of gradually varied flow, the velocity component parallel to the x-axis, u, can be substituted for v without appreciable error. Thus, the resultant force must be parallel to the x-axis and must be equal to the sum of the components in the x-direction of all forces acting, ΣdF_x. Then, $\Sigma dF_x = dm \frac{du}{dt}$ will describe the change in momentum completely. Substituting $\frac{du}{dt} = \frac{du}{dL}\frac{dL}{dt} = u \frac{du}{dL} = \frac{1}{2}\frac{du^2}{dL}$, the momentum equation is

$$\Sigma dF_x = dm \left(\frac{1}{2}\frac{du^2}{dL}\right) \qquad \text{(41a)}$$

Eq. 41a is a momentum equation but the rate of change of momentum is expressed in terms of distance L rather than in terms of time t. As stated by Messrs. Rouse and McNown, u is a function of L, and Eq. 41a cannot be integrated rigorously without taking that relation into consideration. However, it will be shown subsequently that, if the acceleration is assumed constant (or the equivalent of using the average force $\frac{1}{L}\int_0^L \Sigma dF_x\, dL$ as stated by Professor Taylor), reasonably close results for gradually varied flow will be obtained. Eq. 41a is readily transformed into the energy equation—

$$\Sigma dF_x\, dL = \tfrac{1}{2}\, dm\, du^2 \qquad \text{(41b)}$$

—the energy equation in which the work done by the force dF_x equals the change in kinetic energy of the mass dm.

Whether Eq. 41*a* is transformed into Eq. 41*b* by transposing dL or by multiplying both sides by dL, the result is the same—a vector force is multiplied by the distance through which it acts to give the scalar quantity of work. Likewise, the right side of Eq. 41*a* has the dimensions of the rate of change of momentum, $\frac{M\,L^2}{T^2\,L} = \frac{M\,L}{T^2}$, which is a vector quantity. Whether the quantity is multiplied by L, or the divisor L is removed, the result is $\frac{M\,L^2}{T^2}$, the dimension of energy, which is a scalar quantity. There is nothing novel in such a procedure. In fact, it is the standard derivation of the work-energy equation. This transformation is not rigorous except in the differential form.

If both sides of Eq. 41*b* are divided by dt: $\Sigma dF_x \frac{dL}{dt} = \frac{1}{2}\,dm\,\frac{du^2}{dt}$ or $\Sigma dF_x\, u = \frac{1}{2}\,dm\,[du^2]_{t=1}$, the latter being the differential form of Eq. 3*b*. Without imposing the restriction of $t = 1$, and making the substitution $\frac{du}{dt} = u\,\frac{du}{dL}$, the power equation is obtained:

$$\Sigma dF_x\, u = dm\left(\frac{1}{3}\frac{du^3}{dL}\right) \dots\dots\dots\dots\dots\dots \text{(41}c\text{)}$$

Eq. 41*c* is frequently called an energy equation (as was Eq. 3*b* in the paper); but, since it actually represents changes in work and energy per unit time, it will be designated the power equation—especially to distinguish it from Eq. 41*b*.

From the three basic equations of momentum, energy, and power, the three equations of nonuniform flow in an open channel will be derived. Considering Eqs. 41*a*, 41*b*, and 41*c*, the coefficient of velocity distribution seems to be based on the square relation in the momentum and energy equations and on the cube relation in the power equation. This theory will be shown to be correct.

The simplest way to obtain the equations for the entire channel would be to let $dm = \rho\, dA\, dL$ and then to perform the double integration with respect to A and L. To avoid calculus, where possible, and at the same time to give emphasis to the physical significance of the equations, the mass will be taken as the entire mass of the stream tube $\rho\, L\, \overline{dA}$, in which L is the length and $\overline{dA}$ is the average value of the cross section. Thus, $L\, \overline{dA}$ equals the volume of the stream tube. Such a stream tube is shown in Fig. 5, the boundaries of which are fixed in space. In the paper it was found that selecting a volume of water and following the change in energy in that volume with respect to time did not yield practical results; therefore, such a method will not be given further consideration.

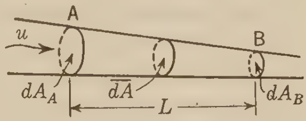

FIG. 5.—STREAM TUBE (VOLUME = $L\,\overline{dA}$)

Although the stream tube is fixed in space, the water particles at any point within the tube will change from instant to instant. In steady flow, each particle arriving at a given point will have exactly the same momentum or energy possessed by the particle which just left that point. As a result, the total momentum or energy contained within the stream tube will be the same at every instant of time. During any interval of time a volume of water dB will flow out of the stream tube, and by the continuity of flow an equal volume dB will flow into the stream tube. Thus, the total change in momentum or energy of the water flowing through the stream tube during a given interval will be represented by the difference between the momentum or energy of a volume dB leaving the tube and the momentum or energy of a similar volume entering the tube. The three equations of flow can be developed as follows.

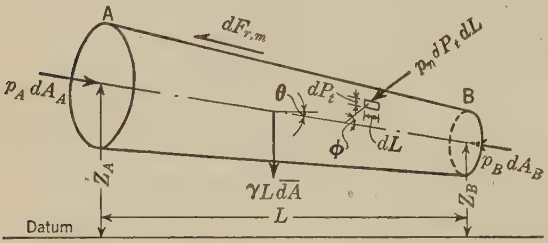

Fig. 6.—Forces Acting on Stream Tube

Revised Development of the Momentum Equation.—In this revised demonstration the effect of the variation of dA with L will be fully considered. The rate of change of momentum is equal to the resultant of all the external forces that are acting. For the stream tube in Fig. 6, the pressure forces are, as before:

$$\int_A^B dF_p = p_A\, dA_A - p_B\, dA_B - \bar{p}_n\, (dA_A - dA_B) \ldots\ldots\ldots (42a)$$

in which the first two terms on the right side represent the pressure forces on the end areas and the third term represents the component in the direction of motion of the normal pressure p_n on the sloping sides of the tube. Since this force is important and usually neglected, it will be considered in detail.

The pressure on any element of area along the side of the stream tube is $p_n\, dP_t\, dL$ in which P_t is the perimeter of the stream tube. For uniform flow, p_n is normal to the direction of flow and the term disappears. In gradually varied flow, p_n is still the normal pressure on the side of the stream tube; but, by reason of the change in area, the side must make a slight angle and p_n an angle ϕ with the direction of flow. The pressure force on the side of the stream tube now has a component in the direction of flow equal to $p_n\, dP_t\, dL \cos \phi$. The total force is then $\int\int p_n\, dP_t\, dL \cos \phi$; but $\int\int dP_t\, dL \cos \phi$ equals the difference in end areas of the stream tube. The value of $\bar{p}_n$ is defined by the relation: $\bar{p}_n\, (dA_A - dA_B) = \int\int p_n\, dP_t\, dL \cos \phi$.

As it is impracticable to attempt to evaluate $\bar{p}_n$, Eq. 42*a* will be written in a more usable form by expressing the forces in terms of the average area $\overline{dA}$. The quantity $\overline{dA}$ has such a value that the total volume of the stream tube between sections A and B is $L\, \overline{dA}$. Let k_1 be a certain portion of the difference in end areas, having a value such that $dA_A = \overline{dA} + k_1(dA_A - dA_B)$ and $dA_B = \overline{dA} - (1 - k_1)(dA_A - dA_B)$. Likewise, let $\bar{p}_n = p_A - k_2(p_A - p_B)$. Substituting these values in Eq. 42*a* gives, for the pressure forces:

$$\int_A^B dF_p = (p_A - p_B)\,\overline{dA} + (k_1 + k_2 - 1)(p_A - p_B)(dA_A - dA_B) \quad \text{..(42}b\text{)}$$

The gravity force $\int_A^B dF_g$ is $\gamma\, L\, \overline{dA} \sin\theta$, and the resisting force is $dF_{r,m}$. The change in momentum during any interval, as explained previously, can be represented by the difference between the momentum of the volume of water dB as it leaves the stream tube at section B and the momentum of an equal volume of water dB as it enters the stream tube at section A. This change can be expressed as $\rho\, dB\, u_B - \rho\, dB\, u_A$. Since the resultant force is equal to the rate of change of momentum, the volume dB in this case must be the volume change per unit time, dQ. Therefore,

$$\int_A^B \Sigma dF_x = \rho\, dQ\,(u_B - u_A) = \rho\, u_B^2\, dA_B - \rho\, u_A^2\, dA_A \quad \text{.....(42}c\text{)}$$

Eq. 42*c* is identical with the expression derived by Messrs. Rouse and McNown through their integration process. In Eq. 42*c*, there was no need for integration because the total change in momentum for the entire length of stream tube L was used. Since the pressure forces are not amenable to practical application when expressed in terms of dA_A and dA_B, Eq. 42*c* will be written in terms of the average area $\overline{dA}$. Let $dQ = u'\,\overline{dA}$ and $u' = u_A + k_3(u_B - u_A)$ (in which k_3 is some portion of the difference in velocity between the ends of the stream tube) and substitute in Eq. 42*c*:

$$\int_A^B \Sigma dF_x = \rho\,\overline{dA}\,[k_3\, u_B^2 - (1 - k_3)\, u_A^2 + (1 - 2\,k_3)\, u_A\, u_B] \quad \text{...(42}d\text{)}$$

Combining the various parts, the general momentum equation is obtained for gradually varied flow in a stream tube between sections A and B in terms of the average area of the tube $\overline{dA}$:

$$(p_A - p_B)\,\overline{dA} + (k_1 + k_2 - 1)(p_A - p_B)(dA_A - dA_B) + \gamma\, L\,\overline{dA}\sin\theta$$
$$- dF_{r,m} = \rho\,\overline{dA}\,[k_3\, u_B^2 - (1 - k_3)\, u_A^2 + (1 - 2\,k_3)\, u_A\, u_B] \quad \text{...(42}e\text{)}$$

Eq. 42*e* is complicated by the proportionality factors k_1, k_2, and k_3. These factors represent the portion of the difference between the values at sections A and B by which the average value of the area, pressure, and velocity is greater or less than the value at section A. It seems reasonable to suppose that for gradually varied flow the values of k_1, k_2, and k_3 will be so close to 0.5 that they can be assumed to have that value. Making this assumption, Eq. 42*e* becomes, after substituting $\sin\theta = \frac{Z_A - Z_B}{L}$ (actually $\tan\theta$) and rearranging:

$$dF_{r,m} = \gamma \left[\left(\frac{p_A}{\gamma} + Z_A \right) \overline{dA} - \left(\frac{p_B}{\gamma} + Z_B \right) \overline{dA} + \frac{u^2{}_A}{2\,g} \overline{dA} - \frac{u^2{}_B}{2\,g} \overline{dA} \right] \ldots (43)$$

which is identical with Eq. 6 except that the area of the stream tube is definitely labeled the average area. The only assumption is that the average area, pressure, and velocity are the averages of the values at the end sections. The term $\left(\frac{u^2{}_A}{2\,g} - \frac{u^2{}_B}{2\,g} \right) \overline{dA}$ is the practical equivalent of $\frac{u^2{}_A}{g}\,dA_A - \frac{u^2{}_B}{g}\,dA_B$. The same answer would be obtained if d'Alembert's principle of reversed effective force were used, and the momentum changes were represented by pressure forces equal to the velocity heads. These pressures on the end areas, of course, are $\left(\frac{u^2{}_A}{2\,g} \right) dA_A$ and $\left(\frac{u^2{}_B}{2\,g} \right) dA_B$; but the average pressure on the difference in end area must also be considered and, when it is included, the result is the same as Eq. 43.

The integration of Eq. 43 with respect to A yields Eq. 7 as before, and Eqs. 9 to 12 remain unchanged. The symbol $F_{r,m}$ denotes the total boundary shear and is usually assumed to be the product of the average unit shear and the area of the boundary. Professor Kalinske has stated that such an assumption limits the length of channel over which the expression is valid. On the other hand, the length of channel must be long enough that the effect of boundary shear can be measured with reasonable accuracy. Although these conditions limit the application of Eq. 9*a*, the principle involved is the momentum theory of external forces that are acting, and the substitutions made in arriving at the Chézy and Manning equations are empirical expressions for boundary shear. As Professor Rouse has stated[16] for the Manning equation, "The factor *n* is evidently a measure of boundary roughness, since it is invariably tabulated solely as a function of boundary composition." Furthermore, Robert Manning's studies leading to the development of the "Manning" equation included results of experiments on the Hayne (Belgium), Parana (South America), and Mississippi rivers; and modern tables of values of *n* almost always include values for natural streams. The statement by Messrs. Rouse and McNown that "Actually, the [familiar resistance] equations in question have been derived solely for the case of uniform flow * * *" thus appears to be unduly restrictive.

Revised Development of the Energy Equation (*See Heading, "Development of the Power Equation" for Revised Development of the "Energy Equation" of the Paper*).—The change in kinetic energy represented by the difference between the energy of volume *dB*, as it leaves the tube at section B, and the energy of an equal volume *dB*, as it enters the stream tube at section A, is the result of the work done by all forces acting on the tube during the same interval of time. Since work is a scalar quantity, the total work done is the algebraic sum of the product of force times distance moved in the direction of the force. The work done by the pressure forces is the sum of the pressure force on each bounding surface of the tube times the distance of movement across that surface in the interval of time considered. Since there is no movement across the sides of the tube, the only work done by the pressure forces is on the ends of the tube. To visualize this work, assume the stream tube to be separated in space, as in Fig. 7. The water will approach the tube as a filament of uniform cross section, dA_A, and will leave with a uniform cross section, dA_B. If the volume passing through the tube in a given time interval is defined as $dB = s_A\,dA_A = s_B\,dA_B$ (in which s is a small distance in the direction of flow, the dL of Eq. 41b), the total work done by the pressure forces is $p_A\,dA_A\,s_A - p_B\,dA_B\,s_B$.

[16] "Evaluation of Boundary Roughness," by Hunter Rouse, *Proceedings*, 2d Hydr. Conference, June 1–4, 1942, State Univ. of Iowa, Iowa City, *Bulletin No. 27*, Studies in Eng., 1943, p. 108.

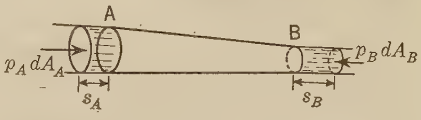

FIG. 7.—STREAM TUBE AS A FREE BODY SHOWING WORK DONE BY PRESSURE FORCES ($s_A\,dA_A = s_B\,dA_B$)

The total work done by the gravity force is equivalent to the weight of volume dB times the distance volume dB moves in the direction of the gravity force while being moved from section A to section B. This distance is the difference in elevation, $Z_A - Z_B$. The work done by gravity is therefore $\gamma\,dB\,(Z_A - Z_B)$. The change in kinetic energy, of course, is $\rho\,dB\,\frac{u^2{}_B}{2} - \rho\,dB\,\frac{u^2{}_A}{2}$.

During the interval required for volume dB to enter or leave the stream tube, work is done by the water in the tube against the shearing force at the sides. There is also a dissipation of energy as heat from the turbulence set up by the resistance of the sides of the tube. The net result of these effects is a loss of energy within the tube that, for convenience, will be expressed as a loss of potential energy $\gamma\,dB\,h_L$, in which h_L is the energy lost per unit weight of water passing through the stream tube, usually referred to as the loss of head. The work-energy equation is, then:

$$p_A\,dA_A\,s_A - p_B\,dA_B\,s_B + \gamma\,dB\,(Z_A - Z_B) - \gamma\,dB\,h_L = \rho\,dB\,\frac{u^2{}_B}{2} - \rho\,dB\,\frac{u^2{}_A}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (44a)$$

Rearranging, and substituting $dB = s_A\,dA_A = s_B\,dA_B$, gives

$$(p_A + \gamma\,Z_A)\,s_A\,dA_A - (p_B + \gamma\,Z_B)\,s_B\,dA_B = \rho\,\frac{s_B}{2}\,u^2{}_B\,dA_B - \rho\,\frac{s_A}{2}\,u^2{}_A\,dA_A + \gamma\,h_L\,dB \quad \ldots\ldots\ldots\ldots (44b)$$

It must be remembered that in Eqs. 44 the change in energy of the volume dB during the displacement from A to B was used as the equivalent of the change in energy of the stream tube during the displacement s. In integrating over the cross section, therefore, the volume B obtained is that resulting from the displacement s of the mass of the entire stream between A and B (see Eq. 41b and subsequent discussion). Hence s_A and s_B are both constant.

Proceeding with the integration, making use of the coefficient C_s previously defined, and letting $h_s = \frac{1}{B}\int_A h_L\, dB$ (in which h_s is the average for the entire stream of the energy lost per unit weight because the stream passed over the length of channel L), the following expression results, after dividing by the weight of the volume B:

$$\frac{p_A}{\gamma} + Z_A + C_{s,A}\frac{V^2{}_A}{2\,g} = \frac{p_B}{\gamma} + Z_B + C_{s,B}\frac{V^2{}_B}{2\,g} + h_s \ldots\ldots\ldots (44c)$$

Development of the Power Equation.—Power is the time rate of doing work. To obtain the power equation it is only necessary to divide the work-energy formula, Eq. 44*b*, by the time interval Δt during which the volume dB entered or left the stream tube. Since s is a small distance, $\frac{s}{\Delta t} = u$. Performing the division:

$$(p_A + \gamma\, Z_A)\, u_A\, dA_A - (p_B + \gamma\, Z_B)\, u_B\, dA_B$$
$$= \frac{\rho}{2} u^3{}_B\, dA_B - \frac{\rho}{2} u^3{}_A\, dA_A + \gamma\, h_L\, u\, dA \ldots\ldots\ldots\ldots (45a)$$

Integrating Eq. 45*a* with respect to A by making use of the coefficient C_t previously defined, letting $h_t = \frac{1}{V\,A}\int h_L\, u\, dA$ (in which h_t is the average for the entire stream of the energy lost per unit weight per unit time because the stream passed over the length of channel L), and then dividing by the weight per unit time, $\gamma\, Q$:

$$\frac{p_A}{\gamma} + Z_A + C_{t,A}\frac{V^2{}_A}{2\,g} = \frac{p_B}{\gamma} + Z_B + C_{t,B}\frac{V^2{}_B}{2\,g} + h_t \ldots\ldots\ldots (45b)$$

Comparison of Equations.—Three equations have been developed for gradually varied flow in open channels as follows:

Momentum—

$$\left[\frac{p}{\gamma} + Z + C_s\frac{V^2}{2\,g}\right]_A \approx \left[\frac{p}{\gamma} + Z + C_s\frac{V^2}{2\,g}\right]_B + \frac{\bar{\tau}_0\,\bar{P}\,L}{\gamma\,\bar{A}} \ldots\ldots (46a)$$

energy—

$$\left[\frac{p}{\gamma} + Z + C_s\frac{V^2}{2\,g}\right]_A = \left[\frac{p}{\gamma} + Z + C_s\frac{V^2}{2\,g}\right]_B + h_s \ldots\ldots\ldots (46b)$$

and power—

$$\left[\frac{p}{\gamma} + Z + C_t\frac{V^2}{2\,g}\right]_A = \left[\frac{p}{\gamma} + Z + C_t\frac{V^2}{2\,g}\right]_B + h_t \ldots\ldots\ldots (46c)$$

The approximation symbol is used with the momentum formula (Eq. 46*a*) to emphasize the fact that the equality exists only under certain specified conditions and to aid in the comparison with the energy formula, Eq. 46*b*. In the following discussion it will be assumed that the conditions of gradually varied flow are such that the approximation becomes an equality.

Eq. 46*a* indicates that the momentum equation can be put in the form of the Bernoulli equation only by making restrictive assumptions. Therefore, the statement made in the "Summary" of the paper that "* * * the Bernoulli equation is also a momentum equation * * *" appears to be erroneous if the Bernoulli equation of ordinary hydraulics is considered, despite the fact that at least seven modern textbooks on hydraulics and fluid mechanics give the derivation based on the rate of change of momentum as one proof of the Bernoulli equation. Examination of these textbooks discloses that in only one is any consideration given to a variation in cross-sectional area and that one[17] disposes of the variation in a manner somewhat similar to the writer's original development. In uniform flow there is no variation in area and consequently no change in velocity; thus, the velocity terms cancel out of the equation. Obviously, the Bernoulli equation without the velocity terms is not the Bernoulli equation. Furthermore, in applying the momentum theorem to local phenomena (the hydraulic jump, for example), approximations cannot be made that are valid for gradually varied flow, and the similarity to the Bernoulli equation becomes more remote. Therefore, it is not proper to derive the Bernoulli equation of ordinary hydraulics from the momentum theorem.

The similarity of equations derived by the momentum and energy principles has been emphasized to show how readily the two can be confused. Thus, by rearranging Eqs. 46*a* and 46*b*, the following expressions are obtained:

$$\frac{\bar{\tau}_0 \bar{P} L}{\gamma \bar{A}} \approx \left[\frac{p}{\gamma} + Z + C_s \frac{V^2}{2 g}\right]_A - \left[\frac{p}{\gamma} + Z + C_s \frac{V^2}{2 g}\right]_B \ldots\ldots (47a)$$

and

$$h_s = \left[\frac{p}{\gamma} + Z + C_s \frac{V^2}{2 g}\right]_A - \left[\frac{p}{\gamma} + Z + C_s \frac{V^2}{2 g}\right]_B \ldots\ldots\ldots (47b)$$

Each term in Eqs. 47 has the dimension of length. Therefore, as lengths, the right sides of the two equations are identical. However, these lengths represent different physical quantities. The lengths in Eq. 47*b* represent the usual energy per unit weight because they were obtained by dividing the energy equation by γB, the weight of water passing through the reach L. On the other hand, the lengths in Eq. 47*a* represent force per unit area because they were obtained by dividing the momentum equation by γA. The significance of the equality of the right sides of the two equations is that, for conditions satisfied by Eq. 47*a*, the loss of energy within the stream is the result of boundary shear alone.

The principal distinction between Eqs. 47*a* and 47*b* is that the latter is rigorous because it is the definition of the quantity h_s and is not necessarily limited to gradually varied flow, whereas the former defines the resistance to flow as the boundary shear for the specified conditions of flow. Since the length given by the right side of Eq. 47*a* is defined as h_s in Eq. 47*b*, it is permissible to write $\frac{\bar{\tau}_0 \bar{P} L}{\gamma \bar{A}} \approx h_s$ as long as h_s is considered as a length only. If

---

[17] "Hydraulics and Its Applications," by A. H. Gibson, 4th Ed., Constable & Co., Ltd., London, 1934, 82–84.

h_s is considered as loss of energy per unit weight, the foregoing substitution is not permissible because it implies that h_s is to be multiplied by γB and this would make the expression nonhomogeneous, since there is also the implication that the left side is to be multiplied by γA. In other words, making approximations that involve little error and writing the momentum equation in the form of Eq. 47*a* (the right side of which is identical with the energy formula, Eq. 47*b*) do not make Eq. 47*a* an energy equation. Such a procedure, however, is apparently what Messrs. Rouse and McNown visualize as a basis for the statement,

> "The customary loss coefficients of nonuniform flow * * * are simply means of evaluating the quantity H_l of Eqs. 37 and 39 in terms of the boundary geometry and the Reynolds number, and hence have no source whatever in the momentum principle."

The coefficient of velocity distribution is C_s, the ratio of the mean of the squares of the local velocities to the square of the mean velocity. Further examination shows that both the resisting force and the energy lost are related to the length of channel L without consideration of the time factor. The coefficient C_s, therefore, is the proper coefficient for use in space equations.

Turning to the relation between the energy and power equations, it will perhaps be simpler to show the difference by using an illustration. Consider a stream flowing out of a large lake. At cross section A near the lake, the velocity distribution will be very uniform and no appreciable error will be involved by assuming $C_s = C_t = 1.00$. This particular condition was chosen to simplify the demonstration. Suppose that at a second cross section B some distance downstream, away from entrance conditions, the stream channel is complex and the value of C_s is 1.2 and that of C_t is 1.6 (which is considered reasonable for a complex natural channel). Conditions will then be as shown in Fig. 8.

FIG. 8.—PROFILE DIAGRAM

In the development of the energy equation, h_s was defined as the average energy lost per unit weight in the distance L between sections A and B. Therefore, from Eq. 47*b* it appears that the quantity $\frac{p}{\gamma} + Z + C_s \frac{V^2}{2\,g}$ must be the energy possessed by a unit weight of water passing any section. Since $\frac{p}{\gamma} + Z$ represents the elevation of the water surface, the point plotted a distance $C_s \frac{V^2}{2\,g}$ above the water surface in a profile diagram such as Fig. 8 must represent the energy content per unit weight passing that section. A line connecting all such points would then be the "energy content line." Obviously, for steady flow the energy content line will not change with time and its slope becomes the "energy gradient" when this term is defined as the rate of loss of energy per unit weight per unit length of channel. The distinction between "energy content line" and "energy gradient" is important only in the case of unsteady flow.

In the same way the power equation can be written in the form (compare Eq. 47*b*):

$$h_t = \left[\frac{p}{\gamma} + Z + C_t\frac{V^2}{2g}\right]_A - \left[\frac{p}{\gamma} + Z + C_t\frac{V^2}{2g}\right]_B \ldots\ldots\ldots (48)$$

and the quantity $\frac{p}{\gamma} + Z + C_t\frac{V^2}{2g}$ is the average energy per unit weight passing any section per unit time, or the power at any section. Likewise, in a profile diagram such as Fig. 8, a line plotted a distance $C_t\frac{V^2}{2g}$ above the water surface will be the "power content line" which for steady flow has a slope that represents the average loss of energy per unit weight per unit time per unit length of channel and is the "power gradient."

Thus, h_s is the average energy lost by the stream for every pound of water passing through the reach from section A to section B, but h_t is the average energy lost per second per pound of water passing through the reach. Although h_s and h_t have different numerical values, they represent the same physical quantity—energy lost by the stream in distance L. Therefore, it should be possible to obtain h_s by multiplying h_t by $\bar{t}$, the average time needed for a pound of water to pass any section. To do this, since both h_L and t vary for each stream tube, the multiplication must be made before integration as in the development of the base equations.

The coefficient of velocity distribution for use in the power equation (where the loss of energy per unit time is considered) is C_t, the ratio of the mean of the cubes of the local velocities to the cube of the mean velocity.

The use of the energy or power equation is largely a matter of choice. In either case, coefficients for loss of energy will be determined experimentally by using the equation selected. There are certain considerations that affect the choice of equation. Since the total loss of energy depends on the volume passing any cross section, the most convenient volume to use is Q, the volume per unit time. This leads to the selection of the power equation and (since power is energy per unit time) the frequent designation of the power equation as the energy equation.

There may be two objections to such a procedure. In the first place, even though the energy equation or the power equation is the logical choice for the solution of a given problem, the effect of friction will usually be obtained by the use of the Manning equation or the Chézy equation. Since these are momentum equations and only the energy equation uses the same velocity distribution coefficient, C_s, the energy equation may be more suitable for general use than the power equation. Secondly, the velocity distribution coefficients are usually ignored. Disregarding them in the power equation will introduce about three times the error caused by disregarding them in the energy equation. To avoid confusion it is suggested that the name "Bernoulli equation" be used only in connection with the flow through a single stream tube or through a channel with uniform velocity distribution.

Several discussers have suggested that since the velocity distribution coefficients were small, especially in relation to other unknowns, one should neglect them rather than become concerned over their proper use. For those accustomed to thinking of open channels in terms of canals or similar channels of regular cross section, such a procedure may seem appropriate. The writer believes, however, that the velocity-distribution coefficient will become an important tool in the analysis of flow in natural channels of complex section. There are indications that values of C_s and C_t for such channels can easily be as great as 1.2 and 1.6, respectively, and can vary quite rapidly from section to section. This paper has been presented for the benefit of those engineers who find themselves confronted with situations in which velocity-distribution coefficients must be considered. In closing, the writer desires to thank all those who offered discussions. The critical comments led the writer to make such extensive revision of the paper. He hopes the result will be found sufficiently rigorous and suitable for explaining some of the confusion on the subject.

CONSTRUCTION AND DESIGN PROBLEMS

By James H. Stratton,[1] M. Am. Soc. C. E.

Synopsis

The procedures in use by the Corps of Engineers, U. S. Army, in the design and construction of airfield pavements, are described in this paper. The design procedures for heavy airplane wheel loads having been in use only since the beginning of the present war construction program, it is too early to forecast the ultimate service behavior of airfields of recent construction. However, to the extent permitted by the pressure of the war construction program and the demands of air traffic, the design and construction procedures have been verified by accelerated traffic tests utilizing heavy, rubber-tired earth-moving equipment. The service performance, under severe operating conditions, of pavements designed and constructed in accordance with these procedures, on the whole, has been extremely gratifying.

Criteria for airfield site selection and for grading and clearance of runways, taxiways, and aprons; investigation and test procedures; and airfield drainage are also discussed.

Loading Criteria for Military Airfields

Military airplane wheel loads adopted by the Corps of Engineers for pavement design are shown in Table 1. Class IV military airfields are exceptional; a wheel loading of 15,000 lb may be considered the minimum military design standard. Loadings greater than 60,000 lb may be anticipated in the near future, but no design provision is being made yet for such loadings.

TABLE 1.—Military Airplane Wheel Loads for Pavement Design

Class	Wheel load (lb)	Contact pressures (lb per sq in.)	Contact area (sq in.)
I	60,000	75	800
II	37,000	65	570
III	15,000	55	273
IV	5,000	45	111

Impact.—That the buoyancy or wing lift of moving planes markedly reduces rolling impact stresses at runway joints and cracks is indicated by the excellent service performance of runways as compared to apron and taxiways of the same design. The lesser effect of wing buoyancy in reducing such stresses on apron and taxiway concrete pavements results from the slower rate of plane travel on these pavements.

In the design of aprons and taxiways, special allowance is made for vibration stresses caused by the warming of airplane engines, and this allowance is considered as providing for rolling impact on these pavements.

Investigations by the Army Air Forces and the Corps of Engineers disclose that landing impact for good two-wheel landings is not severe, whereas one-wheel landings result in high impact stresses. The generally excellent service performance of the parts of runways on which most landings occur indicates that landing impact does not contribute to pavement failures. Hence, stresses due to landing impact are ignored.

---

[1] Col., Corps of Engrs., U. S. Army, Arlington, Va.

Frequency of Loading.—In general, the loading frequency of airfield runway pavements is considerably less than on highways, due both to inherent traffic limitations of airfields (air saturation) and to the natural traffic distribution that results from the relatively greater widths of runways (150 ft to 300 ft).

Stresses Due to Warming of Airplane Engines.—Airplane static loadings and the loadings of airplanes when engines are being warmed induce higher stresses than those produced by rapidly moving planes. This has been verified by noting the relatively large increases in deflections of flexible pavements imposed by standing airplanes and by standing planes, and slowly moving planes, when their motors are being warmed at high speed (dynamic loading). The dynamic loading is taken into account in designing turnarounds, aprons, hardstandings, and taxiways that are subject to the stresses thus caused.

The dynamic loading is adjusted by increasing the loadings, in Table 1, 25% for the design of turnarounds at the ends of runways, aprons, hardstandings, and taxiways subject to normal frequency of use. This load increase assumes a 25% increase in the wheel load distributed over a tire print area (see Table 1) which is also increased by 25%. Warming engines on runways is exceptional, and dynamic loading is not considered in runway design.

Design of Certain Facilities for Limited Use.—In the interest of economy, a reduction in design requirements is feasible for certain airfield pavements, such as stub-end and peripheral taxiways and the pavements of auxiliary and all-over fields which are used infrequently ("limited operation"). For flexible pavements the combined thickness of base course and the pavement required for the specified load assumption is decreased 20%. For rigid pavements a higher working stress is used. Pavements are not designed for both dynamic loading (warming of airplane engines) and limited operation.

Criteria Governing Selection of Pavement Types.—Service aprons and hardstandings are subject to the high shearing stresses that occur when a plane is turned with locked wheels, and to the action of oil and gasoline dripping and spilling. Since bituminous pavements are unsatisfactory for such facilities, as well as for turnarounds at the ends of runways (which are subject to similar high shearing stresses) concrete generally is used. Concrete is not warranted for hardstandings at temporary airfields. Since reasonable maintenance is practicable and economical, for the most part they are constructed of surface-treated base courses designed for the specified loadings. Ordinarily, stub-end and peripheral taxiways are constructed with surface-treated base courses.

Turfing of Airfields.—Where climatic and soil conditions permit, runway and taxiway shoulders are turfed to control dust and erosion. Such turfed runway and taxiway shoulders will support reasonably high loadings under reasonably favorable ground conditions, and thus will reduce the likelihood of accidents when the shoulders are used inadvertently by planes. Where turfing is impracticable or uneconomical, the shoulders are treated with a dust palliative of a texture and color which distinguishes them from the taxiways and runways, and thus prevents their being mistaken for landing and traffic areas.

CONCRETE PAVING

The design of concrete pavements generally is based on the methods of H. M. Westergaard, M. Am. Soc. C. E. (1)(2)(4)[2] which contemplate loads applied at the corners, edges, and the interior of pavement slabs. The Westergaard analysis omits consideration of temperature variations and other influences that tend to change the slab volume, effect of edge thickening, effect of local hard or soft spots in the subgrade, horizontal components of the reactions of the subgrade, and inertia of pavements and of subgrades. However, these factors have a direct bearing on pavement performance, and to the degree of their importance are considered in the design and construction of airfield rigid pavements.

The design of airfield concrete pavements is an empirical application of the Westergaard formulas for interior slab loadings for large tire imprint. A design factor is selected to provide a pavement sufficiently thick to withstand the design stresses at interior corners and under the conditions of load repetition normal at military airfields. Typical design curves for the specified allowable working stresses and wheel loads are shown in Fig. 1. After the modulus of soil reaction k has been determined, the required thickness of slab, except at free edges and along longitudinal expansion joints, is taken directly from the design curves. The results of accelerated traffic tests using rubber-tired earth-moving equipment with wheel loads and tire imprint areas comparable to those specified for the design of Class I, II, and III airfields, and of load tests on

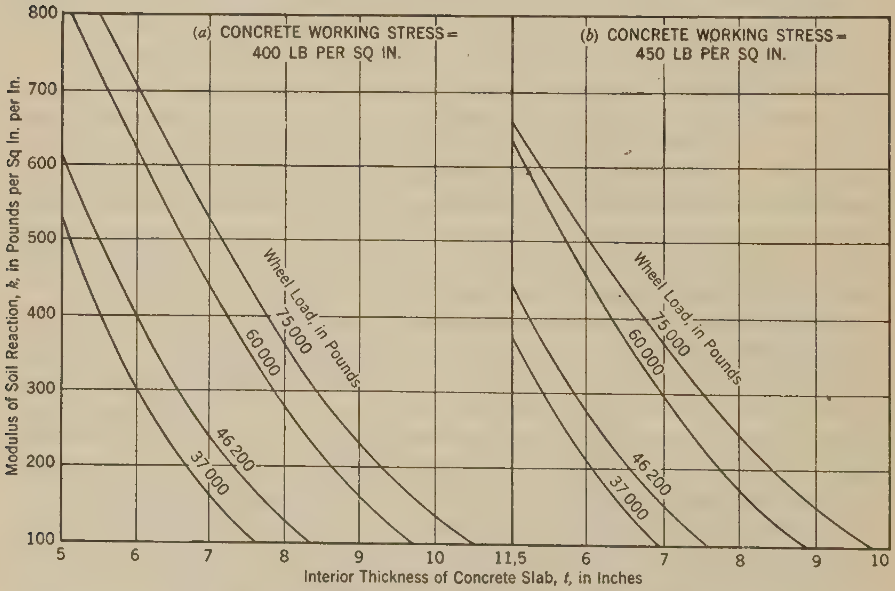

FIG. 1.—DESIGN CURVES FOR CONCRETE PAVEMENTS

concrete slabs of various thicknesses placed on subgrades of various types, were used in selecting the design factors and in checking the design method. Airfield pavement service performance has verified the design method, which is being checked further by additional traffic and plate bearing investigations and by observation of the service behavior of rigid airfield pavements.

---

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography at the end of the Symposium.

Temperature Stresses.—Temperature differences between the upper and lower surfaces of concrete slabs cause warping; the effect of warping varies with the magnitude of the temperature differential. Midday temperature differentials of 24° F in a 6-in. slab, and of 31° F in a 9-in. slab, have been recorded in the vicinity of Washington, D. C. (5). It is probable that greater differentials are experienced elsewhere, as, for example, in the southwestern United States. Temperature differentials and their effects are discussed by Dean Westergaard (6), L. W. Teller, Sr., M. Am. Soc. C. E., and E. C. Sutherland (5), E. F. Kelley (7), and R. D. Bradbury, Assoc. M. Am. Soc. C. E. (8). Mr. Bradbury concludes that, for the purpose of design, a maximum temperature differential of 3° F per inch of slab thickness may be assumed when the top of the slab is warmed by the sun and the bottom is cooled by the subgrade. He suggests a differential of 1° F per inch of slab thickness when, at night, a reverse temperature differential may prevail. The design differentials proposed by Mr. Bradbury are less than those recorded by the Public Roads Administration (5), and probably are considerably less than those that may be expected at some localities.

Actual warping stresses noted by the Public Roads Administration (5), in summer in the vicinity of Washington, D. C., were 320 lb per sq in. for a 6-in. uniform slab, and 416 lb per sq in. for a slab with thickened edge (9 in.-6 in.-9 in.). The investigations of the Public Roads Administration and the analyses by Dean Westergaard indicate that temperature warping stresses may be reduced materially by shortening the slabs. For example, for a 10-ft slab the interior longitudinal stresses are 66%, and the free edge stresses 89%, less than the corresponding stresses in a 20-ft slab.

Excessive warping stresses are avoided by imposing design limitations on slab lengths and by permitting relatively thin slabs for the design loadings when base courses are used to improve subgrade support. This is better practice than to place thick slabs directly on subgrades of low bearing capacity. The relatively low volume of traffic at airfields results in relatively infrequent occurrence of the critical combined stress condition at midday when warping stresses are at a maximum.

Factors Affecting Subgrade Support.—Variations of subgrade reaction as they affect stresses in a slab are regarded by Dean Westergaard (1) and others as not particularly significant. This conclusion is based on values of the subgrade moduli ranging between $k = 50$ and $k = 200$ lb per sq in. per in. The bearing value of a subgrade is influenced by a number of factors, including variations in the soil moisture resulting from fluctuating ground water, seepage through joints, and capillarity—which induces condensation at the underside of the paving slab—and also subgrade deformation due to loading and to temperature warping. Warping of a concrete pavement tends to deform the subgrade, which in turn affects the magnitude and distribution of the stresses in the pavement. Compaction of subgrades and the use of compacted base courses to improve and to develop uniformity of the subgrade support mitigate these adverse influences.

Highway Procedures for Determining the Subgrade Modulus.—In the design of rigid highway pavements it is customary to assume a value for the subgrade modulus generally ranging from $k = 50$ to 200, with $k = 100$ most commonly assumed as representing fair average subgrade conditions. No method of evaluating the subgrade support for concrete pavement design has been devised and generally adopted.

In corner-load testing of concrete slabs on a synthetic subgrade of moist clay, M. G. Spangler, M. Am. Soc. C. E. (9), computed an apparent initial subgrade modulus of $k = 275$ corresponding to a deflection of 0.0232 in. maximum, and an apparent final value of $k = 40$ corresponding to a deflection of 0.0620 in. maximum at 400 to 500 load repetitions. This decrease was the result of deformation of the subgrade under the repetition of load. Although this reduction resulted in a computed increase in slab stress of about 20% to 25%, Mr. Spangler, concurring with Dean Westergaard, concluded that variations of subgrade reaction of this magnitude have relatively little effect upon the stresses in the slab. However, he suggests the need for further investigation. In a discussion of Mr. Spangler's paper, the late Clifford Older, M. Am. Soc. C. E., observes that warping of slabs under field conditions will result in permanent subgrade depression, and that this indicates the fallacy of using stress formulas that are based on the assumption that the subgrade reaction is proportional to slab deflection. Mr. Older concludes that test slabs should be traffic tested to confirm the design assumptions and relationships of load, subgrade reaction, and slab stress.

The stress increases accompanying the decrease of subgrade reaction as noted in the laboratory by Mr. Spangler probably are less than those often observed under field conditions. The result of repeated deflections of a slab, particularly at joints where water has ready access, may be a remolding of a plastic subgrade soil, or a pumping action with a consequent marked loss of support at the locations where slab stresses are most critical. Base courses contribute to the alleviation of conditions destructive to the supporting capacity of a subgrade.

Determination of Subgrade Reaction.—Designs of airfield concrete pavements are based on the modulus of soil reaction k determined by field plate bearing tests. Tests to determine k are conducted prior to design, whenever feasible. The pressure of the war construction program has precluded field bearing observations and other required investigations in some instances and, to estimate the k values, it has been necessary to use, interpretatively, the results of field plate bearing tests at other sites. To represent the subgrade in cut, bearing test areas are stripped of vegetation, scarified, and compacted at optimum moisture to a depth of 6 in. To represent graded fill, test embankments at least 30 in. high are constructed with the same compaction control that is used in the airfield construction. Where low subgrade support is apparent, base courses are placed at selected thicknesses on the compacted test area (both cut and fill) and then evaluated by plate bearing tests. These tests of both subgrade and base course are repeated sufficiently often to give representative values. The results of the plate bearing tests are plotted as stress-deformation curves, and the subgrade modulus k_u (and base-course modulus) at optimum moisture is selected as the slope of a chord passing through the origin and the curve at 0.05-in. deflection. This value of deflection and the size of the bearing plates (30 in. in diameter) were selected after a series of bearing and traffic load tests. The selected deformation tolerance of 0.05 in. for the determination of this modulus may not be a proper one for all types of subgrades nor for base courses placed on subgrades to improve the pavement support.

The optimum moisture condition at which the subgrade and base courses are placed does not represent the moisture condition after the passage of time. To evaluate the subgrade support that might obtain as a result of moisture accumulation, principally in the subgrade, field plate bearing tests were made on subgrades that were saturated after initial testing at optimum moisture. The results of these investigations were not satisfactory, and an alternate procedure has been adopted tentatively to adjust for possible decrease in subgrade support due to moisture accumulation. This consists of utilizing the results of laboratory consolidation tests on subgrade samples compacted at optimum moisture, and on duplicate samples similarly compacted which are saturated by immersion prior to testing to represent probable future moisture accumulation and swelling of the subgrade. The duplicate sample is saturated under a restraining load representing the weight of the overlying pavement. The adjusted value of subgrade modulus is determined by the formula:

$$k = \frac{p_s}{p} k_u \qquad (1)$$

in which p is the load intensity on the 30-in. plate that produces a settlement of 0.05 in.; p_s is the load in pounds per square inch required to consolidate the saturated specimen to the same extent as the load of intensity p when applied to an unsaturated laboratory specimen. The adjustment for possible subgrade saturation takes into account neither the attendant remolding of the subgrade, the effects of cyclical swelling and shrinkage of the subgrade, permanent subgrade deformation resulting from slab warping or load application, nor the effects of frost heaving or thawing.

The interpretation of plate bearing test results requires the exercise of judgment based on experience with accelerated traffic tests and upon observation of pavement service performance for extended periods. Such interpretation requires full information on the subgrades, base courses, and concrete which implies extensive laboratory tests of the subgrade, base-course materials, and the concrete; on such factors as the effects of subgrade restraint and of changes in the subgrade induced by change in moisture content; the amount and effect of temperature warping and of frost action and thawing; and the effect of slab dimensions and of stress transfer devices. Field plate bearing tests are so expensive and time consuming, and require the mobilization of such large amounts of equipment for test embankment construction, compaction, load jacking, and base-course construction that such testing often is precluded.

Base Courses for Concrete Pavements.—When used in pavement designs for Class I and II airfields, wheel loading values of the subgrade moduli commonly assumed in highway practice result in excessively thick pavements (10 in. to 14 in.). Such thick slabs obviously are undesirable because of the high-temperature stresses that would result. Furthermore, experience has shown that concrete slabs more than 8 in. thick are inferior in the lower portion, due to difficulties in vibrating the concrete.

The excessively thick pavements for Class I and II airfields required for subgrades of low bearing value are avoided by the use of base courses to improve the support for the pavements. High-quality base materials are less subject to the adverse influences which readily deteriorate the susceptible low-quality subgrades. They also serve to insulate and protect the underlying subgrades, and thus to preserve, to a large degree, whatever value and uniformity of support the subgrades offer. Recent plate bearing investigations have disclosed that improvement of the pavement support by use of base courses is not always evidenced in the values of k as determined by the plate bearing tests. Accelerated traffic tests and pavement service performance, however, demonstrate the value of base courses under concrete pavements.

Allowable Working Stresses for Concrete Pavements.—For normal operation, the allowable working stress of the concrete is determined by dividing the 28-day flexural strength by a design factor of 1.75. This value was chosen after giving due consideration to warping stresses, effect of loading at joints, concrete fatigue, and increased strength of concrete with age. For limited operation a design factor of 1.40 is used. The results of traffic tests and observations of rigid pavement service performance were considered in selecting these design factors.

Airfield Concrete Pavement Sections Used by Corps of Engineers.—Standards of the Corps of Engineers for concrete pavement sections are shown in Fig. 2. Edges are thickened only at free sides and at longitudinal expansion joints. Where slabs have thickened edges (joints), the shaping (troughing) for the thickened edges results both in material disturbance to the subgrade or base course and in reduction in base-course thickness, with resulting reduction in the value of the slab-supporting medium. Since pavement slab stresses are critical at edges and corners, it is imperative that the integrity of the slab support at these locations be especially protected. The shaping of base courses is particularly difficult, and it is probable that the benefits to be expected from the use of base courses are not realized when the base material is disturbed to thicken the edges. For this reason, edges are not thickened at interior joints (except at free longitudinal expansion joints), and adequate stress transfer devices are provided.

Stress Transfer Across Joints.—Observations of paving construction have disclosed the difficulties in providing high quality concrete at construction keys. Honeycombing due to lack of consolidation by spading and vibration of the concrete vitiates the functioning of the keys as devices for stress transfer. Messrs. Teller and Sutherland (5) have shown the need for supplemental transfer devices at keyed joints. Their conclusions and the observed poor workmanship at keys have resulted in the decreased use of keys in military airfield pavements.

The widths of pavement strips range generally from 20 ft to 30 ft, the present trend being toward wider lanes. Where strips exceed 18 ft in width, continuous longitudinal dummy joints are run down the center. Tie bars are placed at longitudinal dummy joints in the paving strips adjacent to longitudinal expansion joints and outside pavement edges. The provision of stress transfer devices at other joints than those shown in Fig. 2 is left for local consideration.

Fig. 2.—Concrete Pavement Section

Joint Spacing.—The spacing of expansion and contraction joints is largely a matter for local determination. The character of the subgrade and base course (including their restraining influences), the climate (particularly daily temperature range), and the season of construction, as bearing on the question of initial shrinkage, are factors that affect the spacing of expansion joints.

Longitudinal expansion joints are laid out generally at intervals of 75 ft to 100 ft, and for widths of 100 ft or less no longitudinal expansion joints are required. Transverse expansion joints are at intervals of 50 ft to 120 ft depending on the judgment of the district engineer. Transverse expansion joints are equipped with dowels that have been painted, greased, and capped at one end.

Transverse contraction (dummy groove) joints are at intervals of 10 to 25 ft, most pavements having spacings of less than 20 ft. The likelihood of high warping stresses due to temperature differentials has an important bearing on the spacing of transverse joints, and the practice is to use short slabs where the differentials may be high.

Construction of Concrete Pavements.—A well-prepared rigid pavement design may be vitiated by carelessness or improper construction, and emphasis is placed on the quality of subgrade and base-course construction; protection of the prepared subgrade, base courses, and the concrete during the construction; the selection of proper equipment for construction; construction sequences; and adequate curing of the concrete. For thick slabs particularly, there is need for improvement in placement methods. Alternate lane construction of multistrip airfield pavements is conducive to serious disturbance to the subgrade by the operation of construction equipment and by ponding of rain water on the intervening subgrade between completed strips. On the other hand, in successive lane construction serious cracking has resulted from the operation of paving machines mounted at one end on previously placed concrete which has not yet gained sufficient strength to support the paving-machine load. The latter procedure is preferred, however, and the construction schedule is established, where feasible, to permit proper aging of the concrete before imposing the paving-machine loading.

Concrete curing is highly important and construction instructions emphasize the need for protecting the concrete to avoid the adverse effects of temperature warping before strength gain is sufficient to resist warping stresses.

Because of the war shortage, steel reinforcement has been omitted from the rigid pavements of airfields.

Summary of Factors Affecting the Design of Concrete Pavements.—Load, temperature warping, and subgrade reaction are the principal factors affecting the stress condition of concrete pavement slabs. By improving the slab support through the use of base courses it is possible to reduce the theoretical stresses from airplane wheel loadings to values which are commonly accepted in highway practice, and to keep slab thicknesses to dimensions that obviate excessively high-temperature warping stresses.

Subgrades deteriorate and lose their supporting value as a result of moisture accumulation and remolding of the subgrade soil or because of deformation due to loading and to temperature warping. This degradation of the subgrade results in cracking of the overlying pavement. Base courses which improve the support for rigid pavements insulate the underlying subgrades against the adverse influences to which many are highly susceptible. Properly designed base courses are highly resistant to these same influences.

Flexible Pavements

The wide variety of aggregate types suitable for bituminous pavements often permits economies through the use of local materials. The so-called "low type of flexible pavements" is generally unsuitable for military airfields, except for traffic facilities used infrequently. Central hot-plant bituminous concrete construction is preferred for pavements subject to normal use.

Flexible pavement construction for airfields (10) generally requires base courses to distribute stresses to the subgrade. The various formulas in vogue for determining the combined thickness of base course and pavement required for a specified loading generally depend on a rating of the subgrade bearing capacity. The subgrade is usually rated by plate bearing tests.

Bearing plate investigations and accelerated traffic tests using heavy, rubber-tired earth-moving vehicles indicate that flexible pavements on airfields, designed on the basis of subgrades rated at deflections commonly considered acceptable, are not satisfactory for present-day airplane loadings. It has been found infeasible to fix a maximum value for the deflection tolerance that would be applicable in rating subgrades of various soil types for flexible pavement design. Moreover, the effects of moisture change, rate of load application, stress repetition, and frost heaving and thawing cannot be evaluated directly by the plate bearing method of rating subgrades. The effects can be evaluated, if at all, only by empirical correlation of the results of a large number of plate bearing tests with the service performance of pavements on a wide variety of subgrades. These facts led to the consideration of other design methods.

California State Highway Department Method of Design.—The standard method of design adopted by the California State Highway Department (13) has been accepted for the design of flexible pavements at airfields. To extend the experience gained in California to the loadings required for airfield pavements, the design curves for wheel loadings in excess of 12,000 lb, shown in Fig. 3, were prepared by the engineering staff of the Chief of Engineers based upon its design, construction, and operating experience and with the advice and assistance of O. J. Porter and Arthur Casagrande, Members, Am. Soc. C. E. A series of accelerated traffic tests on pavements with varying thicknesses o base courses, founded on several distinctive types of subgrades to represent the range of subgrade soil types which might be encountered, resulted in substantial confirmation of the design curves tentatively established for wheel loadings in excess of 12,000 lb.

As the result of more recent accelerated traffic tests to determine the relationship of the values of the California bearing ratio (CBR) to required combined thicknesses of pavements and base courses, the curves have been revised in the range covering cohesionless subgrades to reduce the required combined thickness of pavements and base courses.

Evaluation of Subgrade.—The CBR of a subgrade soil is its relative stability as determined by an arbitrary penetration test and is expressed as a percentage of the stability value of a selected crushed stone. The penetration values for the crushed stone have been established. The CBR of a subgrade is tested by forcing a circular piston, 3 sq in. in area, into the subgrade soil in a cylindrical test mold at the density and moisture conditions to be expected after the passage of time as a result of moisture accumulation, and noting its load deformation characteristics. The procedure has been fully described by Mr. Porter (11). It is applicable to highway construction methods used in the State of California and to conditions and soils in that state.

Inconsistent test results on certain of the many types of soils encountered in the construction throughout the continental United States, and elsewhere, have made it necessary to modify the California test procedure to insure representative results consistent with the character of the construction. As more tests are performed, it may be necessary to alter further the CBR test procedure.

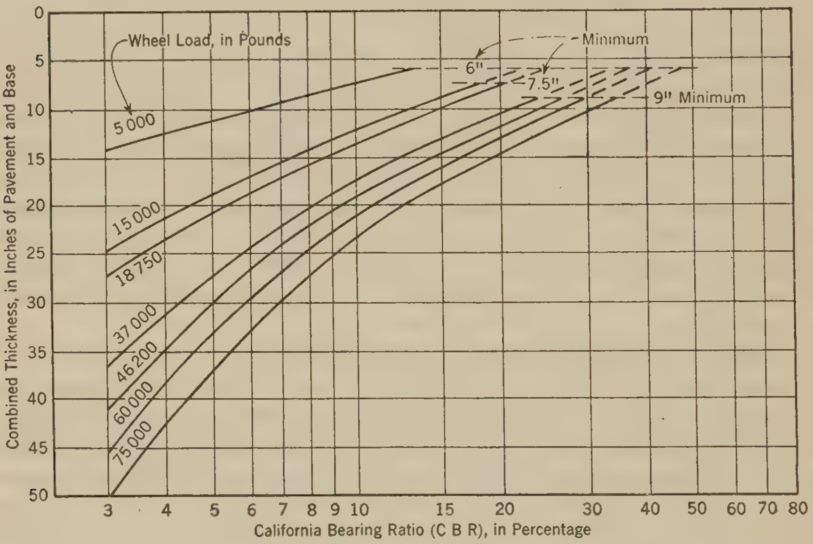

FIG. 3.—CURVES FOR THE TENTATIVE DESIGN OF FLEXIBLE PAVEMENTS (CALIFORNIA METHOD)

Instead of compacting soils in the test mold under a load of 2,000 lb per sq in. (termed static load), as in the California method, it has been found advisable to tamp the soil in the test mold as is done in laboratory testing for density and moisture control for field compaction. The control test for most soils is a modification of the well-known Proctor test. The densities of some soils when compacted by the static load vary as much as 10% from the densities obtained by tamping the soil in the mold. Static loading compaction of some soils results in nonuniform densities or a crust-like surface condition in the upper zone. This is the part of the specimen which is penetrated by the test piston, and the effects influence the CBR test results.

Adoption of a tamper similar to the Proctor tamper, to compact the soil in the CBR test mold, has led to other modifications in the testing procedure and also in the testing equipment. Since the CBR test results are greatly affected by the surface condition of the specimen penetrated, the test mold has been redesigned to facilitate inverting the mold and penetrating the bottom end of the sample, which is relatively smooth, free of crusts, and of relatively uniform density.

For some soils the California method of soaking the CBR test specimen to represent the density and moisture conditions that may obtain in the subgrade after the passage of time results in a very soft, mushy testing surface. This condition is prejudicial to the results of the CBR test and is not representative of the actual subgrade moisture and density conditions. Soils of this type now are soaked by permitting the water to rise from the bottom until expansion ceases, or until free water appears on the surface.

Tests of granular materials in accordance with the original procedure give CBR values which result in excessive base thickness requirements. The weight of the annular ring that encircles the piston when it penetrates the soil sample, and which is used to represent the confining effect of the overlying base and pavement, has been increased to represent the restraining effects of the overlying base and pavement material.

The value of the CBR method of design lies in the correlation with pavement performance by the California Highway Department over a period of thirteen years for the range of loadings common to highway practice, and with the results of accelerated traffic tests conducted by the Corps of Engineers with loadings comparable to those of present-day airplanes (see Table 1).

Incomplete laboratory tests in process suggest the following tentative conclusions:

(*a*) The moisture content of low to medium plastic soils at the time of compaction in the test mold affects the CBR. The CBR decreases with increase of moisture content.

(*b*) A change in density affects the CBR value for most cohesionless and low to medium plastic soils.

(*c*) The magnitude of the penetration surcharge (annular ring) has a marked effect upon the CBR of cohesionless soils, and some effect on low plastic soils.

(*d*) The CBR is increased for some soils if the length of the sample is less than 4 in.

(*e*) Erratic CBR values result from testing soils containing a high percentage of particles greater than $\frac{1}{4}$ in. in size. It is considered necessary to make numerous tests of such soils.

Design for Capacity and Limited Operation.—The required combined thickness of pavement and base course, based on the CBR test of the subgrade soil, is taken from Fig. 3 unless an additional thickness of base course is needed to insulate the subgrade against frost action. The CBR method of design is based on the performance of flexible highway pavements under a wide variety of conditions over a period of years. The combined thickness of base course and pavement requirement, as specified by the design curves for a given loading, provides for the depreciation in the subgrade bearing value by subgrade saturation, subgrade moisture change, stress repetition, and other influences (except frost action) which tend to decrease the stability of the subgrade material. The total combined thickness given by Fig. 3 is used for capacity operation, but for pavements subject to limited operation it is reduced by 20%.

Where field compaction of the subgrade is impracticable or inadvisable, or where unusually weak strata underlie the compacted subgrade layer, the CBR tests are conducted on undisturbed subgrade samples. The effects of saturation on the uncompacted subgrade are determined by duplicate tests on saturated, undisturbed specimens of the subgrade.

Design of Base-Course Layers.—Suitable base courses can be constructed using soils of relatively low CBR in the deeper layers. This practice is often economical if materials with high CBR are costly to process or must be transported from more distant sources. The required combined thickness of base material and pavement above any given base-course layer depends upon the CBR of the base-course layer and may be determined from Fig. 3. If the base course is designed for several layers of material, the economic thickness of each layer is determined. If a material of high bearing value is used for the full depth of base a lesser thickness is required than if lower CBR material is used in the lower portions of the base. If this opinion is verified by further tests, this fact will permit a change in the CBR design curves.

The base course directly under the pavement should be sufficiently stable to withstand the high stresses produced in the zone directly under the wheel of a plane. The required stability depends upon the type and thickness of pavement, the action and effect of a moving or skidding wheel, the type of plane, etc., and cannot be determined by Fig. 3. For highway pavements used by heavy trucks, the base-course material immediately under a bituminous pavement should have a CBR of at least 80%. Preliminary tests disclose that materials of lower CBR directly under airfield pavements would probably give satisfactory performance for airfield traffic conditions. When material with a CBR of 80% is not available locally, and transportation facilities are inadequate for importing suitable material, the requirements for the top 6 in. of base course have been tentatively established as follows:

Gross weight of plane, in pounds	Minimum allowable CBR for upper base material
10,000 to 30,000	50%
30,000 to 74,000	65%
74,000 to 120,000	80%

Recent investigations refute the results of the preliminary tests and indicate that material of less than 80% CBR should not be used directly under pavements when the subgrade soil is plastic.

Pavement Thickness.—The cross section of a bituminous pavement may comprise several courses, depending on the total thickness required, economic use of materials, practical construction limitations, the possibility of stage development of the airfield, etc. Pavement thicknesses are designed with a surface course, or surface and binder courses, to resist displacement and shear under the design wheel loads, giving consideration to the type of bituminous material used. Pavement thicknesses are not less than 1.5 in., for wheel loads up to 15,000 lb, and not less than 3 in., for wheel loads up to 37,000 lb. For wheel loads exceeding 37,000 lb the thicknesses are designed in accordance with the requirements in each specific case, but in general do not exceed 6 in.

Pavement Quality.—A high density in surface courses is required for resistance to water absorption and raveling under traffic, and is achieved by the proper gradation of aggregates, thorough mixing with the bitumen, and thorough compaction to produce a low void ratio. Bituminous surfaces are compacted from 90% to 95% of the theoretical maximum density, depending on the type. Grades of bitumen are selected which will remain soft and pliable and will promote healing of incipient cracks induced by weathering and wear, without benefit of a substantial amount of traffic kneading.

The non-skid requirements for runway surfaces are less important than for highway surfaces, because of the primary difference in type of traffic, alinement, and grades. Pavements with rough surface textures provided by the coarse graded mixtures, which have been widely favored for highways because of their high non-skid properties, are not needed for runways, and are undesirable from the standpoint of excessive tire wear. The reasonably fine-grained, gritty texture produced by coarse sand or small stone chips, gravel, or crushed slag, used as cover aggregate for seal coats, is desirable for runways.

Subgrade and Borrow Investigations

Explorations are made to determine the location of ledge rock, elevation and slope of the water table, and soil profiles, and to provide representative soil samples for testing. The subgrade soil survey is extended to a depth equal to at least twice the equivalent diameter of the tire contact area, but in no case less than the maximum depth of frost penetration or less than 4 ft below the final elevation of grading at each point where grading is required.

Laboratory tests on subgrade soil samples include mechanical analysis and soils classification, Atterberg limits, moisture content, natural density, CBR, expansion, permeability, and compaction control. Shear strength and consolidation tests are made if the pavement is to be supported on embankment fill. Soils are classified in accordance with the Casagrande Soil Classification (12). Local classification often is used to supplement this general classification, where it is necessary to describe the soil adequately.

Compaction Tests and Control

Compaction of soils is controlled, wherever applicable, by the AASHO Method (American Association of State Highway Officials) modified as follows to give densities comparable to those obtained by specified field compaction equipment: The weight of the rammer or metal tamper is 10 lb instead of 5.5 lb; the tamper is dropped from a height of 18 in. above the sample instead of 12 in.; and the samples are compacted in five equal (approximately 1-in.) layers instead of three layers. The densities of some cohesionless sands and gravels as obtained by the Modified AASHO Method often are not representative of obtainable field densities, and the control specimens of such soils usually are compacted by tamping, static pressure, or vibration alone or in combination.

Fill is constructed in 9-in. layers, loose measurement, and compacted to at least 90% of the maximum unit weight at optimum moisture, except that directly beneath the base course or pavement where a base course is not provided, the subgrade is compacted to at least 95% of the maximum unit weight at optimum moisture, for a depth of not less than 6 in. In cut areas most subgrade soils are scarified and recompacted so the unit weight of the top 6 in. is at least 95% of the maximum unit weight at optimum moisture. Scarifying, reworking, and compacting certain types of clay soils often result in lowering the bearing value below that of the natural clay in place. For this type of material, tests are made to determine the relative bearing values of the recompacted soil and of the undisturbed soil; and, if the undisturbed soil has the higher bearing value, construction operations are conducted to produce the least possible disturbance of the subgrade.

Treatment of Soils with Expansive Characteristics

Natural subgrades with expansive characteristics are compacted at a moisture content, not necessarily the optimum moisture, to a unit weight which will minimize expansion. The selected moisture content and unit weight are approximately equal to those of an expanded sample after the soil has been compacted at optimum moisture and saturated.

Pavement Design for Frost Action

The stability of some soils is greatly reduced by frost action, the loss of stability and extent of heave depending upon the type of soil and the drainage conditions. Several investigators have established limiting grain-size curves defining the boundary between frost-action and nonfrost-action soils for uniform grading. The most generally accepted method of insuring pavement or base-course stability over a potential frost-action soil is to provide sufficient thickness of insulating material. Where the required thickness of base-course material as determined by CBR is not sufficient to preclude frost penetration in the subgrade, additional thickness of insulating material often is required. In general, to insure stability of flexible pavements and surface-treated bases, the combined thickness of pavement and base material not subject to frost action is made equal to the average depth of frost penetration as determined from local records.

Base Courses

Wide varieties of gravels, base-course materials, sands, and gravelly and sandy soils as well as crushed rock, shell, caliche, etc., are used alone or blended to provide base courses. Processing by crushing and screening often is required to produce the required grading.

Where crushed gravel or stone is used for base courses directly under concrete pavements, a reasonably smooth top surface of base course is provided to reduce restraint to the pavement. Base-course materials sometimes are stabilized with commercial admixtures such as portland cement, cut-back asphalts, emulsified asphalts, and tars. Such admixtures are most advantageous with relatively sandy or friable soils.

All base courses are compacted to the maximum density obtainable with heavy field compaction equipment. If the Modified AASHO Method is applicable, the base course is compacted to at least 95% of the maximum density at optimum moisture content.

Special Investigation of Airfield Pavements

Various tests and investigations have been made by the Corps of Engineers for the purpose of improving design and construction methods. Procedures for the investigations and tests were devised to determine conclusions which might be applied to the current construction program. The investigations fall into three categories: Laboratory tests, field bearing tests, and accelerated traffic tests using rubber-tired earth-hauling equipment with wheel weights comparable to the airplane wheel loadings given in Table 1.

Laboratory Investigations.—The special laboratory investigations comprised all the routine tests ordinarily made for site selection and pavement design. The extensive use of the CBR test soon disclosed that the results are influenced by sample density; variation in density of the sample; moisture condition of sample; method of saturating sample to represent moisture conditions that may result in the subgrade after the passage of time; weight of the annular surcharge used to represent the confining effects of the overlying pavement and base course; and rate of penetration. Although considerable laboratory investigational work has been done to adjust the CBR testing procedure to permit proper evaluation of these variables, the results have not been fully correlated with the service performance of flexible pavements.

Field Bearing Test.—A large number of plate bearing tests were made to develop the design method for flexible pavements and to develop a satisfactory procedure for determining the modulus of subgrade reaction which could be used in the design of concrete pavements.

The investigation of design methods for flexible pavements included plate bearing tests on subgrades, pavements, special test sections, and on actual highways in use for several years. It was concluded that the supporting power of subgrades could not be evaluated by plate bearing tests which, for their interpretation, predicate a universal value of allowable deformation for all types of soil. Various values of allowable deformation, ranging from 0.1 in. to 0.5 in., have been proposed by different authorities for rating the unit bearing capacities of subgrades by plate bearing tests.

A study was made to determine if subgrades could be rated by determining in each test the point at which the rate of deformation is accelerated under load application. This would correspond to the yield point on the stress-deformation curve. Fig. 4 is a typical stress-deformation curve obtained by a plate bearing test. The yield point, as can be seen by the curve, is not definite, but can be assumed to be at the point indicated. For this particular test, a bearing value between 15.5 lb per sq in. and 40 lb per sq in. will result if the usual assumptions as to allowable deformation are made.

These studies indicate that the bearing value probably could be selected at some value for the deflection (deformation) less than that at the yield point. However, various factors, including moisture condition and density of the subgrade soil at the time of testing, and the effects of moisture change, stress repetition, and other influences on the behavior of each subgrade under in-

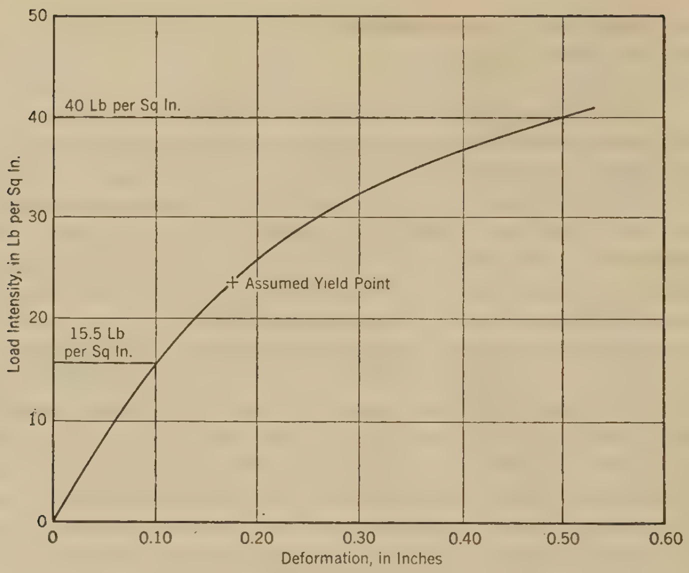

FIG. 4.—LOAD-DEFORMATION CURVE OF A PLATE 30 IN. IN DIAMETER PLACED ON THE SUBGRADE (LOADS APPLIED IN INCREMENTS OF 5 LB PER SQ IN. AND ALLOWED TO ACT UNTIL DEFORMATION CEASED)

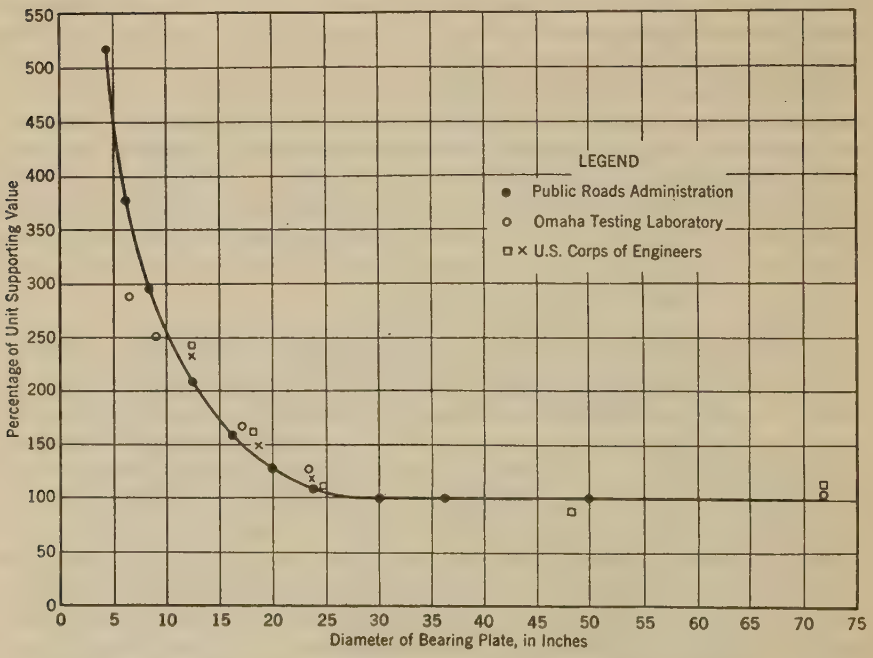

FIG. 5.—RELATION BETWEEN BEARING PLATE DIAMETER AND SUPPORTING VALUE OF SOIL

vestigation, present complications in the selection of a value for the allowable deformation which, in each instance, would represent an evaluation of these influences on the supporting capacity of the subgrade. Small promise of a satisfactory solution was offered by a general investigation of the plate bearing method of rating subgrades with the view of establishing a satisfactory design procedure. Moreover, the pressure of the war construction program made such an investigation infeasible.

Plate bearing tests were made to determine the relation of the area of the plate to the bearing value of the subgrade (see Fig. 5). The results agree closely with those obtained by other investigators and show that, for all practical purposes, the bearing value is the same for all plates with a diameter greater than 30 in. To eliminate the effect of area, a circular plate 30 in. in diameter was selected to determine the modulus of soil reaction for the design of concrete pavement.

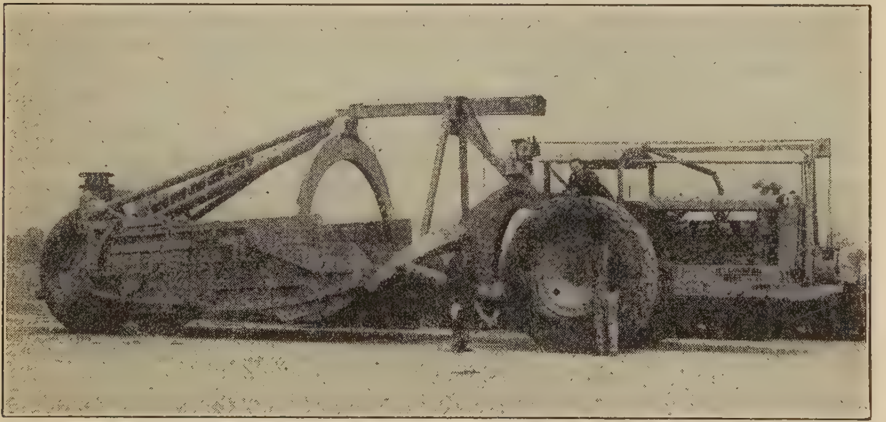

Fig. 6.—Equipment for Accelerated Traffic Tests with Wheel Loads of 37,000 Lb to 60,000 Lb

Accelerated Traffic Tests.—Fig. 6 is a picture of the rubber-tired earth-hauling equipment which is being used to produce traffic wheel loads from 37,000 lb to 60,000 lb. Smaller equipment similar to this is used to produce loads of 15,000 lb to 30,000 lb. Fortunately, the tire imprint of such equipment is practically equal to that of airplane tires carrying similar loads. This type of equipment is used in making accelerated traffic tests of specially constructed test sections of both flexible and concrete pavements and also of actual airport pavements.

The severity of the accelerated traffic test with respect to fatigue stresses in the concrete pavements, and the rapidity of the repetitions of stress in the tests on both rigid and flexible pavements, as compared to the frequency of their occurrence under service conditions, must be weighed in evaluating the test results.

Fig. 7 is a cross section of an embankment constructed for testing CBR design procedures for flexible pavements. This type of construction permits economies and insures a uniform subgrade condition. On such a test section deflection measurements were made with planes standing, with planes moving at slow rates with engines turning at high rates, and with planes standing with engines revolving at high rates to represent the condition of engine warming. For the results of testing one such flexible pavement embankment, reference is made to the Stockton Test Report (3).

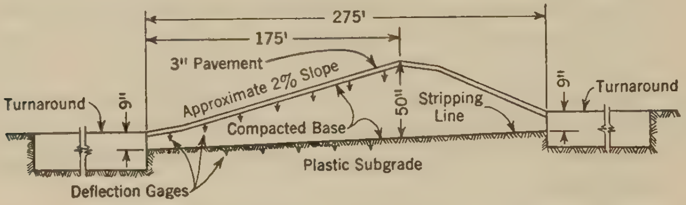

Fig. 7.—Longitudinal Section of Embarkment to Test Flexible Pavement

In the accelerated traffic test the selection of the number of wheel coverages to represent the action of airplane traffic for the full life of a pavement must be based on judgment. A minimum of 3,000 to 5,000 coverages with the design wheel loading over every part of a test strip 5 ft to 8 ft wide on flexible pavements and a minimum of 10 ft wide on concrete pavements have been selected tentatively as representing the use which the airfield pavement may be expected to receive in the course of its normal useful life.

Reinforcement of Existing Airfield Pavements

The increasing number of heavier planes has created a demand for airfields of greater load capacity. In some instances this demand has required reinforcement of existing pavements to take heavier loads than were contemplated in the original designs. Accelerated traffic tests have been an invaluable aid in evaluating the capabilities of such pavements.

Existing pavements are reinforced and pavements that have failed are rebuilt usually by overlay construction, which involves the use of bituminous pavements, or concrete on concrete or bituminous pavements. Where concrete is laid on concrete, an intermediate slippage course of $\frac{3}{4}$ in. to 2 in. of bituminous stabilized sand is used. The joints and joint spacing of the overlay concrete pavement are made to correspond, as far as practicable, with the joints of the concrete pavement being reinforced.

Drainage of Airfields

There has been a gradual development of airfield drainage from the era of the early turfed field relying entirely on the existing natural drainage features, through the period of combination storm and subsurface drains in stone-filled trenches along runway pavements, to the present use of separate storm and subsurface drainage systems with the surface runoff modulated by controlled ponding. These changes in design have been necessitated largely by the exacting requirements of military operations as described by Mr. Hathaway in the companion paper of this Symposium.

Surface Drainage Systems.—The storm drainage system must be adequate in design and areal extent to remove a selected design storm without damage to airfield facilities, undue saturation of the subsoil, or significant interruption of normal traffic. Furthermore, the drainage must be so designed that storms greater than the design storm will not cause undue damage or serious interruption of traffic.

A drainage system plan for a typical airfield is shown in Fig. 8(*a*). For economy in drainage installation there should be a proper relationship between the grading plans and the drainage design to obtain the maximum use of temporary storage of storm runoff.

Depending on the functional requirements of the airfield, storm drainage systems usually are designed to remove runoff from rainfall having a certain average frequency of occurrence. The infiltration capacity estimated to be characteristic of a given soil following a rainfall of one hour serves as the most convenient index to the probable volume of loss through infiltration during the design storm.

Subsurface Drainage Systems.—Subsurface drainage frequently can be eliminated by providing an adequate and properly designed surface drainage system. However, where the ground water is above the frost line or causes soft, boggy conditions in areas where soil stability is required, subsurface drainage is necessary. Two principal types of subsurface drain installations are encountered, the more frequent being a single line of drains adjacent to either side of the runway pavement and so constructed as to drain the pavement base courses and subgrade (see Fig. 8(*b*)). The second type of installation consists of a grid system of drains, not unlike a farm tile drainage system.

The design of a subsurface drainage system is a very approximate procedure based largely on the judgment of the engineer.

Failures in the operation of combined storm and subsurface drainage systems have led to the general requirement that the two systems be so designed that surface runoff cannot backflow into the subsurface drains and result in saturation of pavement base courses and subgrades.

Collectors on pavements are used only to handle the melt of heavy accumulations of snow stacked at the edges of runways. The design of such a collector system is shown in Fig. 8(*c*), the connection being made directly to the storm drains along the edge of the landing strip, either at a manhole or by a special tee in the line. It is imperative that this type of collection system shall not contribute to the moisture accumulation in the subgrade and base course.

SELECTION AND SITE PLANNING OF AIRFIELDS

Airfield sites are selected by the Engineer Department in close coordination with representatives of the Army Air Forces. The requirements of the Air Forces which influence selection and planning of the airfield embrace: (1) Type of aircraft, including wheel load and other characteristics affecting the design of runways, the size of parking areas, hangars, etc.; and (2) type of unit to be accommodated (bomber, fighter, or other) whose different operating procedures demand different facilities. Upon these items are based the number, direction, and dimensions of runways, taxiways, parking aprons, hardstandings, and other

facilities. These, in turn, determine the area of the airfield, which normally varies between 1,000 and 1,500 acres for non-dispersed layouts, and proportionally more for dispersed fields. To accommodate constantly increasing demands of new equipment, all new stations are planned with a view to expansion of housing and airplane landing and parking facilities.

Two other main factors influencing site selection and design of airfield layouts are the physical condition of the site and provisions for safety. Crosswind velocities as great as ten miles per hour do not seriously affect the landing or taking off of military aircraft, but winds of greater velocity present serious problems unless the aircraft can be landed or taken off within approximately 22½° of the wind. For this reason, when laying out runways it is necessary to obtain accurate wind information and to interpret it correctly. Although flat terrain is ideal for aircraft operations, it often presents drainage problems that can be solved only by a compromise between the flatness required for aircraft operation and the slopes required for proper drainage. This must be accomplished with a minimum of grading to conserve time, cost, and use of critical equipment. In the choice of a site and in the design of the airfield, the topography of surrounding areas is considered with a view to permitting clear approaches to all runways and future expansion of initial facilities without excessive additional cost of grading or land acquisition.

Safety Provisions.—Safety is provided in: (1) Approach zones, (2) clear zones, (3) lateral clearances from runways, taxiways, aprons, and hardstandings, and (4) building restrictions (see Fig. 9). Approach zones for runways and other prepared landing strips are trapezoidal areas two miles long, 1,500 ft wide at the inner end, 4,000 ft wide at the other end, and symmetrical about the extended axis of the runway or landing strip. Within these limits all obstacles are cleared which would project above a plane sloping upward at the rate of 40 horizontal to 1 vertical, except at certain types of schools and auxiliary fields where a 1 on 30 plane applies. Wherever a clear zone is required, the approach zone begins at its outer limit; otherwise, it begins at the end of the runway or landing strip.

Fundamental regulations for the design of roadways, clear zones, and approach zones are shown diagrammatically in Fig. 10. Except at auxiliary fields and at certain special-purpose airfields, a clear zone usually is required at either end of the runway or landing strip, and extends 1,000 ft in the direction of the center line of the runway or landing strip prolonged.

Lateral clearances from runway center lines, taxiways, aprons, and hardstandings to movable objects (aircraft, vehicles, railway cars, etc.) and to fixed obstacles (buildings, trees, rocks, and terrain irregularities) are prescribed (see Fig. 10) to assure the elimination of all objects that may constitute hazards to the safety of aircraft. Buildings are not permitted between the ends of runways and the boundary of the reservation in the area extending 750 ft each side of the runway center line prolonged, even though such buildings would not project above the approach plane of 1 on 40.

Layout, Dimensions, and Grades of Runways.—Where practicable, runways are laid out to make either 90° or 45° angles with one another, permitting landings and take-offs within 22½° of any prevailing wind. Runways usually are oriented with the eight principal directions, but this may be varied to decrease the amount of grading required, to permit clear approach, or to aline runways in directions best suited to future extension.

Current prescribed dimensions for runways call for 7,000-ft length at sea level, of which only 5,000 ft is initially graded and paved, the remaining 1,000 ft at either end constituting the clear zone. The normal width is 500 ft of graded area, of which the center 150-ft strip is paved. Sometimes, 75-ft shoulders on either side of the paved strip are authorized. For every 1,000 ft above sea level, runway length is increased 500 ft.

Fig. 9.—Safety Provisions in Airfield Design

Maximum allowable grades are as follows: For runways, 1.5% longitudinal and transverse; for turfed all-over fields, 3% in any direction (except where the field is included within a runway field, when 1.5% in any direction applies); and, for surfaced all-over fields, 1.5%. When runways are designated for 120,000-lb gross load, the maximum allowable longitudinal grade is 1%, although 0.5% is preferred.

FIG. 10.—REGULATIONS FOR THE DESIGN OF RUNWAYS, CLEAR ZONES, AND APPROACH ZONES

Grade change tolerances are illustrated in Fig. 11. The minimum distance between points of intersection (P.I.) at grade changes is 1,000 ft. Parts of a runway having different longitudinal grades are joined by a vertical curve at least 666 ft long for each per cent of the algebraic difference between the two grades. This relationship is maintained for a distance of at least 150 ft from the center line of the runway. Runways are graded for unobstructed visibility between any two points 10 ft above the surface of the runway. If the runway is longer than 7,000 ft, clear visibility is maintained between any two points 10 ft above the surface and 7,000 ft apart.

Airplane Parking Areas.—Although frequently it is feasible to park aircraft on turf, the wear resulting from traffic, propeller blasts, and spillage of oil and gasoline, often renders the turf unusable, and paved parking spaces are necessary. Parking spaces usually are large aprons in the vicinity of maintenance and repair facilities; however, individual hardstandings sometimes are provided in lieu of a center parking apron.

Where conditions permit, the parking apron is placed parallel to the runway upon which the greatest volume of traffic is anticipated, thus shortening the amount of taxiing required by aircraft and permitting full observation of traffic from the control tower. The maximum allowable grade on aprons is 1.5% in any direction. At hardstandings, a small servicing apron is constructed adjacent to the maintenance and repair buildings. Size of parking apron is based upon the number and type of aircraft to be parked on it.

Taxiways.—Ordinarily, taxiways are laid out in straight lines, with angle turns not sharper than 90°, and avoid crossing runways or other taxiways. The standard width for taxiways is 50 ft, with a 12.5-ft shoulder on each side.

Fig. 12.—Permissible Grade Changes for Taxiways

Maximum allowable grades are 2.5% longitudinal and 1.5% transverse. Portions of taxiways having different grades are connected by vertical curves having a minimum length of 100 ft for every per cent of algebraic difference between the grades. Vertical curves of less than 300 ft are not permitted under any circumstances, and the minimum distance between points of grade intersections is not less than 750 ft. Examples of permissible grade changes are shown in Fig. 12.

SUMMARY

The trend toward heavier wheel airplane loadings has led to a reexamination of the methods used in the design of airfield pavements. As a result of this reexamination it has become apparent that testing procedures for the evaluation of subgrades and for the economical use of base courses and pavements must be conducted under carefully controlled conditions if efficient and economical designs are to be attained.

Good designs may be vitiated by poor construction and high quality construction control (inspection) is essential.

Accelerated field traffic tests and service performance of airfields have verified the methods of design and construction described. Continuing observations of pavement performance may lead to further revisions and refinements in the design and construction procedures.

Proper design and construction of drainage facilities are essential both to effective pavement performance and the safe use of airfields.

Site layouts must be based on uniform standards with respect to grades and clearances. These standards have been progressively raised as size and landing speeds of airplanes have increased.

DESIGN OF DRAINAGE FACILITIES

By Gail A. Hathaway,[3] M. Am. Soc. C. E.

Synopsis

The primary purpose of this paper is to suggest procedures for the design of drainage facilities for airfields utilizing surface pondage for temporary storage of runoff from high intensity storms of short duration. Diagrams have been developed by means of which relationships can be determined between drain-inlet capacities, maximum storage volumes, and the duration of rainfall, for the frequency curve selected, that will produce the maximum rate of runoff for the specific area involved. Standard rainfall intensity-duration curves applicable to the continental area of the United States were derived to represent average rates of rainfall for various durations that have the same average frequency of occurrence. The relationship of overland flow and peak runoff rates to various standard rainfall intensity-duration curves is demonstrated and a typical layout and sample computations for the drainage system of an airfield have been included.

General

A drainage system for an airfield normally serves three functions: Interception and diversion of surface and ground-water flow originating from lands adjacent to the airfield area; removal of surface runoff from the airfield; and removal of ground-water flow (gravitational water) from the airfield area. The respective facilities may be combined or separate depending upon local conditions.

To assure stable soil conditions, subsurface drainage of an airfield is essential in many cases. The need for, feasibility of construction of, and probable efficacy of subsurface drainage should be determined by a study of soil and ground-water conditions at the proposed airfield, but, in general, the efficient removal of surface runoff by a carefully designed storm drainage system will minimize the need of extensive subsurface drainage. Inasmuch as the scope of this paper pertains primarily to surface drainage, discussion of subsurface drainage is limited to the foregoing comments.

The design capacity of the storm drainage systems should be adequate to accomplish the following objectives within the range of economic feasibility, with proper consideration being given to the purpose and importance of the particular airfield:

(*a*) Removal of surface runoff that would result from the selected "design storm," without damage to field facilities, undue saturation of subsoil, or significant interruption of normal traffic;

---

[3] Head Engr., War Dept., Office, Chf. of Engrs., Washington, D. C.

(*b*) Removal of surface runoff from storms greater than the "design storm" with the minimum damage to field facilities and with shortest interruption of normal traffic that is practicable;

(*c*) Maximum reliability of operation practicable under all climatic conditions;

(*d*) Minimum maintenance and operation difficulties and expense; and

(*e*) Adaptability to future expansion of airfield drainage facilities with the minimum of expense and interruption of normal traffic.

The importance of careful planning in the preparation of grading plans for an airfield scarcely can be overemphasized. In many instances, the need for expensive underground drains in sections of a field may be avoided by grading the surface to facilitate natural drainage. In other cases required drain capacities may be reduced greatly by shallow ponding basins in intermediate areas between the runways where runoff from intense short-duration rainfall may be stored for brief periods of time without interfering with the use of runways and other essential areas. On the other hand, improper planning of grading details may cause flooding of an important area in one section of the airfield while the drainage facilities in other sections of the field are taxed to only part of their capacity.

The major limitations on grading are as follows: Maximum longitudinal and transverse grade for runways and aprons is 1.5%, except in the case of fields used by four-motored planes, where the maximum longitudinal grade for runways is 1%. A clear graded shoulder should be provided along each side of each runway to a minimum width of 250 ft from the runway center line. The selected transverse grade for the runway pavement is continued to the edge of the stabilized shoulder, 75 ft from the edge of the runway pavement. Beyond this point the shoulder may be sloped longitudinally to drain into inlets located at least 250 ft from the runway center line. In this area the maximum longitudinal and transverse grade of 1.5% is necessary to develop the ponding areas at drain inlets. Along the line of inlets, generally located about 250 ft from the center line of the runway, a maximum allowable grade change not to exceed a 2% algebraic difference is permitted. Grade changes along this line should be connected by vertical curves of not less than 300 ft. Turfed all-over fields which are used only by light-weight aircraft with traffic dispersed over the entire area, have a permissible maximum grade in any direction of 3%. The maximum change in grade which may be made within a distance of 100 ft is 1%.

It is common practice to design storm drains to provide for disposal of runoff from rainfall having certain average recurrence intervals or frequency of occurrence. The rainfall intensity corresponding to a particular frequency of occurrence varies appreciably with the duration of the rainfall, the average rate for a period of 5 min usually being several times as high as the average for a period of 1 hr. A study of rainfall intensity-frequency data for a large number of precipitation stations indicates that there are fairly consistent relationships between the average intensity of rainfall for a period of 1 hr and the average rates of comparable frequency for shorter intervals, regardless of the geo-

graphical location of the stations or frequency of 1-hr rainfall. Consequently standard curves may be developed to express the rainfall "intensity-duration" relationships with an accuracy satisfactory for airfield drainage problems.

"Standard rainfall intensity-duration curves" were derived for use in airfield drainage problems in the following manner:

(*a*) The area of the United States was divided into 2° quadrangles;

(*b*) Using data from charts compiled by the late David L. Yarnell, M. Am. Soc. C. E. (15), as shown in Fig. 13, and other available information, 1-hr representative rainfall intensities for each 2° quadrangle were plotted against average rates of comparable frequency for intervals of 5, 10, 15, 30, 120, and 240 min, respectively, using data for average frequency of occurrence of once in 2, 5, 10, 25, 50, and 100 years, respectively.

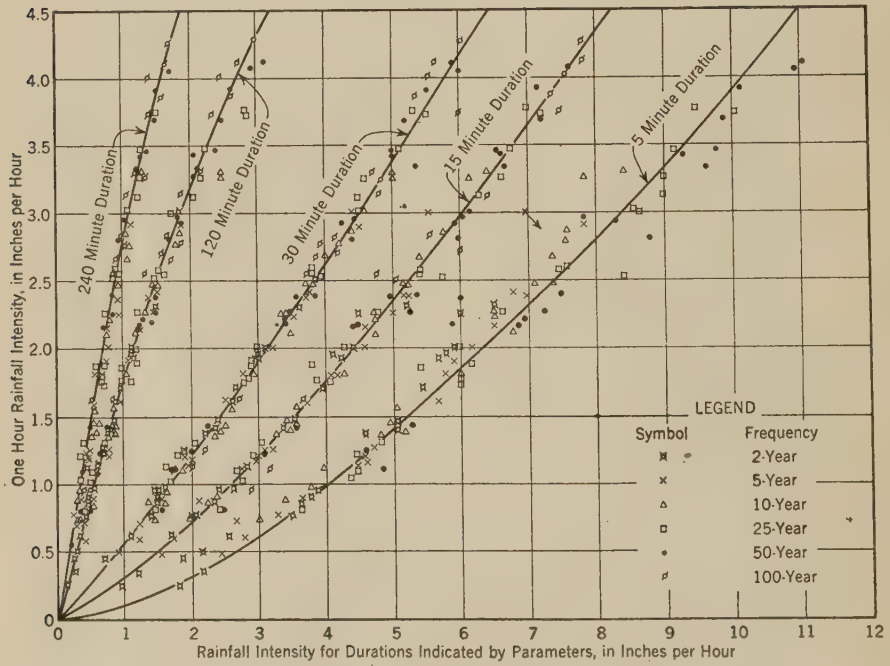

FIG. 14.—RELATION OF 1-HR RAINFALL INTENSITIES TO INTENSITIES FOR DURATIONS OF 5, 15, 30, 120, AND 240 MIN

(*c*) Curves, representing approximately the average of the points plotted in step (*b*), were drawn (see Fig. 14), and data scaled from these curves were replotted in the form shown in Fig. 15. Results of the study indicate that the curves in Fig. 15 may be adopted as general standards in airfield drainage problems with a satisfactory degree of accuracy. For convenience in reference these curves are numbered to correspond with the 1-hr rainfall intensity represented.

Design Storm Criteria

The term "design storm criteria" refers to the rainfall intensity-duration curve adopted as a basis of design for determining the capacity of storm drain facilities for a particular area. The rainfall intensity-duration curves are derived to represent average rates of rainfall for various durations that have the same average frequency of occurrence. Such intensity-duration curves are computed from data for a number of storms; consequently, all of the intensities represented by a particular curve may not be expected in the same storm—at least not with the frequency indicated. For example, if curve No. 2.0 in Fig. 15 represents a 10-yr rainfall frequency at a particular station, it is implied that on the average of once in 10 years a rainfall will occur averaging 3.1 in. per hr for a period of 30 min. This is also shown in Fig. 14 as the point where the 2.0-in. 1-hr rainfall intensity intersects the 30-min duration curve. Although the precipitation continues for a 30-min period at the rate of 3.1 in. per hr, the rain that falls in 30 min totals only 1.55 in. Similarly it is to be expected that on the average of once in 10 years rainfall will average 4.4 in. for a period of 15 min. The precipitation may end at 15 min or continue at some rate equal to or lower than curve No. 2.0, and the intensity for periods less than 15 min may be equal to or less than curve No. 2.0.

The rainfall intensity-duration value required to produce the maximum drain-inlet discharge corresponding to a given design storm criterion, taking into consideration all drainage area characteristics and ponding effects, is referred to herein as the "design storm rainfall." To simplify the preparation of generalized diagrams for estimating drain-inlet capacities required under various conditions for design storm runoff, the following approximations pertaining to the rainfall intensity-duration relations have been accepted:

(*a*) Each standard rainfall intensity-duration curve shown in Fig. 15 is assumed to represent average rates of rainfall for separate storms of various duration that have the same average frequency of occurrence; and

(*b*) Rainfall is assumed to be of uniform intensity during each individual storm, and to end at the duration corresponding to the particular rate on the given intensity-duration curve.

The design-storm frequency serves as an index to the average frequency with which some portions or all of the storm-drain system will be taxed to capacity. The selection of a design-storm frequency for a particular project must be based primarily upon judgment, with consideration of the purpose and importance of the given airfield, and such economic and engineering limitations as may exist. Design-storm frequencies ranging from 2 to 10 years are generally adopted for airfields depending, of course, upon the importance of the field as determined by the class and volume of traffic to be accommodated, the necessity for uninterrupted service and similar factors. It should be observed that, after having selected the design-storm frequency for the particular airfield involved, computations must be made to determine the duration of rainfall for the frequency curve selected that will produce the maximum rate of runoff for the specific area involved. The duration of rainfall required to produce the maximum rate of runoff will depend primarily upon the length of overland flow, taking into account surface detention, roughness factor, and other surface runoff characteristics.

The design-storm frequency alone is not a reliable criterion of the adequacy of storm drain facilities. In many instances, storms appreciably more severe than the design storm may cause very little damage or inconvenience, whereas in other cases flooding of important areas may result. It is generally advisable to investigate the probable consequences of storms more severe and less frequent than the design storm, before making a final decision regarding the adequacy of drain-inlet capacities.

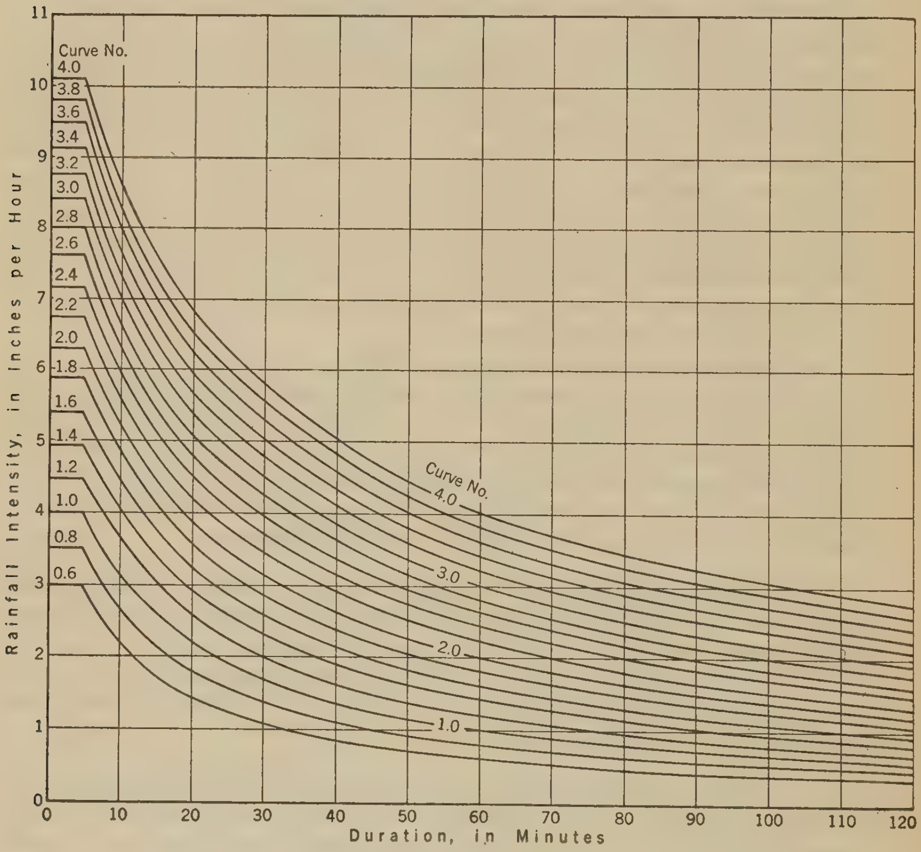

Fig. 15.—Standard Rainfall Intensity-

Notation

DURATION CURVES; OR, STANDARD SUPPLY CURVES

M = an exponent dependent upon the type of overland flow;

n = coefficient of roughness;

Q = drain capacity, in cubic feet per second, at a designated point;

Q_d = drain-inlet capacity, in cubic feet per second;

q = rate of overland flow at the lower end of an elemental strip of turfed, bare, or paved surface, in inches per hour or in cubic feet per second per acre of drainage area;

q_d = drain-inlet capacity, or maximum rate of outflow from a ponding basin, in cubic feet per second per acre of tributary drainage area;

q_p = peak runoff rate, in inches per hour or cubic feet per second per acre of drainage area;
S = slope of surface, or the hydraulic gradient;
t = time, or duration, in minutes; time from the beginning of supply:
t_c = critical duration of supply; that is, the duration of rainfall excess (rate of supply) corresponding to a given "standard supply curve" that would produce the maximum rate of outflow from a given drainage area, taking into account surface detention and the surface runoff characteristics;
t_d = time required for water to travel from a specified inlet to a given point in the drainage system;
t_l = critical duration of supply for an elemental strip of effective length L;
t_r = duration of supply, in minutes;
t_σ = duration corresponding to the assumed supply rate σ;
X = ratio of $\frac{q_p}{q_d}$; defined by Figs. 22 and 25;
y = depth, in inches; and
σ = rate of supply, or rainfall in excess of the rate of infiltration.

INFILTRATION CAPACITY

In view of the several variations that affect the infiltration capacity of a given soil, it is impracticable to determine accurately the infiltration capacity that should be assumed to apply during storms of various durations and frequencies. The rate of infiltration is a variable that changes not only during the course of a storm but also during a season. Moreover, the infiltration rate changes with the type of soil structure, soil cover, temperature (air, soil, and water), moisture content of soil, turbidity of the water, and the amount of organic matter in the soil. The use of cover on the land, such as grass turf, serves as a protection from the impact of rain, retards the rate of runoff and thereby reduces the velocity of overland flow and turbidity, thus permitting a greater infiltration of water into the soil. Rates of infiltration on bare soil can be expected to be considerably less than for turfed areas. For use in connection with the design of storm drains for a particular airfield, the infiltration capacity that is estimated to be characteristic of the given soil, following a rainfall of 1 hr, serves as the most convenient index to the probable volume of loss through infiltration during the design storm.

The term "rate of supply" (σ) refers to the difference between the rainfall intensity and the infiltration capacity at the same instant of a particular storm. To simplify computation procedures, the rainfall intensity and the infiltration capacity are assumed to be constant during any specific storm. On this premise, the rate of supply during a particular storm would also be uniform. The average rates of supply corresponding to storms of different lengths and the same average frequency of occurrence may be computed by subtracting estimated infiltration capacities from rainfall intensities represented by the proper curve in Fig. 15. For convenience and since no appreciable error results, "standard supply curves" are assumed to be the same shape as the curves in

Fig. 15. The "standard supply curve" number corresponding to a given "standard rainfall curve" number is computed by subtracting the estimated 1-hr infiltration value from the 1-hr rainfall quantity.

OVERLAND FLOW EQUATIONS

The term "overland flow," as used herein, relates to surface runoff resembling sheet flow before it has reached a defined channel or ponding basin. Robert E. Horton, M. Am. Soc. C. E., has developed the following general equation that indicates the rate of overland flow to be expected from a uniform rate of rainfall-excess, or "rate of supply," assuming flow characteristics ranging from fully turbulent to laminar (18):

$$q = \sigma \tanh^M \frac{M+1}{M} (\sigma\, K)^{1/M} \frac{t}{60} \ldots\ldots\ldots\ldots\ldots (2)$$

In Eq. 2, q is the rate of overland flow at the lower end of an elemental strip, in cubic feet per second per acre, or inches per hour; σ is the rate of rainfall in excess of infiltration, in inches per hour; M is an exponent dependent upon the type of overland flow; K is a constant dependent upon characteristics of the drainage area involved; and t is the time from the beginning of supply, in minutes. According to Mr. Horton, this equation is strictly rational for 75% turbulent flow ($M = 2.00$) and quasi-rational for other degrees of turbulence from 33% to 100%. The constant K involves slope, roughness and length of overland flow, and percentage of turbulence, and may be expressed by the equation:

$$K = \frac{1{,}020 \sqrt{S}}{I\, n\, L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

In Eq. 3, S is the surface slope; I is the factor of turbulence; n is the coefficient of roughness; and L is the length of an elemental strip of turfed or paved surface in a direction parallel to the maximum slope. The exponent M is equal to 3.00 for laminar flow and $\frac{5}{3}$ for fully turbulent flow; therefore, the factor of turbulence I is given by the equation:

$$I = \frac{3}{4} (3.0 - M) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

For average airfield surfaces, 75% turbulence, corresponding to $M = 2.00$ in overland flow, may be assumed although the percentage of turbulence would be lower for a "dense" grass cover and somewhat higher for very smooth pavement. Substitution of the value $M = 2.00$ in Eq. 2 gives the following formula for the rate of overland flow corresponding to 75% turbulence:

$$q = \sigma \tanh^2 \left[0.922\, t \left(\frac{\sigma}{n\, L} \right)^{0.50} S^{0.25} \right] \ldots\ldots\ldots\ldots\ldots (5)$$

The factor n in the preceding formulas has the same meaning for overland flow as it has for channel flow but is made up differently. Mr. Horton points out that, in the case of a stream channel, n shows the combined resistance effect of true rugosity, bends, noneffective cross section in eddies, bays, and deep holes, and expansion and contraction of cross section. All of these factors except true boundary rugosity may be of small importance in a stream channel, but they are often the major factors in case of overland flow. Available data indicate that the following values of the coefficient of roughness n are approximately representative of surfaces encountered in airfield drainage problems:

Surface	Value of n
Smooth pavements	0.02
Bare, packed soil, free of stone	0.10
Poor grass cover, or moderately rough bare surface	0.20
Average grass cover	0.40
Dense grass cover	0.80

In certain approximate computations of overland flow rates, average roughness values for inlet drainage area have been used. The average roughness factor applicable to a drainage area consisting of a combination of paved and unpaved surfaces (or any combination of surfaces having dissimilar roughness characteristics) may be estimated by selecting values of the coefficient n applicable to the respective surfaces and weighting the values in proportion to the surface areas.

The series of overland flow curves for paved and turfed areas shown in Fig. 16 were computed by the use of Eq. 5, assuming S equal to 1% and n equal to 0.02 for pavements and 0.40 for turf. However, these curves may be applied to surfaces having other roughness factors or surface slopes by using, instead of the actual length L of the surface involved, a hypothetical length that is greater or less than the actual length by a sufficient margin to compensate for the difference between the correct values of n and S and those used in preparing the curves shown in Fig. 16. The values of L may be converted easily by the use of Fig. 17, as follows:

(*a*) *Fig. 17(a)*.—The rate of overland flow indicated by Eq. 5 is a function of the product of $n\,L$; hence, any combination of n and L values that give the same product will result in the same rate of discharge. Thus, a surface having a roughness factor n of 0.40 and a length L of 100 ft would produce the same rate of overland flow as one having an n-value of 0.20 and a length of 200 ft, other factors being the same. The curves in Fig. 17(*a*) represent similar relationships for various values of n.

(*b*) *Fig. 17(b)*.—The discharge rate represented by Eq. 5 is also a function of the quotient $\frac{S^{0.25}}{L^{0.50}}$. Therefore, the overland flow curves in Fig. 16, computed for a slope of 1%, may be applied to a surface having any other slope, if compensating corrections in the value of L are made in accordance with Fig. 17(*b*).

INFLOW HYDROGRAPHS

The rates of runoff from turfed areas of various lengths that would result from continuous and uniform rates of rainfall-excess (rates of supply) are represented by the overland flow rates in Fig. 16. For example, with a continuous and uniform rate of supply (σ) of 2 in. per hr and a length of 100 ft, the

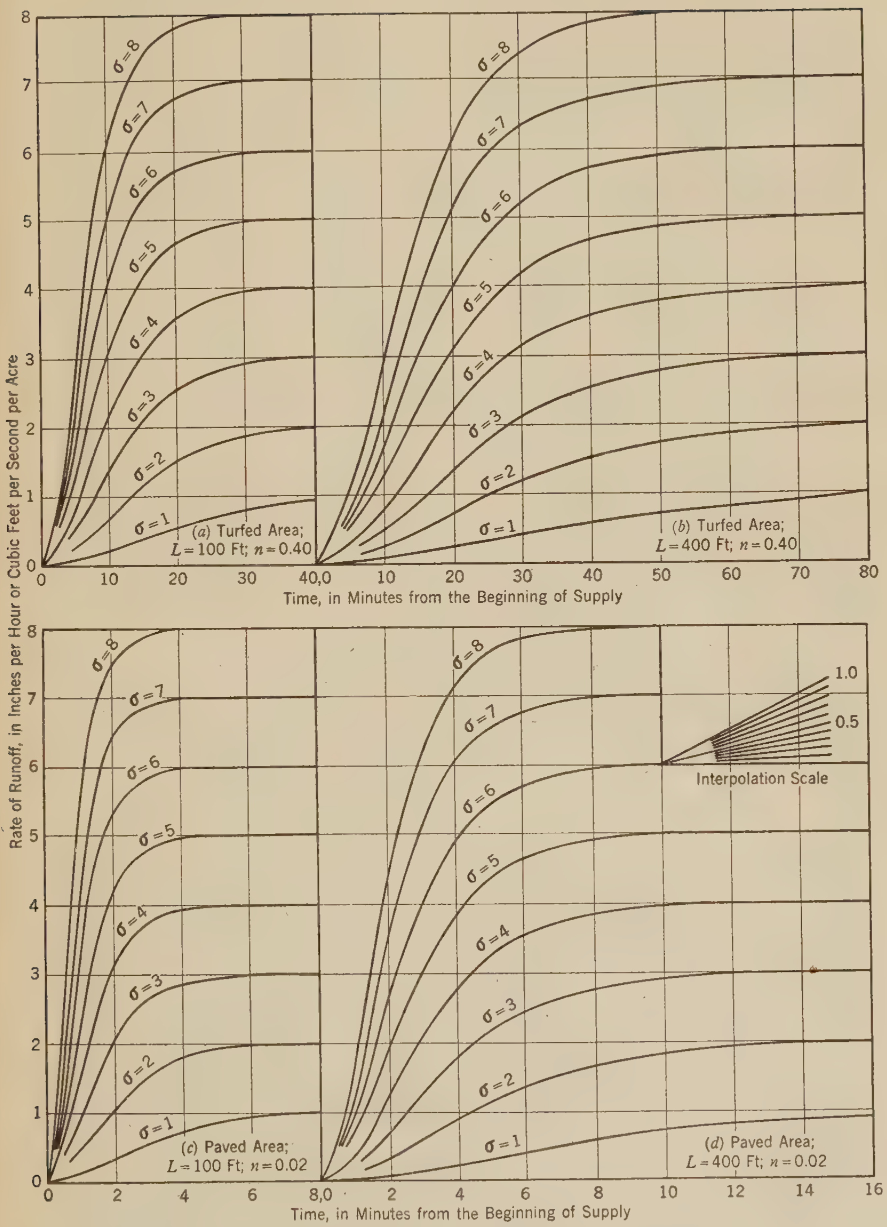

FIG. 16.—OVERLAND FLOW RATES VERSUS DURATION OF SUPPLY FOR PAVED AND TURFED AREAS WITH MAXIMUM SURFACE SLOPE, S, OF 1%

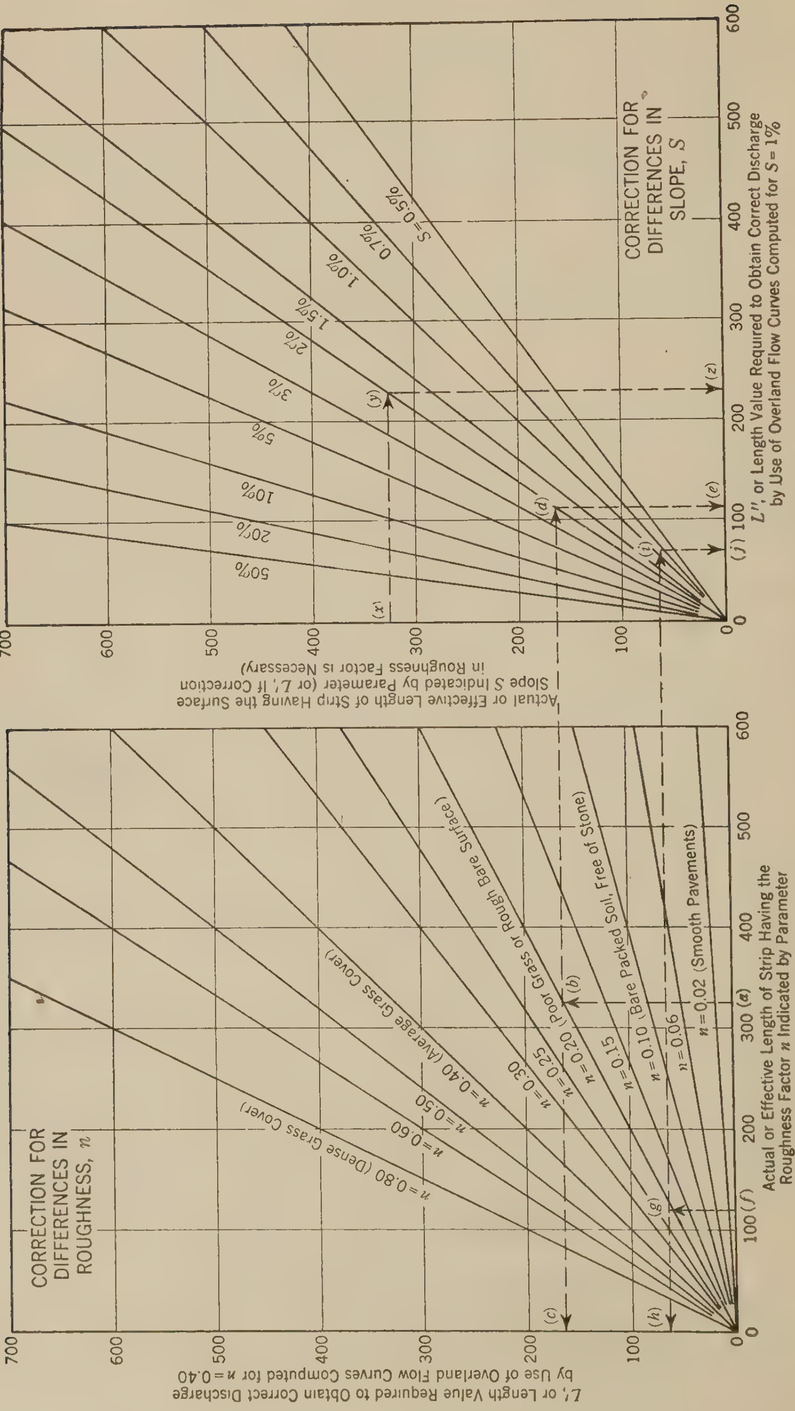

FIG. 17.—MODIFICATION IN L REQUIRED TO COMPENSATE FOR DIFFERENCES IN n AND S

rate of overland flow 25 min after the beginning of supply would be 1.7 in. per hr. Similarly, the rate of overland flow 40 min after the beginning of supply would be 2.0 in. per hr. Hydrographs of runoff corresponding to any selected duration and rate of rainfall excess may be computed from the overland flow rates indicated in Fig. 16 by the procedure shown in Fig. 18. The overland flow curve No. 1, of Fig. 18, represents the runoff hydrograph from an elemental strip of turf 400 ft in length assuming a continuous and uniform rate of supply (σ) of 4 in. per hr. The ordinates of the overland flow curve can be considered to be the sum of the corresponding ordinates of a series of identical runoff hydrographs (2, 2A, 2B, 2C, etc., not as yet determined) resulting from a continuous series of short rainfall periods of specified duration—for example, 20 min. Overland flow curve No. 1A is the same curve as No. 1, but is translated horizontally a time distance equal to the selected duration of 20 min, and represents the runoff for a continuous and uniform rate of supply of 4 in. per hr beginning 20 min after that of curve No. 1. Hydrograph No. 2 is obtained by subtracting the ordinates of No. 1A from the ordinates of No. 1 and approximately represents the runoff hydrograph to be expected from a supply rate of 4 in. per hr for a duration of 20 min. This is verified readily by a consideration of the composition of overland flow curves No. 1 and No. 1A at any particular time, say, for example, at 60 min. Hydrograph No. 2 (identical to 2A, 2B, etc.) must be such that the sum of the first 20-min value, *a*, of No. 2B, plus the second 20-min value, *b*, of No. 2A, plus the third 20-min value, *c*, of No. 2, equals the

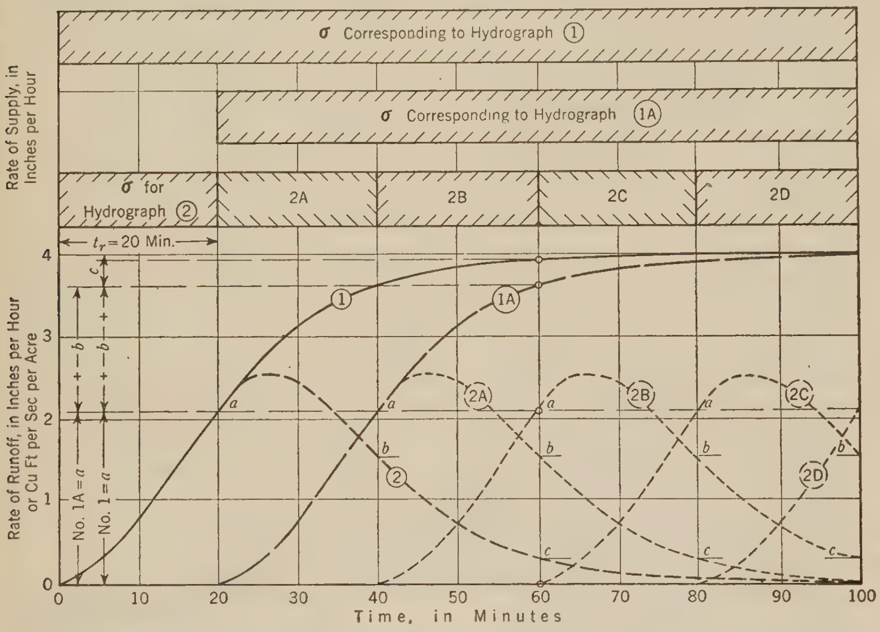

FIG. 18.—COMPUTATION OF HYDROGRAPH TO REPRESENT RUNOFF FROM A SUPPLY OF SPECIFIED DURATION

ordinate of No. 1 at 60 min. However, No. 1A at 60 min equals No. 1 at 40 min by construction, and No. 1 at 40 min is equal to ordinate a of No. 2A plus b of No. 2. Since hydrographs 2, 2A, 2B, etc., are identical, all a ordinates are equal to each other as are the b, c, etc., ordinates. Thus at the time of 60 min No. $1 = a + b + c$ and No. $1A = a + b$. It follows that the ordinates of No. 1 minus the ordinates of No. 1A equal c, which is the 60-min value of hydrograph No. 2.

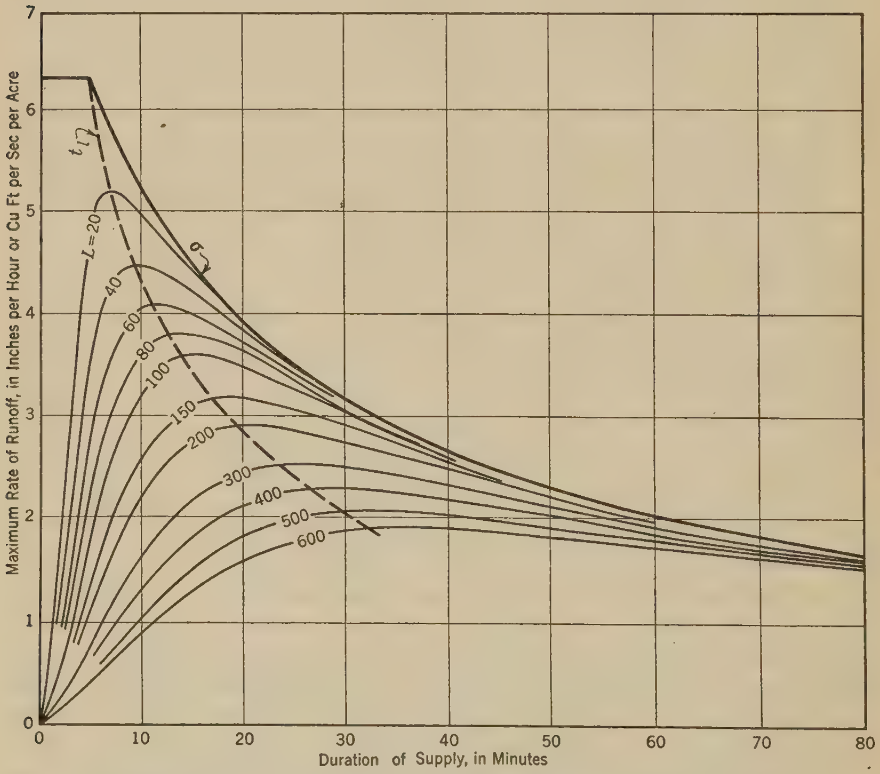

Fig. 19.—Supply Curve No. 2.0; Rates of Overland Flow Corresponding to Standard Supply Curves; $n = 0.40$, and $S = 1\%$

The curves shown in Fig. 19 have been included for the purpose of demonstrating the relationship between the maximum rate and critical time of runoff (t_l) for various lengths L of overland flow and a specific supply curve. The curves were obtained by computing the rates of discharge at successive time intervals that would result from the various rates of supply σ, corresponding to standard supply curve No. 2.0 by application of the overland flow curves shown in Fig. 16. The procedure is illustrated by the sample computations in Table 2. To illustrate the procedure, durations of supply of 12, 20, and 35 min were selected and have been marked by dotted lines in Fig. 20. The rates of supply (scaled from No. 2.0 curve) for durations of 12, 20, and 35 min are 4.83, 3.85, and 2.84 in. per hr, respectively (see Col. 2, Table 2, and points on curve A, Fig. 20). The overland flow rate was then scaled by interpolation between $\sigma = 4$ and $\sigma = 5$ (from curves similar to those shown in Fig. 16) for a length of 200 ft, a duration of 12 min, and a supply rate of 4.83 in. per hr, and determined to be 2.41 in. per hr (see Col. 6, Table 2, and the point on curve B, Fig. 20). The foregoing runoff values are accepted as the maximum under the assumption that surface storage is negligible. Actually the maximum runoff would occur a short time after the rainfall-excess ceases. For all practical purposes, however, the maximum rate of overland flow can be assumed to occur approximately at a time coincident with the ending of the rainfall-excess.

TABLE 2.—RATES OF OVERLAND FLOW CORRESPONDING TO INTENSITIES AND DURATION OF SUPPLY REPRESENTED BY STANDARD SUPPLY CURVE NO. 2.0 IN FIG. 15

[a] Scaled from curve No. 2.0, Fig. 15. [b] As scaled from diagrams similar to those shown in Fig. 16. [c] Critical duration of supply interpolated from Fig. 19.

Attention is directed to the fact that the curves in Fig. 19 are not hydrographs for any specific design storm, but represent the peak rates of runoff from individual storm events of various durations, all of which have the same average frequency of occurrence. The duration of supply corresponding to the maximum discharge for a particular standard supply curve and value of L in Fig. 19 is indicated by the broken line designated as t_l, the "critical duration of supply," defined as "the duration of rainfall-excess (rate of supply) corresponding to a given standard supply curve that would produce the maximum rate of outflow from a given drainage area, taking into account surface detention and surface runoff characteristics."

The curves in Fig. 16 represent the rate of overland flow that would result from various continuous rates of supply of uniform intensity. The maximum rate of runoff for the respective uniform supply rates occurs at a time ordinarily referred to as the "time of concentration," when the rate of runoff becomes equal to the rate of supply. Curves A, B, and C of Fig. 20 are defined as follows:

A.—Standard supply curve No. 2 (Fig. 15 and Col. 2, Table 2);
B.—Maximum rates of overland flow corresponding to specific intensities and durations of supply represented by the standard supply curve No. 2 (Fig. 19 and Col. 6, Table 2); and
C.—Rate of overland flow for turfed areas corresponding to a uniform continuous supply rate of 2 in. per hr.

It will be observed that the rate of runoff represented by curve C, Fig. 20, approaches quite closely the rate of supply of 2 in. per hr at a time 60 min after the beginning of supply. Curve B, Fig. 20, represents the maximum rates of overland flow corresponding to specific intensities and durations of supply selected from curve A. Curve B is approximately equal to the rate of supply

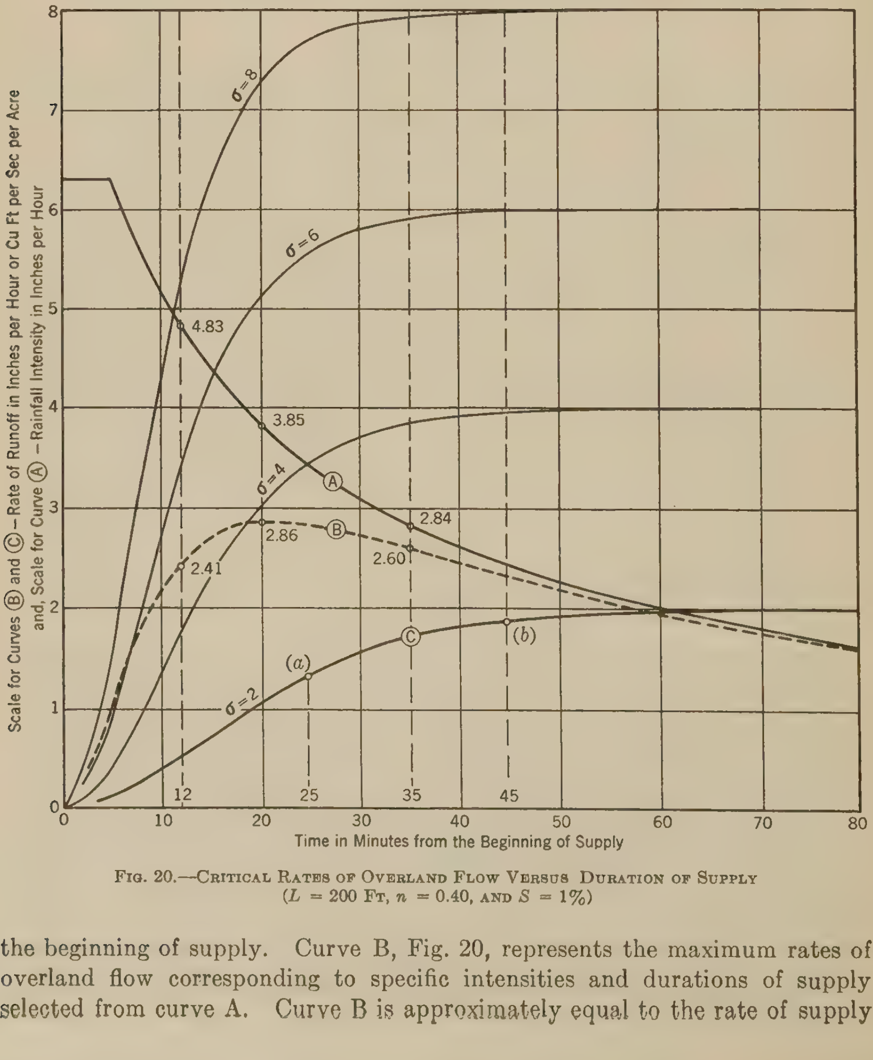

Fig. 20.—Critical Rates of Overland Flow Versus Duration of Supply ($L = 200$ Ft, $n = 0.40$, and $S = 1\%$)

of 2 in. per hr as represented by curve A at a duration of 60 min and is equal to curve C at 60 min. However, further inspection of curve B shows that a discharge greater than that represented by curve C at 60 min will result from durations of supply having the same average frequency (curve A) but higher intensities and shorter durations. In other words, under the assumed conditions, the maximum rate of overland flow for intensities and durations of supply represented by curve A and a length of 200 ft occurs with a supply rate of 3.85 in. per hr and a duration of supply of 20 min (see curves A and B, Fig. 20).

DRAIN-INLET CAPACITY VERSUS SURFACE-STORAGE RELATIONSHIPS

If the rate of outflow from a drainage area is limited by the capacity of a drain serving the area, runoff occurring at rates exceeding the drain capacity must be stored temporarily. As soon as the rate of inflow into the ponding basin becomes less than the drain capacity, the accumulated storage may be drawn off at a rate equal to the difference between the drain capacity and the rate of inflow into the basin. The general relation between inflow, storage, and outflow is expressed by the equation:

$$\text{Outflow} = \text{inflow} \pm \text{storage} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

The rate of outflow from a ponding basin is affected somewhat by the elevation of the water surface at the inlet to the drain serving the area, the rate of outflow increasing as the head on the inlet increases. However, because of the flat slopes of airfield areas, the surfaces of the storage ponds surrounding the drain inlets are usually very large in comparison with the depth of water at the inlets. Therefore, it is reasonable to assume that the rate of outflow through a particular drain inlet would be approximately constant as long as the rate of runoff and accumulated storage are sufficient to maintain the full discharge capacity of the drain inlet serving the particular area. It is also assumed that the rate of outflow would equal the rate of inflow into the pond until the full discharge capacity of the drain inlet is attained. To illustrate these assumptions reference is made to the curves shown in Fig. 21 for a length $L = 400$ ft, $S = 1\%$, $n = 0.40$, and a uniform "rate of supply" (σ) of 4 in. per hr for a duration of 20 min. Length L was chosen to represent the weighted mean distance from the limits of the drainage area to the average limits of the pond. Hydrographs 1, 2, and 3, Fig. 21, are:

1. Runoff that would have occurred if the given rate of supply (4 in. per hr) had continued indefinitely;
2. Runoff from a supply of 4 in. per hr for a duration of 20 min; and
3. Rate of outflow, assuming the inlet capacity as designated, and a constant head-discharge relation.

Hydrograph 3, Fig. 21, would represent the constant rate of outflow corresponding to the inflow hydrograph 2 if the drain-inlet capacity were assumed to be 1.25 cu ft per sec per acre of drainage area. The volume of storage above the outflow hydrograph 3 and below the inflow hydrograph 2 that would be accumulated at successive intervals of time under these conditions is indicated by curve 4, Fig. 21. The maximum volume of storage that would accumulate under these particular conditions is 1,350 cu ft per acre of drainage area and the end of the accumulation period occurs approximately 43 min after the beginning of runoff.

DISCHARGE-STORAGE DIAGRAM

Hydrograph 2, Fig. 21, represents the rate of runoff from one acre of turf with a length of 400 ft, a coefficient n of 0.40, and a slope of 1%, assuming a uniform value of σ equal to 4 in. per hr for a duration of 20 min. A series of hydrographs similar to hydrograph 2 was computed for a "rate of supply" of 4 in. per hr and for durations of supply of 10, 20, 30, 40, 50, and 60 min, successively. In each case the drainage area was taken as 1 acre and the "effective length" (L) as 400 ft. The volumes of runoff under the respective hydrographs and above abscissas representing discharge rates (drain-inlet capacity), similar to that of hydrograph 3 in Fig. 21, equal to 25%, 50%, and 75% of the peak ordinates thereof, were measured by planimeter. The volumes thus determined represent approximately the maximum quantities of water that would be stored temporarily in surface ponds if drain-inlet capacities equal to 25%, 50%, and 75% of the peak ordinates of the inflow hydrograph were adopted. The data

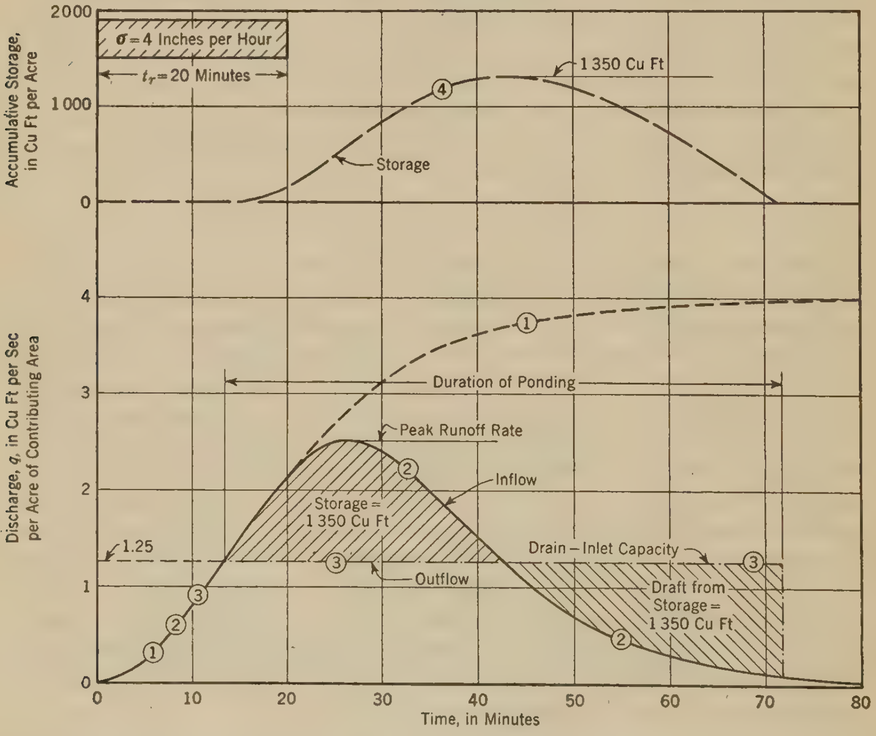

FIG. 21.—COMPUTATIONS FOR STORAGE REQUIRED WITH SELECTED DRAIN-INLET CAPACITY TO PROVIDE FOR RUNOFF FROM 1 ACRE OF TURF; L = 400 FT, n = 0.40, AND S = 1%

were plotted to obtain the series of curves in Fig. 22 for σ equal to 4 in. per hr. The same procedure was followed in developing a series of curves similar to that shown in Fig. 22 for "rates of supply" of 1, 2, 3, 4, 5, 6, 7, and 8 in. per hr assuming effective lengths (L) of 40, 100, 200, 300, 400, and 600 ft, successively. The foregoing procedure is one step in the preparation of "discharge versus storage diagrams" and Fig. 22 has been included to illustrate the step.

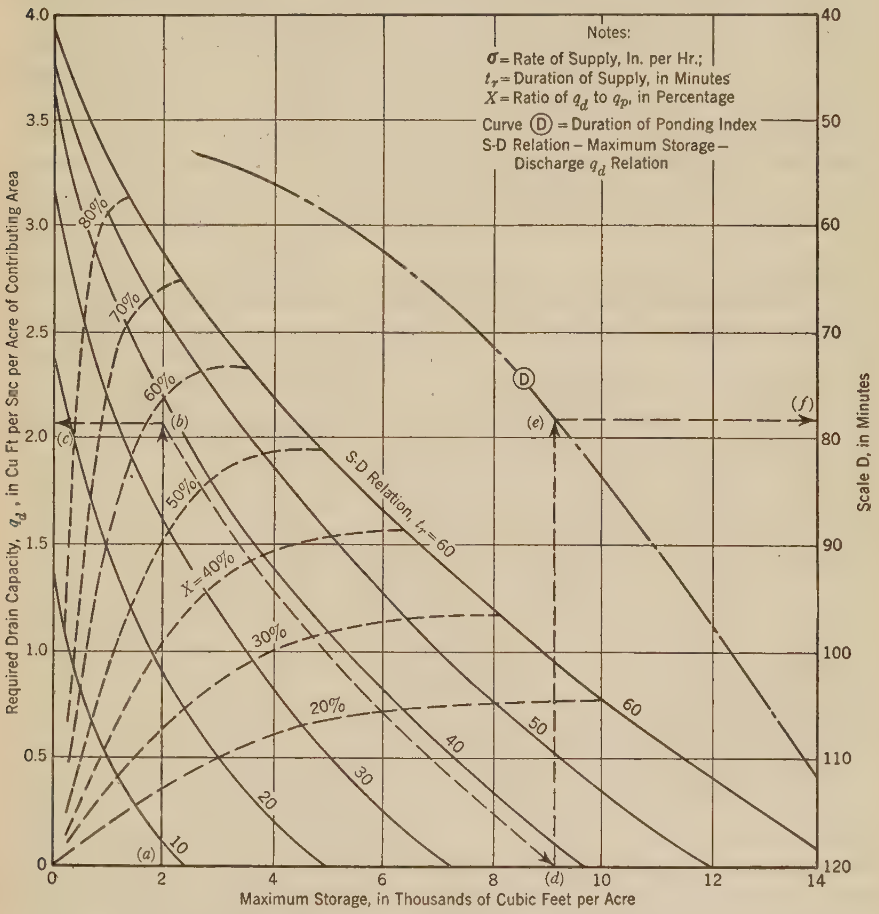

Fig. 22.—Storage-Discharge Relations for Turfed Areas; L = 400 Ft and σ = 4

Inasmuch as the volume of storage accumulated in a ponding area is a function of both the rate and duration of supply, a "trial" computation procedure is necessary to determine the drain-inlet capacity required to limit storage to a specific volume, assuming a design storm criterion represented by one of the "standard rainfall intensity-duration curves" in Fig. 15. The computations involved in this procedure are illustrated in Table 3. The series of diagrams similar to Fig. 22 was used in computing the drain-inlet capacities in Cols. 3 to 9, Table 3. "Rates of supply" (σ), corresponding to values used in preparing the diagrams in Fig. 22, were selected to avoid the need for interpolation (see Col. 1, Table 3). The durations of the supply rate corresponding to the "rates of supply" listed in Col. 1 were scaled from the "standard supply curves" in Fig. 15, and the values were placed in Col. 2, Table 3. The procedure followed in computing drain-inlet capacities required to limit surface storage to volumes indicated in the headings of Cols. 3 to 9, Table 3, assuming the various combinations of rate and duration of supply tabulated in Cols. 1 and 2, Table 3, may be illustrated by the following sample computation. Assume a turfed area for which $L = 400$ ft; $\sigma = 4$ in. per hr; $t_r = 38$ min, and a maximum permissible storage volume equal to 2,000 cu ft per acre of drainage area. The drain-inlet capacity required for the assumed condition would be determined by entering the diagram in Fig. 22 for $\sigma = 4$, at point a (storage 2,000), following a vertical line to point b ($t_r = 38$), and reading the drain-inlet capacity of 2.1 cu ft per sec per acre of drainage area at point c.

[a] Drain-inlet capacity q_d in cubic feet per second per acre of drainage area required to limit storage to the assumed volumes. These values were computed with the assistance of curves similar to Fig. 22. [b] The critical value of q_d, the maximum duration of ponding, and the critical duration of supply were used in preparing diagrams A, B, and C, respectively, in Fig. 23.

As all rates of supply represented by a particular "standard supply curve" (Fig. 15) are assumed to occur with the same average frequency, the drain-inlet capacity required for a particular area should be adequate to limit the volume of storage to the maximum permissible quantity during all storms producing supply rates corresponding to the "standard supply curve" selected as the design criteria. Accordingly, only the "critical" drain-inlet capacities indicated in Table 3 are of prime concern in the determination of design capacities for storm drains. The relationships between "critical" drain-inlet capacities, maximum storage volumes, and "standard-supply-curve" numbers corresponding to those shown in Fig. 15 have been resolved into the convenient curves, an example of which is shown in Fig. 23, diagram A.

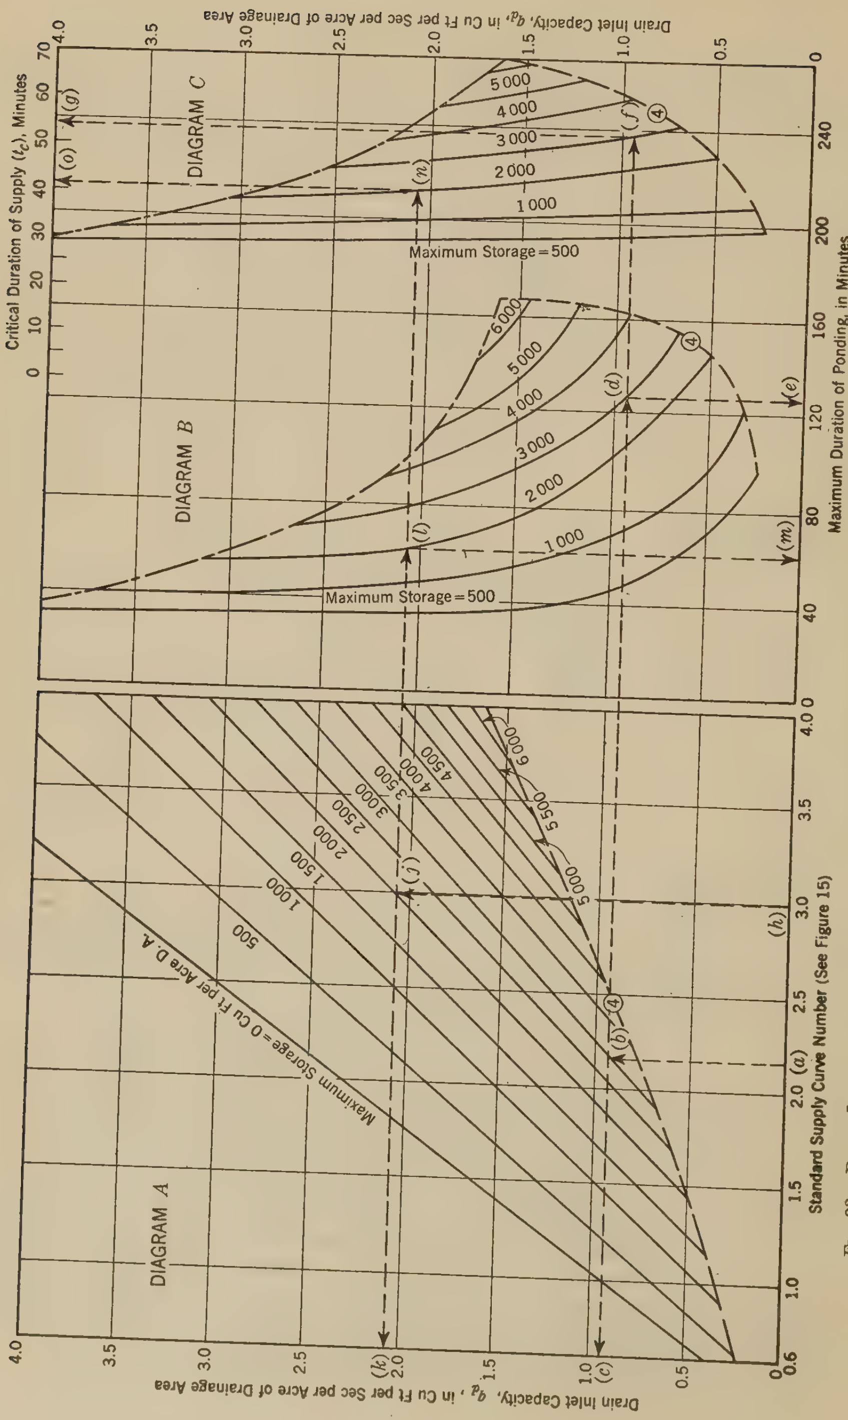

Fig. 23.—Drain-Inlet Capacity Versus Maximum Surface Storage for Turfed Areas; L = 400 Ft, S = 1%, and n = 0.40

The expression "duration of ponding" refers to a period beginning at the time the rate of storm runoff first exceeds the drain-inlet capacity and ending at the instant all the accumulated storage has been discharged (see Fig. 21). The duration of ponding corresponding to various combinations of drain-inlet capacity, permissible volume of surface storage, rate and duration of supply, and rate of runoff may be conveniently computed by use of charts similar to the one shown in Fig. 22 and the charts shown in Figs. 24 and 25.

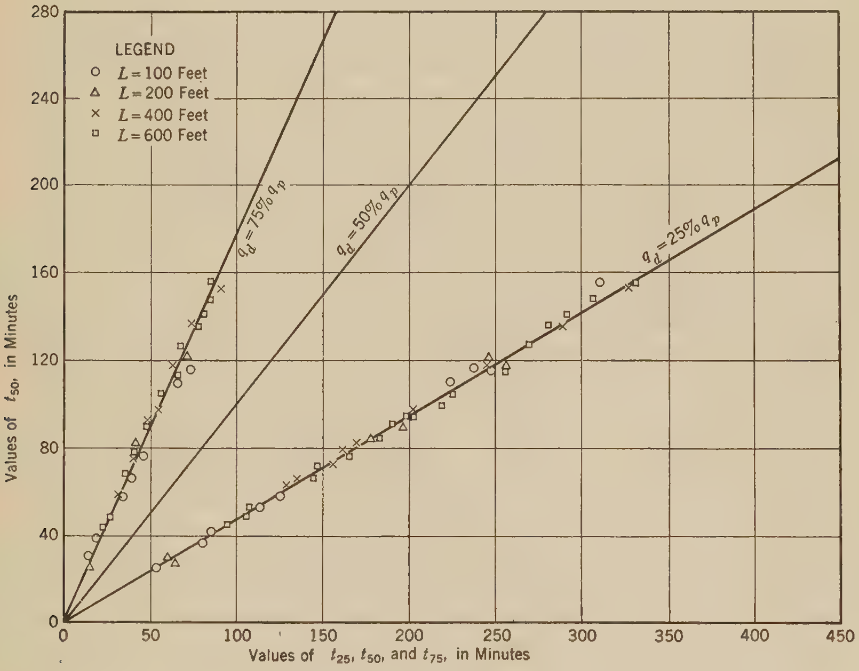

FIG. 24.—BASIC CORRELATION OF D_{50} TO D_{25} AND D_{75}

Figs. 22, 24, and 25 were included only to illustrate the manner in which the curves of diagrams A and B of Fig. 23 were derived; for example:

(*a*) The drain-inlet capacities equal to 25%, 50%, and 75% of the peak ordinates were assumed and the corresponding durations of ponding (t_{25}, t_{50}, and t_{75}) were computed by determining the length of time the drain-inlet capacity would have to remain at, say, t_{50}, in order for the accumulated volume of storage to be drawn off. This storage volume is illustrated clearly in Fig. 21.

(*b*) Values of t_{25} and t_{75}, computed in step (*a*), were plotted against corresponding values of t_{50} to determine average relationships for drain-inlet capacities equal to 25% and 75% of the peak rates of runoff for various sets of conditions (see Fig. 24). (Plotted points in Fig. 24 were computed from hydrographs similar to curve No. 2, Fig. 21, for various rates, durations of supply, and lengths *L*.)

(*c*) To facilitate interpolations, durations of ponding in minutes, scaled from Fig. 24, were plotted against drain-inlet capacity expressed as percentages of peak discharge (q_p) with values of t_{50} as parameters (see Fig. 25(*a*)).

(*d*) A working diagram (Fig. 25(*b*)) was prepared using data scaled from Fig. 25(*a*), with values of t_{50} ("scale *D*," Fig. 22) plotted against duration of ponding in minutes, with ratio (*X* of Fig. 22) of drain-inlet capacity to peak rate of runoff as parameters.

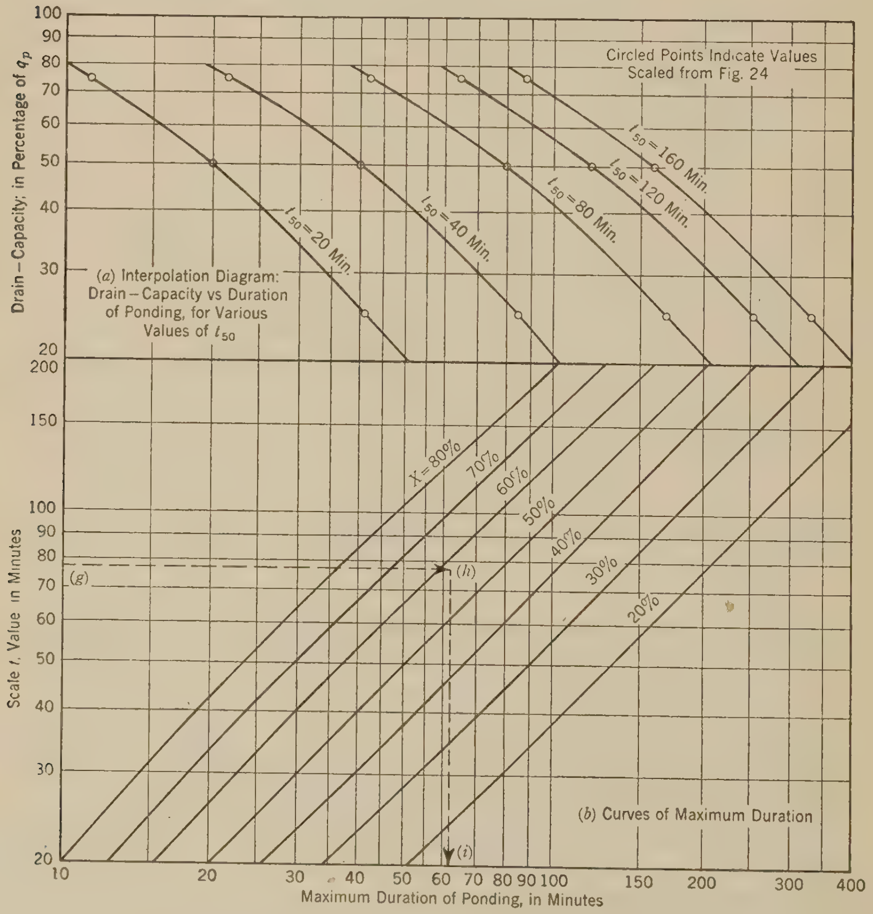

FIG. 25.—METHOD OF DETERMINING MAXIMUM DURATION OF PONDING

(*e*) Values of t_{50} were plotted in Fig. 22 against maximum storage, assuming zero drain-inlet capacity and various durations of supply to obtain the curves designated thereon by the letter *D*.

(*f*) The use of the curves shown in Figs. 22, 24, and 25 may be illustrated by continuing the example referred to previously with a length *L* of 400 ft, σ of 4 in. per hr, a duration of supply (t_r) of 38 min, and a maximum permissible storage volume of 2,000 cu ft per acre of drainage area. Using these values a drain-inlet capacity of 2.1 cu ft per sec per acre of drainage area was determined from Fig. 22. By interpolation determine the value of the *X*-ratio (59%) corresponding to point b, and record the *X*-ratio for future use. Follow the "*S-D* relation" curve to a t_r of 38 min from point b to point d; then proceed vertically to point e and read a "scale *D*" value of 78 min at point f. Enter Fig. 25(*b*) at point g with a "scale *D*" value of 78 min; follow a horizontal line to a point corresponding to an *X*-ratio of 59%; and read a value for the maximum duration of ponding at point i of 62 min on the bottom scale.

(*g*) Results obtained by the procedure outlined in step (*f*), for the critical values shown in Table 3, are tabulated under the subdivisions in Table 3 for the various "supply curve numbers" (see footnote (^{b}), Table 3).

Therefore, to determine the maximum drain-inlet capacity for various durations of supply (Col. 2, Table 3) and for various storages (Cols. 3 to 9, Table 3), the drain-inlet capacity (Cols. 3 to 9) was plotted against the duration of the supply rate in minutes (Col. 2) corresponding to the assumed "rate of supply" in inches per hour (Col. 1). The procedure may be illustrated by specific reference to Table 3: The drain-inlet capacities assuming a "standard supply curve No. 3," for example, for a storage volume of 2,000 cu ft per acre of drainage area are shown in Col. 5. These values were plotted against the duration of the supply rate in minutes indicated in Col. 2, Table 3. A critical (or maximum) drain-inlet capacity of 2.1 cu ft per sec per acre of drainage area was scaled from this curve at an approximate duration of supply of 42 min. Similarly, the critical drain-inlet capacity of 1.7 cu ft per sec per acre for a storage volume of 3,000 cu ft per acre was scaled from the curve plotted for this condition, at a duration of supply of 49 min. The critical drain-inlet capacities obtained by this procedure are tabulated under the subdivisions for the various "supply curve numbers" (see footnote (^{b}), Table 3) and for each of the storage values indicated in the headings of Cols. 3 to 9, Table 3. The results thus presented in Table 3 were plotted in diagram C, Fig. 23 (length of 400 ft), against the corresponding storages and critical drain-inlet capacities. Similar computations were made for lengths of 40, 100, 200, 300, and 600 ft, respectively, the results of which are omitted from the paper.

The use of diagrams A, B, and C, Fig. 23, is illustrated by the following example:

Given.—(1) Length *L* of turfed area = 400 ft; (2) design storm criteria as represented by "standard supply curve No. 3.0" in Fig. 15; and (3) maximum permissible storage = 2,000 cu ft per acre of drainage area.

Solution.—Enter diagram A of Fig. 23 at point h (supply rate of 3.0) and follow a vertical line to point j (storage of 2,000); then follow a horizontal line left to the margin of diagram A to point k and read the required drain-inlet capacity of 2.1 cu ft per sec per acre of drainage area (see Col. 5, Table 3). The maximum duration of ponding is obtained by following a horizontal line from point j to the right to point l (storage 2,000) and reading a value of 62 min on the bottom scale of diagram B at point m (see Col. 5, Table 3). The critical duration of supply (t_c) is obtained by continuing the horizontal line from point l to point n (storage 2,000) to read a value of 42 min at point o on the scale at the top of diagram C (see Col. 5, Table 3).

Effective Length of Drainage Area

As used in the Horton overland flow formulas, L refers to the over-all length of an elemental strip of turfed or paved surface in a direction parallel to the maximum slope. This definition of L must be liberalized somewhat when applied to an area in which a shallow large-area pond will be formed by storage of runoff during the design storm. In estimating the "effective length" for a drainage basin in which an appreciable quantity of temporary storage is permissible, the value of L adopted should be such that the rate of runoff indicated by the corresponding overland flow hydrograph would approximate the actual hydrograph of inflow into the ponding area. In such cases, the selected value of L may be considered as an index to be used in selecting the most applicable set of computation charts rather than as a definite dimension of the drainage area. With storage capacities ordinarily attainable and permissible in intermediate areas, the use of an approximate value of L will not introduce serious errors in the determination of the required drain capacities.

The value of L strictly applicable to a particular area varies as the size of the storage pond fluctuates during the course of storm runoff. As water accumulates in the relatively flat storage area during the process of storm runoff, the size of the pond increases rapidly, thus progressively reducing the distance from the edge of the pond to the outer limits of the drainage area. To simplify computation of the required drain-inlet capacity, it is desirable to select a value of L for the drainage area tributary to each inlet that most closely approximates the average during the period of critical runoff. In most cases it is satisfactory to estimate the "effective length" as the distance from the outer limits of the turfed drainage area to the mean boundary of the ponding area during the period of critical storm runoff. If the drain inlet is not located near the centroid of the turfed drainage area, the "effective length" should be estimated as the weighted average distance from the boundary of the turfed area to the mean limits of the ponding area corresponding to a depth equal to two thirds the maximum during the design storm.

As a general rule, ponding areas are located in turfed intermediate areas that are bordered by paved runways, taxiways, or paved aprons (see Fig. 26). Runoff from these paved areas must pass over turfed slopes to reach the ponding areas and drain inlets, and in so doing is subjected to somewhat the same retardance as the runoff that results from precipitation falling directly on the turfed area. Inasmuch as the time required for water to flow over paved areas is normally short (5 to 10 min), the length of the paved area can be disregarded or given very little weight in estimating the "effective length" (L) for a composite area. In exceptional cases where large paved landing mats or bare areas are involved it will be necessary to determine the modified effective length by means of the diagrams in Fig. 17.

Storm Drains

A sample layout of a storm drain system for a portion of an airfield is shown in Fig. 26. The inlets to the underground drains are located in such a manner as to permit the temporary storage of substantial volumes of runoff during intense storms without interfering with normal use of runways, taxiways, and parking areas. To prevent the concentration of an excessive quantity of storage in the lower parts of the field, the intermediate areas were assumed to be graded in such a manner as to effect drainage toward the several drain inlets and to form shallow, large-area storage basins around each inlet. By providing storage ponds around several inlets a relatively large volume of water can be stored without causing excessive depths of ponding in any area during the design storm.

FIG. 26.—LAYOUT OF PRIMARY STORM DRAIN SYSTEM

The location of drain inlets must be carefully related to the grading plan for the intermediate area if ponding areas having sufficient storage capacity to effect important reductions in required drain-inlet capacities are to be provided without creating objectionable flooding conditions or undesirable rates of change in surface grades. The elevation of the various inlets will be determined by their location with respect to runways, aprons, etc., and the limiting surface grades applicable to the area. The distance between inlets will be determined by the elevation of the respective inlets with relation to controlling elevations of runways, aprons, etc., the general slope of the field, and the limiting grades prescribed. For major airfields a maximum effective length of overland flow in excess of 400 ft (corrected to a slope of 1% and a roughness factor of 0.40) should not be permitted in areas adjacent to runways and aprons, and 600 ft in all-over fields.

The storage capacity that can be provided in intermediate areas without exceeding limiting grades in any direction is determined partly by the general slope of the field and partly by the location of the drain inlets with respect to runways, taxiways, and aprons. To estimate the maximum volume of storage permissible in a particular area, the maximum elevations of ponding allowable therein should be estimated by inspection of cross-sectional profiles, and the limits of the ponding area should be sketched on a map showing the drain-inlet layout. The surface areas of the various ponding areas may be measured by planimeter. Ordinarily, the storage capacity, in cubic feet below the elevation of maximum ponding, may be computed as one third of the maximum depth of ponding at the inlet, in feet, multiplied by the surface area of the pond, in square feet.

In general, the maximum depth of ponding in intermediate areas during the design storm should not exceed approximately one foot at the inlets if the intermediate areas are to be used for landing purposes and the upper limits of the storage ponds should not approach within 75 ft of runway pavements.

Minimum Drain Capacities

In some instances it would be feasible to provide surface ponds of sufficient capacity to store practically the entire runoff from storms less than a few hours in duration, without exceeding the maximum limits of the ponding areas. However, if the maximum permissible volume of storage were utilized in such cases, the drain-inlet capacities provided would be very small and the corresponding period required to remove the stored waters after each storm would be excessive. Furthermore, flooding of the lower parts of the ponding area would be relatively frequent; it may be practically continuous for several days as the result of a series of comparatively moderate storms. Although the area subjected to frequent and prolonged flooding may constitute a small proportion of the maximum permissible ponding area, the creation of unstable soil conditions in such areas would be objectionable in many cases.

Curve No. 4 in diagram A of Fig. 23 represents the minimum drain-inlet capacities that are considered desirable, regardless of the volume of storage capacity that may be permitted without the depth or area of flooding exceeding allowable limits. The drain-inlet capacities represented by curve No. 4, diagram A, Fig. 23, in cubic feet per second per acre of drainage area are equal to the rates of supply corresponding to a duration of 4 hr on the respective "standard supply curves" given in Fig. 15. If a drain-inlet capacity indicated by curve No. 4 is adopted in a particular case, it may be expected that some storage in the ponding basin will result during all storms less than 4 hr in duration that produce supply rates corresponding to the given "standard supply curve." The proper criteria to be followed in estimating minimum drain-inlet capacities depend largely upon the characteristics of the soil involved and the use that is to be made of the intermediate areas.

COMPUTATIONS OF STORM DRAIN CAPACITIES, ASSUMING SUPPLEMENTAL PONDING

The principal procedures involved in the determination of drain-inlet capacities required to limit storage in individual ponding areas to permissible volumes are shown by sample computations presented in Tables 4(*a*) and 5(*a*) for line C in the sample layout of Fig. 26. Assuming the project to be in north central Alabama, the following summarizes briefly the successive steps to be followed:

(*a*) Select a design-storm frequency (say of 2.2 in. per hr) approximately equivalent to a 5-yr frequency in Fig. 13(*d*).

(*b*) Estimate infiltration capacity and determine "standard supply curves" applicable to paved and unpaved areas. The infiltration capacity for a 1-hr rainfall for turfed areas in this case is assumed to be 0.6 in. per hr. The infiltration capacity for paved areas is zero; therefore the "standard supply curves" for paved and unpaved areas are Nos. 2.2 and 1.6, respectively (see Fig. 15).

(*c*) Compute "weighted standard supply curves" for composite drainage areas tributary to the respective drain inlets (see Cols. 15 to 19, Table 4(*a*)).

(*d*) By use of curves such as Fig. 23, compute the drain-inlet capacities required to limit storage above the respective inlets to permissible volumes (see sample computation in Table 4(*a*)).

In general, the methods used in current practice to design city storm sewers are applicable to the determination of pipe sizes for airfield storm drains. It is desirable to maintain the hydraulic grade line as near as practicable to the top of the drain pipe during the design storm. A minimum velocity of 2.5 ft per sec should be maintained in so far as practicable to minimize the deposition of sediment in the drains. Where ponding is contemplated the design of the storm drains should be reviewed, assuming the hydraulic gradient at the top of each inlet, to investigate the possibility of excessive flooding at any of the low inlets. If such conditions exist, the discharge from the inlets contributing to the excessive flooding should be regulated either by an orifice control in the inlet or by designing the inlet connection pipe for the design discharge reduced by ponding.

COMPUTATION OF STORM DRAIN CAPACITY, ASSUMING NO SUPPLEMENTARY PONDING

In certain instances it may be advisable to provide storm drains having sufficient capacities to remove runoff from the design storm without temporary ponding in the areas surrounding the drain inlets. To accomplish this purpose, drain-inlet capacities equal to the maximum rates of design storm runoff from areas tributary to respective inlets are required. An accurate determination of drain-inlet capacities necessary to remove design storm runoff from several inlet drainage areas without ponding entails a rather tedious procedure. Similar computations and a general consideration of the objectives involved indicate that the simple approximate method illustrated in Tables 4(*b*) and 5(*b*)

Col. 9) is permissible. [c] Cubic feet per second per acre of drainage area. [d] These values were determined by
uring the design storm would be somewhat less than the values indicated in Cols. 6 and 9. [e] See Table 5(*b*),

afford a satisfactory degree of accuracy. In order that the design capacities with and without temporary ponding of runoff may be compared for the same conditions, the drain-inlet layout presented in Fig. 26 and the design storm criteria used in the sample computation given in Table 4(*a*) were used in Tables 4(*b*) and 5(*b*). A comparison of Tables 5(*a*) and 5(*b*) shows that the maximum flow is about 189 cu ft per sec without supplemental ponding as compared to 57 cu ft per sec with supplemental ponding.

[a] Critical time required to produce the maximum flow in the underground drain. [b] Table 4(*a*) contains discharge

A comparison of the pipe sizes required for drainage systems utilizing both instantaneous runoff and temporary ponding discloses that, in general, the system contemplating ponding utilizes approximately one third the discharge capacity necessary for the instantaneous runoff system. This apparent saving is somewhat tempered because of the slightly increased grading costs. However, it can be shown that a considerable saving will result where temporary surface ponding is used.

SUMMARY

The facilities required for reasonably adequate drainage of an airfield vary greatly and cannot be defined precisely. Within the range of economic feasibility, the design capacity of the drainage systems should be adequate to remove surface runoff from the selected design storm without damage to field facilities, undue saturation of subsoil, or significant interruption of normal

traffic. Careful consideration should be given to drainage in the preparation of grading plans for an airfield. Results of studies indicate that the standard rainfall intensity-duration curves adopted as general standards provide a satisfactory degree of accuracy for airfield drainage problems.

The overland flow equations developed by Mr. Horton provide a useful tool for the determination of the rates of runoff from paved or turfed areas that would result from continuous and uniform rates of rainfall-excess. The procedures presented herein for the design of drainage facilities for airfields utilizing surface pondage for temporary storage of runoff from high intensity storms of short duration will provide a balanced and economical design consistent with the selected design storm rainfall. The experience to be gained in the operation of the drainage systems of airfields now completed should furnish data for the improvement of present procedures.

ACKNOWLEDGMENTS

The design procedures presented herein were prepared by the writer and his assistant, A. L. Cochran, Assoc. M. Am. Soc. C. E., under the direction of the Chief of Engineers, Maj.-Gen. Eugene Reybold, M. Am. Soc. C. E., Corps of Engineers, U. S. Army. These design procedures have been incorporated in the *Engineering Manual*, Construction Division, Office, Chief of Engineers, and have been issued to the field forces of the Corps of Engineers for guidance in the design and construction of airfield drainage systems. Appreciation is expressed for the assistance of engineers associated with the writer in the Office of the Chief of Engineers and in the various field offices under the Chief of Engineers.

DISCUSSION

JAMES B. NEWMAN, JR.,[5] ESQ.—The development of aircraft, accelerated by war, requires modification of design and of construction of airports at every step. Only a short time ago the experienced airport engineer found no particular problem in the design of a runway pavement. His specialized knowledge was supported by the experience of hundreds of able highway engineers, and by years of accumulation of data resulting from traffic tests and scientific research. Today the problem is vastly different. Loads applied to pavements on military airfields have no precedent in either airport or highway engineering. The necessity for wide runways with comparatively flat crowns and almost negligible grades, coupled with a requirement of broad graded areas on either side and at either end of the pavement, renders drainage of airfields and of runways a much more complex problem than drainage of streets and highways, or even prewar airfields; and yet drainage, always of prime importance in design, has become increasingly critical.

In the face of the requirement of constant change of design, the engineer has been confronted with other unusual difficulties. The expansion of the Army Air Forces has exceeded the imagination of most men. This large striking power could be of no use unless large numbers of planes, manned by properly trained crews, are hurled against the enemy. The constant cry has been, therefore, for extensive work rapidly performed. There has been no time for exhaustive research, for the development of ideal methods, for the conduct of extensive surveys, and for examinations. The Corps of Engineers has been repeatedly required to complete super-airports in less than six months after the need for the developments first has been announced. There has been no opportunity for long deliberation on choice of materials. With the priorities system, the engineer has been forced to accept the materials, equipment, and man power available, and, somehow, to produce the required results.

That the Corps of Engineers has met the challenge of this gigantic problem is proved by the success of the construction program. The few unsatisfactory jobs have an explanation. In almost every case the result was caused by the demand for speed. Completion has been required by definite dates because units have been activated and the initiation of their training has been scheduled for those dates. Labor shortages, nonavailability of materials or equipment, rain, and freezing weather have been obstacles, but completion dates, nevertheless, have governed. In spite of these difficulties, almost without exception, the facilities have met the exacting requirements of the Army Air Forces.

It is difficult to add to the very complete outline of design and construction practices presented by Colonel Stratton. His observations are in accord not only with the practices of the Corps of Engineers, but also with Air Force policy, and are supported by Air Force experience.

Colonel Stratton has indicated the reasons for the selection of a modified California test method for the evaluation of subgrade in the design of flexible pavements. This method is subject to erratic results in tests on some of the many types of soils encountered in the United States, and further modifications of the procedure may be required in the future. The personnel of the Army Air Forces charged with the development of airport criteria and the planning of facilities is inclined to be skeptical of the California method, but has had no logical alternate to offer. More positive results might have been obtained through the use of extensive field bearing tests, but, as Colonel Stratton indicates, the time available for design and construction mitigated against this practice.

---

[5] Brigadier General; formerly Colonel, Air Corps, U. S. Army, Chf., Buildings and Grounds Section, Office of Commanding General, Army Air Force, Washington, D. C.

Nevertheless, plate bearing tests have a definite place in the determination of strengths of completed pavements. The training program of the Army Air Forces is far from static. Changes in the use of facilities develop suddenly and often. Installations are now numerous enough to permit some degree of flexibility in the assignment of airfields for specific purposes. Positive knowledge of actual developed strengths of pavements would insure, to a marked degree, against unnecessarily high maintenance costs and possible occasional complete failures. These tests can be made while the airfield is in operation, and, therefore, the element of time no longer takes precedence over more exact procedure.

The drainage of airfields is a subject that cannot be too strongly stressed. There is no surer way to failure than inadequate and improper drainage for wide expanses of pavement designed for heavy loads. Ponding on runways, even to a relatively minor extent, creates an operational hazard, and may result in excessive interruptions of activity. The airport engineer must master this subject, or confine his efforts to desert areas.

Engineers who have not been engaged in the design of military airports recently may have some difficulty in visualizing the loads for which pavements are designed. The lightest pavement—that for a Class IV military airfield—compares favorably with many high-grade federal highways. Several states limit truck loads to 26,000 lb gross on four wheels and 32,000 lb gross on six wheels. Yet the Class IV airfield will accommodate nothing bigger than the single-engine trainer.

The Class III airfield, intended primarily for twin-engine trainers and transports, and for most fighter types, is designed to carry two-and-one-half times the normal highway truck "wheel load."

The Class II airfield, designed for a gross load of 74,000 lb, wheel load of 37,000 lb, will accommodate the larger four-engine cargo ships fully loaded, and bombers of the Flying Fortress class. These airfields have about the same load bearing capacity as main line railroads.

Quite obviously there is no counterpart for the Class I airfield, designed to carry the heaviest planes now in production. The designed gross load of 120,000 lb and wheel load of 60,000 lb exceed any known pavement requirements; and heavier loads are to be expected in the near future.

In order to judge just how much a load 60,000 lb per wheel is, visualize the weights involved in a test made by Colonel Stratton's organization. A large size "turnpull" with large single tires was used. The rear tires had a footprint of 750 sq in. each. The front tires on the tractor weighed 6,000 lb each and had a footprint of 1,000 sq in. The "turnpull" was loaded to the top with scrap steel; then 30-ft steel rails were piled across the top until the load was exactly balanced with 50,000 lb on each of the four wheels. The tractor could pull this load at about 2½ miles per hr over the paving to be tested, with only an occasional failure of the coupling device. If this load had been amplified by four 2,000-hp engines turning propellers at high rates of speed with the resulting vibration, the wheel loads and general effect would have been more nearly equal to the loads imposed upon runways, taxiways, and aprons on Class I airfields.

Warming-up engines, locked wheel turns, and taxying at low speeds before the wings begin to lift weight and provide buoyancy are a few of the factors never before considered by paving engineers. The use of dual tires helps to solve the tiremakers' problems, and also assists in designing adequate braking surfaces; but dual tires do not lessen the load on a pavement when weights are as great as these. These examples emphasize the need for new and advanced designs, and illustrate the reason for building taxiways, warm-up blocks, and parking aprons 25% stronger than the runways constructed to the full wheel loading. No allowances are made for landing impact.

Early pilots recited a formula for locating airports which had more than an element of truth mixed with comedy: "You find a high tension line, follow it to the intersection of a railroad and highway; then look for a river or a marsh, there is your airport." The runways were to be located so that the glide paths and approach angles passed through the oldest city landmarks, the fine old trees in the central park, or the tallest smokestacks in town. When most of these early airfields were located, flying was done in small planes by "barnstormers." The locations were cheap and they grew up like "Topsy." When new requirements arose, it was always too late to remove existing facilities to proper locations.

For modern airplanes, runways must be at least 5,000 ft long at sea level. This length should be increased with increased altitude by adding 100 ft to each runway for each 200 ft of altitude measured from sea level. Some military airplanes require a basic length of 6,000 ft at sea level. Shelters have been built for bad weather and night flying with runways up to 10,000 ft long. Different areas require different runway arrangements or patterns. The number of runways needed is controlled by wind conditions. In a few airfields, one runway is ample since the wind blows either up or down the valley. Many airports need only two runways since wind records for that area, compiled in the form of wind roses, indicate that winds blow only from four directions, each fully provided for by two runways. Most areas are amply served by three runways bearing a 60° relation to each other. A few localities definitely require four runways to cover all wind directions adequately.

Before selecting a site, the engineer should know the maximum wheel loadings and the anticipated air traffic. He should have at hand all the local wind information available. He should examine the possibility for future developments that might affect his plan. In addition, he should provide needed utilities, facilities, transportation, and all other requirements likely to influence his selection of a site. If a piece of farm land tempts him, the engineer should remember that generations of farmers have spent much time and money making the soil as unsuitable as possible for compaction and load-carrying stability. If it is level, he should remember that when Nature levels a piece of land she usually uses methods and materials which make it unsuitable for either base stability or compaction. If a parcel is level and in a cold country, the frost action may be bad, and the engineer should check all means of draining areas before selecting them. In most airfield construction the engineer has more to fear from ultimate cost of excessive fills than from large and costly cuts.

To make a proper selection he should know how many runways are needed. One will be required in each primary wind direction, or rather within 22½° of each high wind direction. Very small airplanes that would be bothered by winds blowing 10 miles per hr or less are best handled on all-over fields. Planes heavy enough to need runways can adjust themselves to fairly brisk winds crossing a runway at an angle as great as 30° off the course of such a runway. In the case of high winds, 30 miles or more, an adjustment of 22½° may be all that can be expected of either pilot or airplane, in which case a fourth runway would be required if 10% of the stiffer winds were such that three runways were not enough.

When considering runway lengths, 5,000 ft should be the minimum with 1,000-ft clear zones on each end. Some runways, plus clear zones, are 12,000 ft long. With this information, the engineer can eliminate all possible sites and start compromising, but he must not forget that the airplane should have a clear glide path not steeper than 1 on 40 from the extreme end of each clear zone and that this glide path should extend at least 2 miles beyond the extreme end of the runway clear zone. When a few possible sites have been determined, he must check the soil, the cost, and source of base-course material, in place, and, finally, the hazard removal cost and other items necessary for a decision.

THOMAS E. STANTON,[6] M. AM. SOC. C. E.—No one who has been close to the procedure for designing and constructing military airfields can fail to be impressed with the thoroughness with which the Engineering Division of the Corps of Engineers has explored the subject. The magnitude of the problem is more readily appreciated when it is realized that the Corps has been forced to anticipate the development of heavier and heavier planes without always having definite advice as to whether or not a given field, originally designed for light traffic, would be converted into a heavy bomber field as soon as completed. The cost is exorbitant and the work seriously delayed if all fields are to be constructed for heavy duty. However, a more serious condition arises when a field designed to handle light traffic is inadequate because military needs subsequently require a service too heavy for the constructed capacity.

As stated by Colonel Stratton, some of the factors that are of considerable importance in pavement design for primary highways are of negligible importance in runway pavements. For impact and loading frequency, the width of runway is insurance against too frequent or rapid repetition of loads.

---

[6] Materials and Research Engr., State Div. of Highways, Sacramento, Calif.

Furthermore, the relatively large tires on airplane landing gear provide a wider spread and usually a somewhat lower unit loading than vehicle truck tires, thereby permitting greater deflection of the pavement than can be tolerated in highway pavement construction.

On the other hand, the much greater total loading from the large bombers and transport planes can be charged on the adverse side of the ledger and, in the case of relatively weak subgrade soils, requires a much heavier base design than necessary for the heaviest loads permitted on any highway pavement.

Another important factor is the deflection induced by the warming of airplane engines. The assumed designed loadings are increased 25% for all areas subject to warming-up vibrational stresses. This is not a matter of serious concern to the highway engineer.

The heaviest loading permissible on state highways is 9,000 lb per wheel, whereas the designed loading for all but one of the classes of airfields is considerably greater than this amount. The only airfield loading comparable to highway loading is the Class IV field which is based on a design wheel load of 5,000 lb as against 15,000 lb for a Class III field (Table 1). Furthermore, single tires are used on airplanes of this loading, whereas most trucks carrying loads in excess of 6,000 lb to 7,000 lb per wheel have dual tires.

For the same total load, single-tired trucks have proved much more destructive than dual-tired trucks. Part of the reason for this is in all probability the more severe bending of the pavement surface for equivalent total deflections. With heavily loaded single tires, failure results under a relatively small number of load repetitions for deflections of as little as 0.03 in. to 0.04 in. Therefore, with no restriction for the loading on a single tire, except the permissive total load per wheel, designs should be based on permissible deflections of not more than 0.02 in. to 0.04 in., depending upon the flexibility of the base and pavement. However, because of wartime tire conservation measures, trucks have been forced to limit the load per inch of tire width to a much lower value than was prewar practice. Subsequent highway tests with dual tires, and tests with the larger airplane tires, have proved that substantially greater deflections (say, 0.1 in. for the wide airplane tires currently used on the larger airplanes) can be tolerated when the total load is spread over such a broad band. The permissible deflection is also dependent upon the number of maximum load repetitions during the normal life of the pavement.

W. E. Howland,[7] Assoc. M. Am. Soc. C. E.—The main purposes of this discussion are (1) to present a mathematical method for the determination of a runoff hydrograph for a rain of limited duration, and (2) to compare the hydrograph for a particular rain and area so obtained with that presented by Mr. Hathaway. The same differential equation will be used as was developed by Mr. Horton for Eq. 2, which furnishes the basic curve used by Mr. Hathaway (18). Hydrographs have been plotted from the derived formulas and are shown in Fig. 27 for comparison with Fig. 18. Curves 3, 4, 5, and 6, Fig. 27, have been obtained mathematically by the writer's methods, the basic differential equation (18) being:

---

[7] Prof., School of Civ. Eng., Purdue Univ., West Lafayette, Ind.

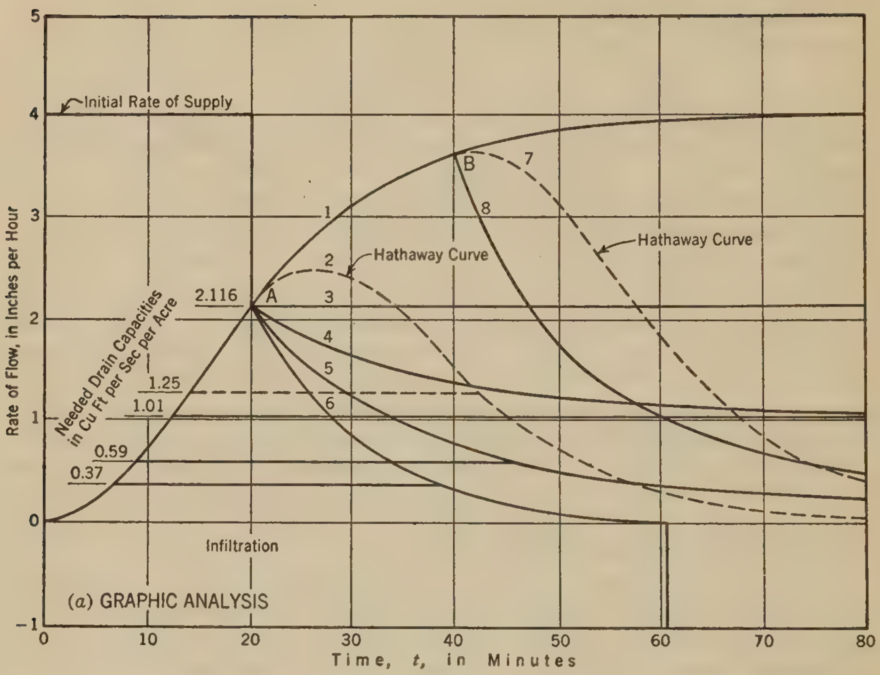
$$\sigma\, dT = K\, y^2\, dT + \tfrac{2}{3}\, dy \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(7)$$

Each of these is intended to be the runoff hydrograph that follows a 20-min-long rate of supply, of 4 in. per hr intensity; but the assumption as to the magnitude of the rate of supply of the rain which follows the initial 4 in. per hr rate is different for each curve. In obtaining curve 3, Fig. 27, the subsequent rate of supply which lasts indefinitely was assumed to be 2.116 in. per hr. (This is a horizontal line.) For curve 4, the subsequent rate of supply of 1 in. per hr is assumed to last indefinitely; for curve 5, the subsequent rate of supply is assumed to be zero. (It might be supposed from reading Mr. Hathaway's explanation that curve 2, Fig. 18, was also based on this assumption of a subsequent zero rate of supply.) In obtaining curve 6, Fig. 27, it was assumed that the ground would absorb water at a rate of 1 in. per hr as long as there was water standing upon it. This assumption might be stated as a negative rate of supply of 1 in. per hr for the subsequent period of ground submergence. This situation might conceivably result from a rain of 5 in. per hr lasting for the preliminary period of 20 min during which time, and also subsequently, the rate of infiltration was 1 in. per hr.

Curve 8, Fig. 27, was computed by the writer's methods for assumptions corresponding to those of curve 5, but with the runoff following a 40-min-long storm. Curve 7 has been constructed for comparison for this case using Mr. Hathaway's methods. The decrease in rate of runoff following the storm is even more abrupt in this case than for that of the 20-min storm.

The sharp break in the writer's hydrographs at the end of the period of high rainfall is the most conspicuous difference between Fig. 27 and Fig. 18. This characteristic has also been noted for comparable areas by others and is recorded in the literature (24)(25).

The effect of the different hydrographs on the estimate of needed drain capacity when storage is provided is also shown in Fig. 27. The same storage was assumed as in the example illustrated by Fig. 21 of the Symposium; and similar methods of analysis were employed. Using hydrograph 2, Fig. 27, the necessary drain capacity is 1.25 cu ft per sec per acre; but, with hydrograph 5, the needed capacity is only 0.59 cu ft per sec per acre; with hydrograph 4, the capacity is 1.01 cu ft per sec per acre; and, with hydrograph 6, the capacity is 0.37 cu ft per sec per acre. On the other hand, with hydrograph 3, the capacity becomes 2.116 cu ft per sec per acre. (The areas were measured in this analysis by a planimeter.) Thus, in this example the drain capacity requirement as determined from Fig. 18 seems about equivalent to that which might be needed for a rate of supply of 4 in. per hr lasting for 20 min, followed by a rain of somewhat more than 1 in. per hr with a rate of supply lasting indefinitely, or for a rain whose rate of supply is 4 in. per hr and lasts for 20 min, followed by another of about half that rate of supply which lasts for another 20 min and then diminishes to zero. Whether or not this example makes possible a true appraisal of the meaning of the results of Mr. Hathaway's methods would have to be determined by more extensive studies.



(b) Mathematical Analysis

Curve No.	General equation[a]	Conditions[b]		Formula for given conditions
		σ	y_a(c)
